A large range of physical problems is covered which some readers may welcome. But I would have welcomed more time spent on the fundamental theory even at the expense of a restriction of the applications. A student reading the book, with no previous knowledge of the subject, will probably find it difficult to decide which is the basic theory. It was particularly irksome to find that there are no equations or subsections in the book numbered, the latter even being difficult to find on the page. There are some problems scattered throughout the text but no collections of problems at the ends of the chapters.

J. E. HEBBORN

SPECIALIZED CRUSTACEANS

The Taxonomy, Morphology and Ecology of Recent Ostracoda

Edited by John W. Neale. Pp. ix + 553. (Oliver and Boyd: Edinburgh, 1969.) 220*s*.

DURING the latter part of the nineteenth century and the early part of this century, the Ostracoda shared in the great outburst of attention that was paid to the world fauna. Then interest flagged. To the geologist, partly as a result of the economic pressures on stratigraphic studies, fossil forms continued to be studied intensively, but to the zoologist the stigma of "too small and highly specialized" became attached. Of recent years there has been a resurgence of interest. The palaeontologist, particularly in relation to palaeoecology, has ventured into the fields of functional morphology and ecology of recent ostracods, while a number of zoologists, though starting from different concepts, have converged onto the same interests. This renewed interest among workers scattered over the world has stimulated international meetings, and this volume constitutes the papers presented at a very successful symposium held at Hull during July 1967.

The title of the book gives an indication of the range of papers, which extend from such fields as numerical taxonomy through detailed morphological studies to distributional ecology. The editor has not only achieved a logical grouping of the papers but has also added clear and valuable summaries of the discussions which took place at the meetings and a most helpful general index as well as a separate index to genera and species. The papers are not all in English, but one would not expect this with the publication of an international symposium which one hopes will have an international circulation.

Naturally the standards of the papers vary, but are in general high. To criticize the volume is to criticize the work of experts, and it must always be remembered that the approach of the palaeontologist differs from that of the zoologist so that it is always possible for the one to criticize the work of the other. It does seem a pity, however, that no papers are included on some of the recent work on marine planktonic groups, though no doubt this is a reflexion of the interests of those present at the meeting. As Kilenyi points out, the approach to his paper on ostracod distribution tends to be more palaeoecological than ecological and this is also true of other ecological papers included. Fortunately for the zoologist there are exceptions to this as, for example, the work of Whatley and Wall (southern Irish Sea) and Williams (Anglesey coast) where, among other factors, the authors establish specific association with species of algae. A zoologist may find the work of a geologist lacking where Adamzek only uses *Cyclastrope hendersoni* as a standard for the carapace of a filter feeding ostracod and ignores the other Asteropidae, let alone the Cytherellidae. On the other hand, the geologist may wonder what use Rome's exquisite work on the caudal furka is when he will not find traces of this structure in his fossils.

This volume is in no way a textbook, but to the newcomer to the group it forms a guide to present trends in research, and to the general zoologist or palaeontologist it shows the growing relationship of studies of this group to other fields. Above all, the specialist ostracodologist will find it a unique source of a large number of important papers on new developments in his subject. E. J. ILES

PEDIGREE OF THE VERTEBRATES

Cytology and Evolution

By E. N. Willmer. Second edition. Pp. x + 649. (Academic: New York and London, June 1970.) 257*s*.

THIS book, welcomed in its first edition as a scholarly treatment of a field into which few had ventured, now reappears under the same title but with its range substantially modified. It still opens with an account of the basic cell types revealed by tissue culture, and of their possible relation to the course of early metazoan evolution. In the second half, however, there is now a thorough

redevelopment of Hubrecht's view that vertebrates evolved from nemertines; a view "more or less ridiculed by zoologists", as Willmer challengingly admits.

He presents the nemertine case with the expected wealth of detail, but weakens it by not subjecting it to a sufficiently rigorous analysis and by introducing a substantial element of special pleading. Moreover, when an argument is deliberately based primarily upon considerations of cellular organization, it is difficult to give proper weight to other aspects of animal design and evolution. Thus, the widely held view that vertebrates arose from an echinoderm/chordate (deuterostome) line is summarily dismissed, without benefit of discussion, on the ground that it depends on "somewhat unlikely reasoning" (as though no such charge could lie against the nemertine theory), while the suggested relationship of nemertines to protochordates is discussed with reference to the Enteropneusta, but with no mention of the Pterobranchia. Yet the sessile habit and ciliary feeding of the latter are very relevant, especially in conjunction with the presence of a temporary post-anal tail in the larva of *Saccoglossus horsti*.

The argument runs into no less trouble when histological detail is being considered. Willmer finds it curious that the principal lateral nerves of nemertines are not present in enteropneusts, but it would surely be surprising if they were, considering that the intraepidermal nerve net of the latter is more primitive in organization than the centralized system of flatworms. And the rigours of zoological analysis are wholly swept aside with the suggestion that the insulin-secreting follicles of Langerhans of the lamprey larva may be vestigial nephridia; a thought (admittedly subsidiary to the principal argument) evoked in the author by reflexions on the existence of enteronephridia in some highly specialized earthworms.

Willmer has designedly produced an "unorthodox and unusual" book, intended to provoke interest and investigation and not to be a comprehensive text. It certainly transmits his enthusiasm to his readers, and will give zoologists lively material for many an honours seminar.

E. J. W. Barrington

ASPECTS OF REPTILES

Traité de Zoologie

Anatomie, Systématique, Biologie. Publié sous la direction de Pierre P. Grassé. Tome XIV: Reptiles, fascicule 2: Caractères Généraux et Anatomie. Pp. 680+xxxii. (Masson: Paris, 1970.) 225 francs.

For many years there were very few available texts making comparative surveys of aspects of reptilian biology, and several of these were rather old. This, the first of two reptile "fascicules" in Grassé's *Traité*, is the latest of several works to appear in the past few years. It is nevertheless immediately welcome, for it covers aspects for which there is no other recent survey available.

The title page indicates that the volume is on anatomy, but there are chapters on locomotion and snake venom and in other chapters there are many welcome references to biochemistry and physiology. Otherwise, skin, skeleton, musculature, venom apparatus, nervous system, sense organs, blood and vascular system, respiratory and alimentary systems are covered. Several of the chapters are by persons who have carried out research in the areas concerned and these have many original figures. Most of the chapters, however, are compilations from the literature and have borrowed illustrations, but are no less useful as sources of information on that account. As elsewhere in the *Traité*, all the illustrations are redrawn giving a pleasing uniformity of style. This sometimes has drawbacks, however; Phisalix's figure of the skull of *Coluber hippocrepis* (Fig. 92) has some inaccuracies, bears an out of date name, and does not clearly illustrate some of the well made points in the text which it accompanies.

Few of the references are later than 1966; this is, no doubt, an indication of the time required to assemble and edit twenty-one contributions. The chapter on the eye has some lapses, perhaps because of the death of the author before completion; I was nevertheless astonished to find no reference to the books by Franz, Walls or Rochon-Duvigneaud (the author of the chapter!), all published more than 25 years ago.

In several respects the book should have been more carefully edited. I was rather frequently irritated at being unable to find in the bibliography a work cited in the text. Lapses in the spelling of the names of authors and reptiles are so common that anybody using the work as a source of information would be well advised to check these. For example, a snake found in France is variously cited and indexed as *Natrix maura* and *Tropidonotus viperinus*, almost side by side on p. 252; there are three spellings of *Thelotornis* in the text, two repeated in the index and none of them is correct. *Feylinia* is assigned to the family Dibamidae on pp. 415 and 417, a placement which I have not seen before.

In general, the five principal groups of living reptiles are characterized and compared, and variations at family and lower levels are indicated but not discussed. The book gives a sound introduction to a wide range of topics. Every institution in which there is an interest in reptiles should have a copy on the library shelf—at more than 6*d* per page I doubt that it will find its way onto many private bookshelves.

Garth Underwood

ANIMAL GROWTH HORMONES

Control of Growth and Metamorphosis

Part 2 of *Animal Hormones: A Comparative Survey*. By P. M. Jenkin. (International Series of Monographs in Pure and Applied Biology: Zoology Division, Vol. 47.) Pp. xviii+383. (Pergamon: Oxford and New York, August 1970.) 100*s*; $13.50.

In 1962 Penelope Jenkin published the first part of her "Comparative Survey of Animal Hormones"; but she was overtaken by the growth of published knowledge and was able to cover only "Kinetic and Metabolic Hormones". Now, after eight years, part two has appeared. This was intended to deal with all morphogenetic hormones—but in the event has had to be limited to hormones concerned in the control of growth, moulting and metamorphosis. But it forms a self-contained whole. Although the author assumes familiarity with part one, and provides many cross-references to this, it is none the less a valuable book in its own right. As in the earlier volume, the author has added enormously to her labours by comparing the hormonal regulation, for every topic that comes up for consideration, throughout representatives of the entire animal kingdom, so far as that is known. This has taxed the author; and it taxes the reader—but it was well worth doing.

In the description of the moulting of arthropods much weight is attached to "apolysis", the "freeing of the epidermal cells from the old exoskeleton", as the crisis of moulting. Apolysis is a useful self-explanatory term—so long as it is borne in mind that it is an abstraction. The first sign of moulting is the active synthesis of nucleoproteins in the epidermal cells which usually, but not always, leads on to mitosis. So far as a given cell is concerned, mitosis necessitates separation from the cuticle; but mitosis begins at different times in different regions of the epidermis. Separation is such a gradual process that it is impossible in practice to pin down the time of apolysis. And yet the "actual instar" is here defined as the form of the arthropod over the period from one apolysis to the

next. While it is still covered by the old cuticle it is said to be "pharate" or masked. If one could actually observe the "actual instar" it would show very striking changes in its form, as in an embryo, starting like a soft and folded leaf within a bud and assuming its proper form and appearance only at ecdysis when the old skin is shed. It is a little difficult to understand why the vague time point of apolysis along this continuous process of growth should be selected for separating the instars, which by definition have definitive forms.

But that is a detail. The book as a whole is a product of thought by the author and it demands thought from the reader; it is to be recommended on these grounds both to the advanced student and to the reflective investigator.

V. B. WIGGLESWORTH

MORPHOGENESIS FOR STUDENTS

Tissue Interactions during Organogenesis

By Etienne Wolff. (Documents on Biology, 1.) Pp. xiv + 225. (Gordon and Breach: New York and London, July 1970.) 175*s*, $21.00 boards; 62*s* 6*d*, $7.50 paper.

THIS is an interesting attempt by Etienne Wolff and a group of his past and present colleagues to bring a much needed comfort to the advanced undergraduate student. They have aimed to bridge the gap between textbook and the flood of original literature by a series of didactically written reviews by workers experienced in the subjects on which they write.

An opening survey of problems of determination by Wolff stresses the recent brilliant work on transdetermination in insects from Hadorn's laboratory. This, together with an account of the value of immunochemistry in studies of induction and cytodifferentiation (by Y. Croisille), gives a more general setting to the other seven reviews which all deal with the morphogenesis of avian organs. Those chosen are kidney (by Wolff), liver (le Douarin), skin (Sengel), neurocranium (Benoit and Schowing), lung and stomach (Dameron, Sigot, Marin). The emphasis is, in most cases, upon the *in vitro* analysis of tissue interactions which these workers have exploited so profitably.

The authors have succeeded admirably in presenting their material in a clear and simple way. The manner is excellent, but the matter, though important, is a little restricted. Even if bird material alone were considered for inclusion, the analysis of morphogenesis in limb and eye would have had worthwhile lessons to offer.

D. R. NEWTH

NEUROHYPOPHYSIAL HORMONES

Pharmacology of the Endocrine System and Related Drugs

The Neurohypophysis. (International Encyclopaedia of Pharmacology and Therapeutics, Vol. 1, Section 41.) Pp. viii + 486. (Pergamon Oxford, London and New York, May 1970.) 120*s*; $16.

THIS excellent volume is a valuable addition to the ambitious series published by Pergamon Press, sections of which are gradually appearing.

When applied to the neurohypophysis, the title of the series is misleading. Encyclopaedia it may be; international—judging from the list of its contributors—it certainly is; but pharmacology is only part of its business. It is true that there are chapters on the chemistry of the neurohypophysial hormones, and on the relationship between structure and action, topics which might be termed pharmacological; it is true too that about one third of the contributors work in departments of pharmacology. But the volume contains, in addition, full accounts of the comparative physiology, storage and release, biosynthesis and fate in the body of the hormones it treats. As would be expected, therapeutics is represented only by two short articles on clinical pharmacology at the end.

It must be difficult, in writing such a book, to know what to leave out. It would be impossible to include every reference and mention every possibility without greatly extending its compass. The contributors have managed to select wisely and to build their arguments round the important facts rather than attempting to include everything. The full lists of reviews at the end of each chapter direct the reader to more comprehensive accounts. As would be expected, there is some overlap now and then between chapters, but the editors, themselves distinguished workers in the field, have managed to produce a section which is well proportioned, all of whose parts fit reasonably well together.

One trouble about a book like this is that it is bound to be out of date by the time it is published. In rapidly expanding fields, large numbers of papers are written and important findings are reported almost weekly, while the slow businesses of writing, editing, printing and binding go remorselessly on. In one chapter, for instance on a subject where progress is fast, out of some 250 references there are only five as recent as 1968, and one of these is cited as being "in press". The reader will not find here the latest developments. But he will find intelligently written accounts of the basic physiology and pharmacology of the subject.

This is not a book for the physician, but it will be of great value to every teacher or experimental worker in endocrinology who can afford it.

J. M. WALKER

THYROID ACTIVITY

The Thyroid and the Autonomic Nervous System

By David Leak. Pp. ix + 148. (Heinemann (Medical): London, July 1970.) 35*s*.

THE thyroid is currently a biochemist's gland, and there is something of a gap in knowledge between the synthesis, output and transport of its hormones to the cell receptors, and the final expressions of the gland's level of activity under normal or clinical conditions.

Dr Leak has made a careful and thoroughly critical review of the way—or of one of the ways—in which the thyroid hormones may produce their effects on body function. The evidence is difficult and often conflicting—not least, as he emphasizes, because of differences in response in the various species in which these problems have been studied, and doubts as to their relevance to the situation in man. In addition, it has often been assumed that the reduction of an effect by adrenergic blockage implies that the effect is mediated through the autonomic system whereas the reduction may result simply from this system independently, causing changes which are additive to the effect examined; and Leak seems to make this assumption himself when discussing the ocular effects of thyroid overactivity.

It is unfortunate also that he refers to the levels of thyroid stimulating hormone as being usually increased in hyperthyroidism relying on a reference based on work in 1957 before the long acting thyroid stimulator was recognized. These points, and a curious predilection for treatment with D-thyroxine, are, however, minor limitations to a useful review which defines clearly the evidence for an increased sensitivity to, rather than production of catecholamines in conditions of increased thyroid activity. Even if it does not solve all the problems, this book will help considerably in clearing the ground for their closer study.

E. ERIC POCHIN

Correspondence

Medvedev's Complaint

SIR,—The excerpt from Zhores (that is, Jaurès) Medvedev's book (*Nature*, **227**, 1197; 1970) strikes me as subtle communist propaganda. When I read in your editorial on page 1177 that a Russian scientist was not permitted to travel abroad, lost his job and was for some weeks kept in a psychiatric institution, I was duly incensed. Unfortunately, my indignation continued ebbing with every line of Medvedev's confession.

A few months ago, I was invited to give a lecture in France. I applied to the National Science Foundation for travel funds. After a long delay, my request was turned down. I did not complain to my Congressman, or to the senators from our state, or to the Head of the Foundation, or to the French Ambassador in Washington, or the US Ambassador in Paris, and so on. When the time of his lecture came, Medvedev read the latter to his friends; I did not. Why did I acquiesce in my defeat? Because the official who refused my application had, under the existing law, full right to reject my plea, as had the official who kept Professor Medvedev back.

It would be easy to clarify my position but, naturally, I do not want anyone to suffer from too much light.

Yours faithfully,

J. J. BIKERMAN

15810 Van Aken Boulevard,
Shaker Heights,
Ohio 44120.

Food for Thought

SIR,—The rapidly growing science of nutrition is at a stage at which accurately characterized standard reference materials are urgently needed to provide a common basis for the great number and variety of studies that are being conducted in all parts of the world. Dietary control in animal experiments[1] is only one of many applications to be made of such materials.

About twenty substances pertinent to work in nutrition are included among the standard substances issued by the World Health Organization and by various governmental and other agencies in different countries. These currently available reference materials are issued in specimens in the milligram-to-gram range; such quantities suffice for purposes of identification and analytical control, but are too small for many applications in nutrition where gram-to-kilogram quantities are required. Furthermore, the present materials are usually certified for only a small number of constituents, whereas for many critical nutritional studies it is essential to know the content of many residual and trace constituents, particularly trace elements.

Immediate application can be foreseen for about eighty-five standard reference materials in the following categories: (1) essential nutrients in pure form; (2) basic food products of both natural and synthetic origin; (3) actual or simulated plant and animal tissues and fluids; (4) products involved in or resulting from plant or animal metabolism.

The expense of producing so many standard reference materials in large specimens would be so great that the operation would be feasible only if undertaken on a world-wide basis. For this reason I propose that concerned individuals, scientific societies, and standardizing agencies join in requesting the logical international agencies—the World Health Organization and the Food and Agriculture Organization—jointly to undertake a programme of International Standard Reference Materials. I shall be glad to furnish specific suggestions regarding such a programme to anyone who may be interested.

Yours faithfully,

ARCHIBALD T. MCPHERSON

4005 Cleveland Street,
Kensington, Maryland 20795.

[1] *Nutrition Reviews*, 27, 299 (October 1969).

Misleading Units

SIR,—In a review of mycotoxins (*Economie et Médecine Animales*, **11**, 75; 1970) C. W. Hesseltine gives concentrations of mycotoxins "par billion". I am convinced that they should be written "par milliard". For example, the sentence: "La limite de sensibilité des analyses utilisées s'élevait à 2–5 par billion d'aflatoxine", was almost certainly understood by Hesseltine in the United States as 2–5 per 10^9, whereas in most of the world this French sentence would be read as 2–5 per 10^{12}. Therefore I would like to appeal to toxicologists, and in particular to American colleagues, not to use the misleading term parts per billion (p.p.b.). It is possible to express the same concentrations in parts per million (p.p.m.), which is equally understandable to toxicologists from all over the world.

Yours faithfully,

TEODOR JUSZKIEWICZ

Department of Pharmacology and Toxicology,
Veterinary Research Institute,
Puławy, Poland.

Radiation Hazards

SIR,—Baines (*Nature*, **227**, 869; 1970) quotes some of our data for Australia and New Guinea to support his views on radiation hazards to South Pacific communities. The quotation, however, is hardly relevant. In fact the results of our measurements on fallout from nuclear weapons tests in French Polynesia—the source of Baines's concern—have been assessed by the Australian National Radiation Advisory Committee and found to have no significance as a hazard to health of the Australian community[1].

Measurements on shorter-lived fission products in fallout over Australia and New Guinea[2] following the French nuclear weapons tests of 1966, 1967 and 1968 indicate that:

(1) the highest γ-radiation dose to the whole body estimated from measured fallout from all tests in the three series was 3·3 mrad;

(2) the highest radiation dose to thyroid for young children due to ^{131}I in milk consumed during any 12 month period between 1966 and 1968 was estimated at 226 mrad.

As we pointed out when reporting the measurements, these radiation doses are not only the highest but are also upper limits. Thus weathering, shielding and other effects would reduce whole body doses by a factor of 3 to 5, while decay of ^{131}I before the milk is consumed, and other factors, would result in substantially lower thyroid doses. In any case, these upper limits on estimated dose are far less than dose levels which would be expected to be of biological significance[3]. Although measurements are still in progress on fallout in Australia from the 1970 series of tests in Polynesia, the data accumulated up to the present indicate

levels of fallout which are lower than from previous series.

Reference to widely reported inventories of ^{90}Sr in the stratosphere of the Southern Hemisphere[4,5], and to measurements on monthly deposition of ^{90}Sr in Australia[6], indicates that:

(1) stratospheric burden of ^{90}Sr in the southern hemisphere decreased from some 1,200 kCi in 1963 to 50 kCi in mid-1968, with annual deposit of ^{90}Sr in Australia falling from 2·1 mCi/km² in 1964 to 0·4 mCi/km² in 1968;

(2) high yield nuclear weapons tests in Polynesia in August–September 1968 added some 130 kCi to a total stratospheric burden of 180 kCi ^{90}Sr and an annual deposit of ^{90}Sr in Australia of 0·6 mCi/km² in 1969.

As already reported[6,7], the 1968 test series in Polynesia contributed a substantial proportion of the total monthly ^{90}Sr deposit in Australia in late 1968 and early 1969 but the magnitude of the total deposit remained small.

When planning the Australian programmes for monitoring fallout from tests in Polynesia, consideration was given to possible problems of contamination of migratory fish and birds, which may enter the Australian diet. Evidence available to us on the migration habits of tuna caught in Australian waters suggested that only yellowfin, comprising less than 1 per cent of the total catch, might originate from the Tuamotu Archipelago. Measurements on yellowfin taken in Australian waters showed no change in concentration of fission products following tests series in Polynesia.

Obituary

Dr E. H. Rodd

Ernest Harry Rodd died on July 22, 1970. He was born in 1888, and educated at Christ's Hospital and the Central Technical College, South Kensington, which he entered in 1906 to begin his close association with Professor H. E. Armstrong until the latter's death in 1939. His main research work here, on crystal morphology in the benzene series, was of topical interest in connexion with the then recently published views of Barlow and Pope on valency volumes. On the final closure of the old Central laboratory and the dispersal of Armstrong's research students, Rodd worked for a while at the National Physical Laboratory before joining, in 1917, the research staff at Levinstein Ltd, Blackley, Manchester, later to become part of the British Dyestuffs Corporation and eventually the headquarters of the Dyestuffs Division of Imperial Chemical Industries Ltd. Here he took a full share in the work of the rapidly expanding research department, as emphasis passed from the manufacture of known products to the invention and eventual manufacture of new ones.

In order to promote closer relations between scientists working in the Dyestuffs Division and those working in the universities, in 1929 the Dyestuffs Group Research Committee was set up, the academic members being Sir Jocelyn Thorpe, Sir Robert Robinson and Sir Ian Heilbron, with Rodd as secretary. As the work of this and other liaison committees grew, Rodd became fully employed as academic liaison officer, a post he filled with distinction until he retired more than twenty years later. During this period he became well known in the laboratories of practically all the universities and technical colleges in the UK and several abroad.

After his retirement his name became familiar to a world-wide circle of chemists as the creator and editor of *The Chemistry of Carbon Compounds*, the ten volumes of which were published between 1951 and 1962, an outstanding achievement after a normal lifetime's work in industry. He was particularly pleased when it was decided to publish a revised edition, and right up to the day of his death he took a very active and constructive interest in its progress.

Announcements

University News

Dr N. Uri, a member of the Explosives Research and Development Establishment, Waltham Abbey, and **Professor E. M. Evans,** of British Resin Products Limited, have been appointed visiting professors in the Department of Chemistry of the **City University.**

Professor Malcolm B. Wilkins, University of Nottingham, has been appointed Regius professor of botany in the **University of Glasgow.**

Professor Olaf Rundquist, on sabbatical leave from Hamline University, St Paul, Minnesota, and **Professor J. G. Pike,** professor of mechanical engineering at the Royal Military College of Canada, have been appointed visiting professors at the **Heriot-Watt University.**

Professor M. S. Longuet-Higgins has been appointed visiting professor in the Department of Mathematics, **University of Surrey.**

Dr Paul S. J. Spencer, University of Aston in Birmingham, has been appointed professor of applied pharmacology in the Welsh School of Pharmacy, **University of Wales Institute of Science and Technology.**

Appointments

The following appointments have been made to the **MRC advisory boards:** *Biological Research Board,* **Professor P. M. B. Walker,** already a member of the board, will succeed **Professor R. A. Gregory** as chairman; **Professor C. I. Howarth** and **Professor R. R. Porter** have been appointed. *Clinical Research Board,* **Professor Charlotte M. Anderson, Professor Richard Doll** and **Professor O. L. Wade** have been appointed. *Tropical Medicine Research Board,* **Dr L. G. Goodwin** and **Professor J. N. Morris** have been appointed.

Miscellaneous

The **Alfred Egerton gold medal** for 1970 has been awarded to **Professor A. R. Ubbelohde** for his contributions in the field of combustion.

The **George E. Davis medal** of the Institution of Chemical Engineers has been awarded to **Mr F. E. Ireland,** chief alkali inspector.

A prize of about 500,000 Belgian francs will be awarded in 1973 by the **Fondation de Physiopathologie Professeur Lucien Dautrebande,** for outstanding work in human or animal physiopathology. Further information can be obtained from the office of the Foundation, 35 Chaussée de Liege, 5200 Huy, Belgium.

Entries are invited for the **1971 Maccabaean prize** of 25 guineas and a bronze medal. Candidates, who must be less than 30 years old, should submit an essay of 4,000 to 6,000 words on some aspect of the history of medicine or pharmacy. Further information can be obtained from Dr F. N. L. Poynter, Wellcome Institute of the History of Medicine, 183 Euston Road, London NW1.

Nominations are invited by the **Society of Biological Psychiatry** for three awards to be given in 1971. The gold medal award will be made to a senior scientist in the field of biological psychiatry; the two other awards, of $750, will be made to workers under the age of 35, one for clinical research and one for basic research in biological psychiatry. Further information can be obtained from Dr George Winokur, Committee on Research Awards, Society of Biological Psychiatry, Department of Psychiatry, Washington University School of Medicine, Renard Hospital, 4940 Audubon Avenue, St Louis, Missouri 63110, USA.

A new fellowship programme, established through an endowment from John L. Loeb, has been inaugurated at **Harvard University** and is designed to give persons with exceptional promise for leadership in the fields of urban affairs and design an opportunity for independent study at Harvard, either on a part-time or full-time basis. The **Loeb fellows for 1970–71** are: Alexander Rodriguez, director of planning and development for Suffolk County and Brookline United Community Services; Michael A. Levett, assistant to the Secretary of the Interior; M. Daniel Richardson, jun., director, Boston Area Office, US Department of Housing and Urban Development; John Zeisel, social science editor, *Design and Environment*. Further information about the fellowships can be obtained from Professor William A. Doebele, Robinson Hall, Harvard University, Cambridge, Massachusetts 02138, USA.

ERRATUM. In the article "Regulatory Factor for the Transcription of the Ribosomal Genes in Amphibian Oocytes" by Marco Crippa (*Nature*, **227**, 1138; 1970), the end of the first sentence should read "synthesis changes greatly during oogenesis".

ERRATUM. In the article "Numerical Earth" (*Nature*, **227**, 1090; 1970), reference was made to a paper on the form of radiation from earthquake faults. This represented the joint work of R. Burridge and G. S. Halliday. R. Burridge is a research fellow of the UKAEA Blacknest.

ERRATUM. In the review "Introduction to Life" by John Paul (*Nature*, **228**, 187; 1970), line 18 in the first paragraph should read "little more than a list of known hormones. Those on . . .".

International Meetings

October 22–24, **Thermal Pollution,** Chicago (Institute of Environmental Sciences, 940 East Northwest Highway, Mt Prospect, Illinois 60056, USA).

October 26–30, **Industrial Applications of Small Computers,** Glasgow (Birniehill Institute, East Kilbride, Glasgow, Scotland).

October 29–30, **Environmental Influences on Reproduction,** Edinburgh (Kay Crombie, Inveresk Research International, Inveresk Gate, near Edinburgh, Scotland).

November 2–4, **Caring for the Environment in the Seventies,** Llandudno (Dr T. Pritchard, Countryside in 1970 Committee for Wales, Graig Lwyd, 134 Penrhos Road, Bangor, Caernarvonshire, Wales).

November 3–6, **Technological Advances in Britain,** Rio de Janeiro (Board of Trade, 1 Victoria Street, London SW1).

November 6–8, **The Pollution of our Environment,** London (Conference on Pollution, c/o Mrs S. Robson, 31 Chester Terrace, London NW1).

November 9–13, **Technological Advances in Britain,** Buenos Aires (Board of Trade, 1 Victoria Street, London SW1).

November 16–18, **Powder Metallurgy Joint Group Annual Meeting,** Eastbourne (The Secretary, Powder Metallurgy Joint Group, 17 Belgrave Square, London SW1).

November 16–19, **Computing Techniques for Industrial Applications,** Hendon (The Registrar, Hendon College of Technology, The Burroughs, London NW4).

November 17, **The Use of Organometallic Compounds in Synthetic Organic Chemistry,** London (The Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1).

November 25, **Chromatography and Toxicology,** London (Society for Analytical Chemistry, 9–10 Savile Row, London W1X 1AF).

November 26, **Painting and Protection of Structural Steelwork,** London (Mr G. F. Goody, Construction Industry Research and Information Association, 6 Storey's Gate, London SW1).

November 27–29, **Starting One's Own Business,** Slough (Dr W. E. Duckworth, Fulmer Research Institute, Stoke Poges, Buckinghamshire).

December 1–3, **Production Engineering Research Association of Great Britain Conference and Exhibition,** Melton Mowbray (Conference Department, PERA, Melton Mowbray, Leicestershire LE13 OPB).

December 2–15, **Synoptic Analysis and Forecasting in the Tropics of Asia and the South-West Pacific,** Singapore (World Meteorological Association Secretariat, Geneva, Switzerland).

December 7–12, **Plant Growth Substances,** Canberra (Dr D. J. Carr, Research School of Biological Sciences, Australian National University, PO Box 475, Canberra City ACT 2601, Australia).

December 14–16, **Structural History of the Bay of Biscay,** Rueil-Malmaison (Mr Montadert, Division Géologie, Institut Français du Petrole, 1 et 4 Avenue de Bois-Préau, 92 Rueil-Malmaison, France).

January 4–6, 1971, **The Teaching of Mathematics in Universities and Polytechnics,** London (Registrar, Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea SS1 2JY).

January 4–7, 1971, **Fluid Power,** Guildford (H. Stephens, 2 IFPS, British Hydromechanics Research Association, Cranfield, Bedford).

British Diary

Monday, October 19

Development of Immersed Tunnelling in Europe (5.30 p.m.) Mr Alex Christiani, Institution of Civil Engineers, at Great George Street, London SW1.

Karl Marx and the Withering Away of Social Science (5.30 p.m.) Mr G. Cohen, British Society for the Philosophy of Science, in the Joint Staff Common Room, University College London, Gower Street, London WC1.

The Work of the ALRC (2.15 p.m.) Dr P. T. Haskell and Mr R. D. MacCuaig, Society of Chemical Industry, Pesticides Group, at the Anti-Locust Research Centre, College House, Wrights Lane, London W8.

Physiological and Clinical Results from Cardiac Pacing (4 p.m.) Dr Edgar Sowton, University of London, at the Royal Postgraduate Medical School, DuCane Road, London W12.

Tuesday, October 20

Acoustics as a Diagnostic Tool (conference) Institution of Mechanical Engineers, Nuclear Energy Group, at 1 Birdcage Walk, London SW1.

Electricity Distribution (two-day conference) Institution of Electrical Engineers, in the Assembly Rooms, Edinburgh.

Energy (5.30 p.m.) Professor R. King, Royal Institution, at 21 Albemarle Street, London W1. (Lecture for Sixth Form pupils from Schools in London and the Home Counties. To be repeated on October 21, 27 and 28.)

Soil Survey in Agriculture (10 a.m.) Society of Chemical Industry, Agriculture Group, at 14 Belgrave Square, London SW1.

The Control of Ageing in Man (1.20 p.m.) Dr A. Comfort, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

Wednesday, October 21

A Return to William Smith (5 p.m.) Professor W. S. Fyfe, FRS, Geological Society, at the Royal Society, 6 Carlton House Terrace, London SW1 (25th William Smith Lecture).

Analysis of Materials for Paint and Ink (7.30 p.m.) speaker from ICI, Oil and Colour Chemists' Association, at the Carlton Hotel, North Bridge, Edinburgh.

Changes in Pharmaceutical Analysis (6.30 p.m.) Dr E. F. Hersant, Society for Analytical Chemistry, in the Renold Building, University of Manchester Institute of Science and Technology, Sackville Street, Manchester.

OR Man Looks at IR: Operational Research and Information Retrieval (5.30 p.m.) Mr W. T. Bane, Aslib and the Institute of Information Scientists, at Imperial College, Exhibition Road, London SW7.

The Role and Control of Human Adrenal Androgens (2 p.m.) Professor I. H. Mills, University of London, at the Royal Postgraduate Medical School, DuCane Road, London W12.

To Cover the Country with Good Schools—a Century's Effort (5.30 p.m.) Professor H. C. Dent, University of London, at King's College, Strand, London WC2

Thursday, October 22

Clinical Research (5.30 p.m.) Sir Harold Himsworth, University of London in the Beveridge Hall, Senate House, London WC1. (First of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Conservation and Productivity of Natural Waters (two-day symposium) Zoological Society of London, in association with the British Ecological Society, in the Meeting Room of the Zoological Society of London, Regent's Park, London NW1

Corrosion (7 p.m.) Dr T. P. Hoar, Oil and Colour Chemists' Association, at the Beech Tree Hotel, Beaconsfield, Bucks.

Organic Microchemistry and Its Applications (two-day meeting) Society for Analytical Chemistry, Microchemical Methods Group, at the College of Further Education, Salisbury, Wilts.

Perturbed Angular Correlations of Gamma Radiation in Biological Macromolecules (2.15 p.m.) Professor J. A. Baldeschwieler, University of London, at Queen Mary College, Mile End Road, London E1.

The Basis of Current Fertilizer Recommendations (2.30 p.m.) Mr L. J. Hooper, Fertilizer Society, at the Geological Society, Burlington House, Piccadilly, London W1

The Impact of Process Requirements on Future Trends for Pressure Parts (conference) Institution of Mechanical Engineers, Pressure Vessels Section of the Applied Mechanics Group, at 1 Birdcage Walk, London SW1.

Friday, October 23

Ion Cyclotron Double Resonance (2.30 p.m.) Dr J. A. Baldeschwieler, University of London, at Queen Mary College, Mile End Road, London E1.

Recent Developments in Dye Lasers and Ultra-Short Light Pulses (1 p.m.) Dr T. Morrow, Royal Institution, Photochemistry Discussion Group, at 21 Albermarle Street, London W1.

The Universe and the Arrow of Time (9 p.m.) Dr J. V. Narlikar, Royal Institution, at 21 Albemarle Street, London W1.

Reports and Publications

(not included in the monthly Books Supplement)

Great Britain and Ireland

Scientific Proceedings of the Royal Dublin Society. Series A. Vol. 3, No. 24. Some Observations on the Assimilation of Basic Xenoliths by Acid Magma in the Galway Granite, Co. Galway, Eire. By C. W. Claxton. Pp. 247–256. 7*s*. Vol. 3, No. 25: Geology of the Duvillaun Islands. By M. D. Max, W. E. A. Phillips and P. M. Brück. Pp. 257–268+plate 10. 8*s*. Vol. 3, No. 26: Some Mineralization in Part of Northwest County Mayo, Ireland. By Michael D. Max. Pp. 269–274. 6*s*. Vol. 3, No. 27: Mainland Gneisses Southwest of Bangor in Erris, Northwest County Mayo, Ireland. By Michael D. Max. Pp. 275–292+plate 11. 10*s*. Vol. 3, No. 28: The Termon Granite and Associated Minot Intrusives, Co. Mayo, Ireland. By J. S. Sutton. Pp. 293–302. 9*s*. Series B. Vol. 2, No. 22: Aneuploids of *Brassica oleracea*. By P. L. Curran. Pp. 217–220+plate 13. 4*s*. Vol. 2, No. 23: Comparative Trials on the Effects of (2-Chloroethyl) Trimethylammonium Chloride (Chlorocholine Chloride; CCC) and N-Dimethylamino Succinamic Acid (B-Nine; Alar) on Vegetative Characteristics of Apple. By P. F. McDonnell and J. P. Edgerton. Pp. 221–232+plates 14–16. 9*s*. Vol. 2, No. 24: Donegal Herring Investigations 1967/68. By J. J. Bracken and D. R. Phillips. Pp. 233–250. 6*s*. Vol. 2, No. 25: A Study of the Utilization of (2-Chloroethyl) Trimethylammonium Chloride (Chlorocholine Chloride; CCC) Under Irish Conditions. 1: The Effect of (2-Chloroethyl) Trimethylammonium Chloride and Nitrogen on the Yield of Spring Wheat. By E. J. Gallagher. Pp. 251–262. 6*s*. (Dublin: Royal Dublin Society, 1970.) [159

Bulletin of the British Museum (Natural History). Geology. Vol. 19, No. 2: A Revision of the Brachiopod Subfamily Kingeninae Elliott. By Ellis Frederic Owen. Pp. 27–82+14 plates. 105*s*. Botany. Vol. 4, No. 6: New and Little Known Himalayan Species of *Swertia* and *Veratrilla* (Gentianaceae). By H. Smith. Pp. 237–258+plates. 22–37. 31*s*. (London: British Museum (Natural History), 1970). HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

***12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire..... **£14 0 0 each**

United States of America.....(by air freight)..... **$48 each**

Canada.....(by air freight)..... **$52 each**

Elsewhere overseas by surface mail..... **£14 0 0 each**

(Charge for delivery by air mail on application)

*Shorter periods *pro rata*. (Minimum three months.)

Science is a Trojan Horse

THE problem of South Africa touches everything and everybody. If artificial activities such as playing cricket should become entangled with *apartheid*, how can the development of science be unaffected? The survey of the present state of research and scientific education in South Africa which appears on page 310 must therefore be regarded as incomplete without some assessment of the way in which the life of a professional scientist and the character of his work must be affected by the regulations by which the present government of South Africa seeks to guide the development of its population, one sixth white, in the decades ahead. To pretend otherwise is to ask for the Moon even if it must also be acknowledged that, in a nation that has galloped a long way in the sixty years of its existence but still has a long way to go, social harmony must be peculiarly difficult to attain. So far as scientific research is concerned, however, the conduct of South Africa's affairs is by no means irrelevant. First, *apartheid*, even translated as "separate development", is bound in due course to affect the character of academic life in South Africa. Second, it will affect the efficacy of the efforts spent on scientific research. Third, it will limit, as it has already limited, the freedom with which intellectual people can conduct intellectual business. That is a sufficient reason for this commentary.

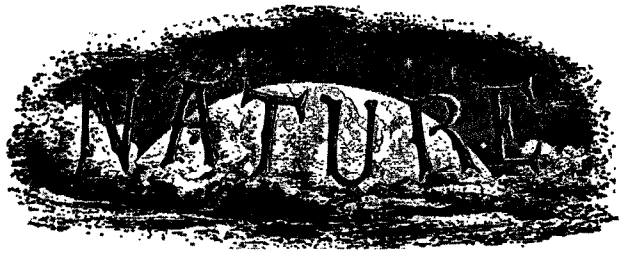
Charity requires, however, an acknowledgement of the difficulties with which the government of South Africa must contend. One of the most serious is the vivid memory of recent struggles with which a large part of the population is imbued. The Boer War was, after all, only seventy years ago, and the bitterness with which it was fought still leaves its mark on that part of the population of South Africa which is of European descent. If there are Irish brooding over Cromwell still, there is at least some reason why some Afrikaaners should still resent those who do not naturally speak their language. It must also be acknowledged that most modern governments would shrink from the difficulty of persuading a vociferous and divided European minority that the time has come to endow the much larger native population with elementary political rights. Although the government of South Africa has frequently been able to justify the policy of separate development on the almost theological grounds that people of one "nation", whatever that may mean, have a natural hankering for separate development, the sad truth is that the doctrine may well appeal to South African voters principally because it perpetuates their present dominance. In circumstances like these, it is only proper that questions should be asked not merely about the propriety of what is happening in South Africa but also about the feasibility of what is planned.

Honesty requires a plain statement that outsiders find the present conditions in South Africa as offensive as many residents think them natural. At a time when Western society is overwhelmed by the discovery that underprivilege breeds underprivilege—children from underprivileged homes do less well at school, for example, while the infant mortality rate is inversely correlated with family income—it is an assault on modern sensibility to pretend that communities already underprivileged can be sent out into the bush, sometimes literally, and there invited to take a chance on separate development. The theorists are no doubt sincere in their belief that by this chastening route, the national identities of the native communities of South Africa would be characteristically expressed, but in reality this course of action is more certain to ensure that the gap, cultural and economic, between Europeans and Africans is permanently huge. To be sure, for those who believe in miracles, there may be some way out of the simple truth that deprivation is the origin of underprivilege, but miracles are not part of the fabric of modern government.

Modern sensibility is also offended that separate development is cruel. Black men in South African urban townships are now most of all alarmed that, if they die, their wives and children will be sent to some distant and often unknown homeland, as the saying goes. Another anxiety is that the regulations of separate development, with their implicit definition of several distinctive African peoples, often impede normal personal relationships between black people who have been foolish enough, in marriage or their choice of parents, to fail to anticipate the definitions now prevalent. For the time being, luckily for everybody, native Africans seem to be less acutely conscious than they might be of the ways in which they and their families are damaged by isolation in distant suburban townships, by wage packets that are smaller than those of Europeans doing comparable work, by a school system that requires even poor families to pay up, and by the indignity of the supposition that, for the sake of a proposed urge towards separate development that flies in the face of the known flair for urbanization that most Africans possess, social intercourse between blacks and whites should be more restricted now than at any time in the past century. The question is not whether *apartheid* is moral but whether it can be indefinitely stomached.

Where does science fit in? Two things must be said. First, to the extent that the present arrangements in South Africa may limit the efficacy of scientific research, the whole world and not merely small sections of the South African population will be deprived. There is a danger that the arrangements made for non-

white education may limit the population from which bright ideas will in the long run be derived. Elsewhere than in South Africa, experience has now shown that a diversity of universities is a blessing, not a curse, at least so long as there is intercourse between them. The policy for higher education in South Africa seems paradoxically to be seeking opposing objectives—supposedly identical universities but with hardly any communication between them. Most probably the system is unworkable; otherwise, it is unwise.



The other side of this coin is the extent to which science can especially illuminate the problems with which South Africa is confronted (and which nobody should ignore). First, it is by now apparent that many of the steps in the arguments which demonstrate the virtue of separate developments are fallacious. There is no objective basis for the assertion that native Africans seek a national identity in a community with people of closely similar geographical origins, but, rather, every sign that they will embrace urbanization as willingly as other people have done if only given half a chance. (The question whether economic development for native populations may not permanently rob them of the chance to reach some quite different social organization is an unreal fear—that should be for the natives to decide.) Equally, there is no evidence that they differ in ways that are significant from those parts of the South African population now registered to vote, even though they may differ in ways that are culturally important and valuable. Moreover, there is no weight of experience to support the rigorous puritanism of the belief that self-improvement is the only improvement that is worthwhile—rather the opposite. This is why one component in the long-term solution of South Africa's problems is an academic and scientific community vigorous enough to do battle for these simple truths.

What other conditions must be met? It would be absurd for anyone to hope that a political solution to the internal problems of South Africa could be engineered overnight. Decades must go by before everything can be settled. In the meantime, the best hope is that there will be no violent breakdown of the social fabric, externally or, more dangerously, internally. The immediate goal—and distant it must seem to many people—is that the two communities in South Africa should be brought so closely into articulation with each other that there is a chance for the natural processes of social evolution to do their work. Luckily, there are now signs that pressures in the right direction are beginning to work. The white population of South Africa seems increasingly aware of what is going on. There is growing recognition that the policy of separate development is an economic nonsense.

In circumstances like these, the universities and the scientific community which they embody are essential bridgeheads to the outside world and to the future. Whatever people may do about cricket matches, the present circumstance requires that links between South Africa and the outside world in science and academic life should be strengthened, not weakened. The universities, even those commonly supposed to be reactionary, are enlightened and even sometimes liberal. Nobody expects that they will ever lead a social revolution, and with the weight of prejudice in the voting population there is little that they can do to lead voters by the hand. Yet politics in South Africa are so explicit that there is much that the universities can do (and should have been doing all these years) to argue the detailed as well as the general case against the present arrangements. This does not imply endless declarations by university senates but, rather, more vigorous argument by individuals who will need as much time as they can be given to change the present climate. The greatest danger is that time is running out.

100 Years Ago

BRITISH EDIBLE FUNGI

MUSHROOMS and their congeners seem never to have been in good repute since Agrippina employed one of the tribe to poison her husband, and Nero with villanous pleasantry called it the "food of the gods." With proverbial tenacity the bad name thus incurred has clung to the whole family of agarics, and what within certain limits might be called a wholesome dread has become a deep-rooted and irrational prejudice, excluding from popular use a really valuable class of vegetable esculents. We cannot altogether go along with those enthusiastic mycophagists who recognise a substitute for meat in every edible fungus, and dilate on the ozmazome and other nutritious properties of the tribe; but we readily acknowledge that their merits as secondary sources of food-supply have hitherto been unduly neglected. The great difficulty always felt in advocating the claims of the class to more extensive use has arisen from the want of some definite rules, some formula at once simple in expression and universal in application, by which to distinguish the noxious from the innocent members. Pliny, in his Natural History, goes so far as to say that the first place amongst those things which are eaten with peril must be assigned to agarics, and he expresses his surprise at the pleasure which men take "in so doubtful and dangerous a meat." But his observations show that fungi of all sorts, including even such growths as the *Fistulina hepatica*, were known to his countrymen and eaten by them without scruple. Indeed, in one particular the wisdom of the ancient Romans seems to have been superior to that of their descendants, for, while Horace lays down the rule—

Pratensibus optima fungi
Natura est; aliis male creditur—

the modern Ædiles of the Roman market condemn to instant destruction every specimen of the meadow mushroom (*A. campestris*) which comes within their reach. Although, however, it is not always easy to distinguish the wholesome from the unwholesome fungus, and the organs of sight and smell require some training before they can be wholly trusted in the matter, yet the dangers have been greatly exaggerated, and, as a matter of fact, hogweed is more often mistaken for parsnip and aconite for horse-radish than are *Boletus sátanas* and *Amanita verna* for their innocent brethren.

OLD WORLD

ATOMIC ENERGY AUTHORITY

Quiet Before the Storm

THE annual report of the UK Atomic Energy Authority, published last week (HMSO, 17*s*), has cheerful things to say about fusion. At the Culham laboratory, for example, joint Anglo-Russian experiments on the Russian Tokamak device have raised hopes that a fusion reactor may be more than a fantasy, and progress has been encouraging on several other aspects of closed line systems at Culham. Yet funds for Culham continue to be cut in accordance with decisions made several years ago, even though, as the report puts it, "progress fully justifies the maintenance of a strong and viable programme in the United Kingdom".

The chief preoccupation of the AEA remains the development of new reactor systems, on which it spent £43·3 million last year, compared with £41·3 million in 1968–9. Of this, 62 per cent was spent on the fast reactor programme and 20 per cent on water cooled systems. Sir John Hill, chairman of the AEA, emphasized in London last week that the AEA was keen that the first commercial fast reactor should be large enough to be replicated without major modifications. He thought that construction work on the first fast reactor power station would probably start in 1974.

On water cooled systems, the report recalls that the AEA provided the nuclear design and construction consortia with plans for a commercial 450 MW steam generating heavy water reactor. But there is no mention of the gloomy commercial forecasts for the SGHWR, which is beginning to look more like the AEA's answer to Concorde with every month that passes. The Radiochemical Centre at Amersham increased its profit last year by 22 per cent, of which about 60 per cent was from exports. This may encourage the new government to take up the threads of the fuel bill prepared by Mr Wedgwood Benn, former Minister of Technology, in which the Radiochemical Centre was seen as the backbone of one company and the plants at Springfields, Capenhurst and Windscale were to be the focus of a second company, British Nuclear Fuels.

One point which is hardly clarified in the report is the extent to which the Atomic Weapons Research Establishment at Aldermaston has kept pace with the changing orientation of the AEA. An over-enthusiasm for classifying projects of very marginal secrecy may have hampered progress in fields such as computer applications in engineering, in which the AWRE has considerable experience. A computer system for the control of machine tools, for example, had to make its way to the open market through the workshops at AERE, Harwell.

Both the total expenditure and number of staff at the AEA fell last year, although for quite different reasons. The drop in expenditure of about £7 million is attributed chiefly to the delay in completion of the prototype fast reactor at Dounreay and to deferment of purchases of plutonium for fabrication of its fuel. The reduction of staff has continued consistently since 1961, standing now at 30,000 or 10,000 less than in 1961. This represents a drop of 1,300 in the past year, partly due to transfers to the design and construction companies.

ACADEMIC FREEDOM

Law of Protest

by our Education Correspondent

A REPORT that defines the legal rights of students within an institution of higher education has been published this week by the National Union of Students and the National Council for Civil Liberties (*Academic Freedom and the Law*, NUS, 10*s*). The chief recommendation is that every student should enter into a legally binding contract with his college or university guaranteeing certain rights and limiting methods of protest. This is the first attempt so far to define the limits to which student protest should be taken; it is remarkable because to some extent it flies in the face of trade union opposition to legally binding contracts.

The National Union of Students clearly intends that contracts will be subject to negotiation between individual student unions and the institutions to which they belong, but the report lays down several guidelines. For example, it recommends that "college regulations should prescribe the following offences, and no others: (i) to engage in conduct which actively disrupts the teaching or study or research of the college; (ii) to damage or deface any property of the college". In return, the student would be guaranteed academic freedom, defined as "(i) the right to study and to have access to facilities for study; (ii) the right of freedom of thought and interpretation; (iii) the right of those who teach within or service an institution to withdraw their labour for industrial reasons". In particular, disciplinary proceedings should never be taken in the event of a boycott of classes or an occupation provided that these actions do not involve any conflict with the rights of others to study.

Although there may not seem anything particularly novel about these recommendations, if the report is adopted by the NUS conference next month, it would mean that protests such as that at the London School of Economics, where gates were removed and college property damaged, and at Warwick, where occupation of the administration block infringed the rights of others to study, would be forbidden. On the other hand, the report suggests that disputes arising in colleges are often a product of bad government, and there is a strong hint that such disputes can be prevented only by changing college government to incorporate representatives of all members of the academic community. The report also comes out strongly against bringing police on to college campuses to settle disputes.

Another recommendation in the report is the setting up of a higher education advisory board. This body is envisaged as a watchdog to safeguard academic freedom, and also as a final appeals body which would hear appeals against a college decision to expel a student or to refuse admission on academic grounds.

The report also protests against confidential files. In particular, it points out that no information about the political activities of a student should be gathered or recorded. Some aspects of this part of the report may be difficult for student activists to swallow, especially its suggestion that students should have access to those parts of their own records which are not confidential. At Warwick, and at many other universities which were engulfed last year by the wave of protest about students' files, however, the students maintained that no information should be filed which they are unable to inspect.

NOBEL PRIZES

Neurophysiologists Honoured

WITH the news from Stockholm last week that the Nobel prize for medicine had been awarded to the neurophysiologists, Professor Ulf von Euler, Dr Julius Axelrod and Sir Bernard Katz, the wheel has, in a sense, turned full circle. Sir Henry Dale and Otto Loewi were awarded the prize in 1936 for showing that nervous impulses travel through the nervous system in two different ways. In 1963, Eccles, Hodgkin and Huxley were similarly honoured for their part in unravelling the first of these two systems—the electrical transmission of the impulse along the nerve fibre. And now von Euler, Axelrod and Katz share this year's prize, worth £32,000, for their separate work on the second puzzle—how nerve impulses are transmitted chemically across the minute insulating gaps, or synapses, which separate nerve from nerve or nerve from muscle.

Professor Ulf Svante von Euler, 65, was born in Stockholm and has spent most of his scientific life at the Royal Karolinska Institute, where he is now professor of physiology. In the early 1930s he worked for a time at University College, London, where a major influence was Sir Henry Dale. Von Euler's chief contribution to neurophysiology is his demonstration in 1947 that the transmitter substance which diffuses from the ends of stimulated sympathetic nerve to bridge the synaptic gap is the catecholamine, noradrenaline.

Von Euler's work cleared the ground for the later studies of Julius Axelrod. Born in New York City in 1912, Axelrod was trained both as a biochemist and as a pharmacologist, and is now chief of the section of pharmacology at the National Institute of Mental Health, Bethesda, Maryland. After investigating the metabolism of drugs and the function of the pineal gland, he became interested in the fate of the noradrenaline molecule after it had been discharged into the synaptic gap. Clearly the molecule would have to be inactivated after passing on its message, or the nervous system would be thrown into chaos, just as would a telephone exchange if all the plugs were left connected after the calls had ended. Axelrod discovered two control mechanisms; an enzyme, catechol-o-methyl transferase which methylates and destroys the noradrenaline molecule, and a process found only at sympathetic nerve endings by which discharged noradrenaline molecules are reabsorbed by the nerve endings.

Whereas von Euler and Axelrod have been concerned with the transmission of nervous impulses mediated by noradrenaline—the adrenergic nervous system—Sir Bernard Katz has devoted his energies to nervous transmission mediated by acetylcholine—the cholinergic nervous system. His work has led to the important conclusion that synaptic gaps are bridged in essentially the same manner in all parts of the nervous system.

Bernard Katz was born in Leipzig, Germany, in 1911. In 1935 he fled from the Nazis to London, beginning his studies on nerve and muscle function under the supervision of Nobel laureate A. V. Hill at University College, London, where he is now head of the biophysics department. Working initially on the cat neuromuscular junction, and later on giant nerve cells from the squid, Sir Bernard has used microelectrodes, fine glass electrodes which can be inserted into single cells, to study the electrical behaviour of nerve endings. He has shown that the transmitter substance, acetylcholine, is contained in small vesicles at the nerve endings. In the resting state a very small number of these vesicles are discharged spontaneously, but when a nervous impulse reaches the nerve ending many millions of acetylcholine molecules are released to bridge the synaptic gap between the nerve ending and the adjacent cell. More recently, Sir Bernard has been working on the role of calcium ions in the release of acetylcholine.

In announcing the awards, the Royal Karolinska Institute, Stockholm, said the three scientists had "greatly stimulated the search for remedies against nervous and mental disturbances". Whilst drugs tailored to cure mental illness may be far in the future, no one can deny that the work of von Euler, Axelrod and Katz has led to a new understanding of the nervous system and its chemistry.

FORESTRY

English Elm Threatened

THE future of the elm tree in Britain looks bleak unless the epidemic of Dutch elm disease, at present ravaging the British population of *Ulmus procera*, is quickly checked. The disease was first recorded in Britain in 1927, but was a comparatively minor problem until two years ago, when, helped perhaps by a series of fine summers, the present epidemic exploded. Dr John Gibbs of the Forestry Commission Research Centre described the current situation as "devastation, with more than sixty per cent of the elm population destroyed in some areas".

Hedgerow elms blighted by Dutch elm disease. On the left, a healthy elm; on the right, a newly killed tree left gaunt and leafless by the disease.

Dutch elm disease is caused by the fungus *Ceratocystis ulmi*, but the infection is carried and spread by the elm bark beetles *Scolytus scolytus* and *S. multistriatus*. The sticky fungal spores become attached to the body of the beetle and are transferred from in-

fected to healthy trees when the beetle feeds on the young shoots. The manner in which the fungus kills the branches or the entire tree is macabre. Fungal spores find their way into the conducting tissue of the tree and are carried along in the vascular stream. The tree reacts to the presence of these foreign particles by manufacturing gums and resins. It is the accumulation of these substances in the wood which form a kind of embolism, eventually blocking the transport system and killing the tree. In addition, the fungal mycelium produces a toxin to which the elm is susceptible.

It is difficult to assess how much the present epidemic has cost, for elm is rarely grown on a commercial scale. Nevertheless it is an important landscape tree, especially in areas which have been badly devastated, such as the Severn valley and the Thames estuary. Furthermore, elm is a native hardwood of some quality, and recently has been assuming considerable importance in the manufacture of furniture.

There is at present no sure way of eradicating the disease, but research has been developing along three main lines. In America, where the native elm is much more susceptible to the disease than the British species, some success has been obtained by attacking the elm beetle directly and destroying its breeding ground. This has been achieved by clearing infected trees, and spraying healthy trees with DDT in the early part of the season before bud break. In the present climate of conservation, however, this latter practice is causing some embarrassment. In Britain, systemic fungicides are currently being tested, but perhaps the greatest chance of control lies in the development, in Holland, of a strain of elm with genetic resistance to the disease. This is a fast growing species called the Commelin elm, but development has not yet advanced to the stage where the quality of the wood can be assessed.

If these measures prove unsuccessful in combating the spread of the disease, it seems all too certain that within a few years the elm in Britain may be but a verdant memory.

WATER QUALITY

Changes in Moskva River

by our Soviet Correspondent

THE recently published data from the spring scouring of the Moskva River in the Moscow city area reveal some interesting changes in the quality of the river water (*Priroda*, No. 9; 1970). Since the building of the Perervinskaya dam below Moscow in 1937, and the later building of dams on the headwaters of the Moskva and its upper tributaries, the water regime of the Moscow reaches of the Moskva has changed considerably. To avoid stagnation, an annual scouring of these reaches is carried out. A massive discharge of water from the reservoirs is timed to coincide with the natural spring floods on the Moskva. The water coming downstream to the "reservoir" of the Moscow reaches during scouring (estimated at 650 million cubic metres this year, with a peak flow of 500 cubic metres per second) considerably exceeds the capacity of the "reservoir" reaches, and so scouring is effected rapidly. Scouring usually takes place in mid-April, and samples of the river water are analysed one calendar month later. The figures for 1970 include transparency of the water (compared with standard alcohol), 30; content of carbon dioxide, 6·6 mg/l.; total mineral salt ions, 245 mg/l. and oxidizing power against bichromate 12·3 mg of oxygen/l. Compared with pre-scouring figures, the transparency increased seven-fold, the carbon dioxide decreased four-fold, and the amount of organic admixtures decreased considerably because of the increase in oxidizing power. On the whole these measurements follow the pattern of previous years; it is interesting, however, that the phosphate content of the water, which was 0·044 mg/l. in 1965 and 0·004 mg/l. in 1966, has now declined to zero.

JOURNALS

Goodbye *Science Journal*

THE proposed merger between *Science Journal* and *New Scientist*, which was announced last week, will not only create a gap in the field of scientific publishing, but it is also likely to leave in its wake considerable ill-feeling among the editorial staff of both magazines. The proposal means that most of the staff of *Science Journal* will be transferred to the weekly *New Scientist* and it seems likely that *New Scientist* will be expanded to include special features articles. This means in effect that when the final issue of *Science Journal* is published next January, there will no longer be a monthly general science journal published in Britain.

The driving force behind the merger is clearly the poor financial position in which *Science Journal* now finds itself. Mr Walter Williams, group director of IPC Science and Technology Publications, which publishes *Science Journal*, said for example that the accumulated losses of the magazine during its five year lifetime indicate that it will never be financially viable. Moreover, Mr Williams pointed out that there has been an absolute decline in the advertising space sold in *Science Journal*, and that its sales have deteriorated during the past year or so.

This, however, has not deterred a few publishing companies from sounding out the possibilities of taking over *Science Journal*, and the *Financial Times* even put in a firm offer to buy the magazine. By rejecting the offer, and deciding to merge the two magazines, IPC is clearly hoping that the new-style science magazine will be able to pick up most of *Science Journal's* advertising revenue and readers—especially foreign readers. An added advantage, from IPC's point of view, is that the company will be able to retain most of the editorial expertise which has been built up in *Science Journal*.

Although *Science Journal's* editorial staff accept that the magazine has lost money, their general feeling is that in the past few months there has been considerable improvement and that the financial prospects are far from gloomy. The magazine's chapel of the National Union of Journalists therefore immediately invoked the disputes clause in the editorial staff contract, because it is not convinced of the viability of the merger plans. The chapel's attitude at the moment is that *Science Journal* should be kept going as an independent publication. Redundancy is not yet a chief point of concern because all the writing staff, with the exception of editor Robin Clarke have been offered appointments on the new magazine.

If the merger goes through as planned, the January 1971 issue of *Science Journal* will be the magazine's final edition, and the first issue of the new-style *New Scientist* will be published on January 21. A measure of IPC's faith in the selling power of the new magazine is that it will have a print order of 100,000—at present, each separate magazine has a circulation of about 50,000.

COMPUTERS

Demand and Supply

ALTHOUGH more than £20 million has been spent in less than four years on computers for research, the second report of the Computer Board for Universities and Research Councils published last week (HMSO, 3*s* 6*d*) reveals that academic research in Britain is still weak in overall computing power.

The Computer Board was established in September 1966 following the publication of the Flowers report on the present and future computing requirements of research (*Working Group on Computers for Research*, HMSO, 1966). There has been considerable progress since then, and most research groups now have access to some kind of computing facility, but the Computer Board's report emphasizes that there is still a long way to go.

The report describes the past two years as a period of consolidation. Since 1966, 33 new computers have been installed at a cost of £9·4 million, and 8 new computers worth £6·6 million have been ordered. These include five British International Computers Ltd (ITL) 1906A systems, and two of the very large American Control Data Corporation (CDC) 6400 series machines have been earmarked for London University. The capacity of computers already installed at 31 universities has been enhanced at a total cost of £2·9 million, and equipment worth a further £2·2 million has been ordered to upgrade other existing hardware.

The board, under its new chairman, J. D. Finney, University of Edinburgh, is understandably anxious to buy British equipment where possible, especially where large capacity units are required. Their plans to use the ICL 1908A computer for regional computer centres were thwarted when ICL cancelled research on this system to concentrate on the development of Project 52, a radically new computer of comparable size to the 1908A. Details of Project 52 are still confidential, but it seems likely that its novelty will lie in vastly improved ease of operation rather than electronic innovation. Project 52 will not mature until 1972 at the earliest, and until then the board will probably have to turn to the United States for supplies of very large computers.

An important new feature of the board's activities will be responsibility for the provision of computers and computing facilities for teaching as well as for research. This was recommended earlier this year by a joint working party set up by the UGC and the Computer Board (*Nature*, **227**, 1079; 1970) and means that universities will no longer have to limit the use of computers supplied by the board for research purposes. The working party estimated that an extra £1 million would be required to finance the extra hardware required for teaching purposes, but so far the government has not been able to provide further funds. Fortunately, the board's original estimates had taken such contingencies into account, and a small surplus is available to support this extra commitment.

URANIUM SUPPLIES

New Reserves Needed

THERE will be an acute shortage in the world's uranium supplies by the mid-seventies unless new reserves are discovered and exploited. This fact emerges from the latest report of the European Nuclear Energy Agency and the International Atomic Energy Agency (*Uranium: Resources, Production and Demand*, OECD, $3, £1). The agencies estimate that the present consumption of 15,000 short tons of uranium oxide ore a year will increase to 38,000 short tons a year by 1974–76—a figure equal to the existing production capacity—and by 1980, the demand will be about 73,000 short tons a year. The estimate assumes an increase in the nuclear generating capacity of the world from 18 to 300 GW in the next ten years, and it is based on information gathered from all countries known to have a nuclear power programme, with the exception of the People's Republic of China, the USSR and the countries of Eastern Europe.

Anticipation of the future demand has been the chief impetus behind the recent boom in prospecting: since 1967, discoveries of uranium in Canada, Australia, the Central African Republic, Gabon, Niger and the US have increased the estimated world reserves from 700,000 to 840,000 short tons. The report points out, however, that if the consumption of uranium increases at the estimated rate, it will be necessary to discover and develop an additional one million short tons of uranium oxide by 1985. In the opinion of the working party responsible for the report, it would be prudent to give greater emphasis now to relatively low cost primary prospecting with the objective of discovering new uranium provinces suitable for subsequent, more detailed exploration. It is difficult to predict where new reserves will be found, however, but of the nine uranium producing countries, Canada and South Africa seem to have the most room for expansion of existing industry.

The future demand should end the lean days of the uranium mines. At present, low prices, fluctuations in the market and an unexpectedly slow movement of the world nuclear power programme have produced a state of over production and hesitancy in the industry. At Elliot Lake in Canada, for example, where once there was a bustle of activity to supply the military needs of the US government, many of the mines lie idle.

But when the promised boom does come, it could produce the familiar pattern of sudden shortage followed by over supply. The report suggests that consumers could improve the market stability either by making advance purchases or by negotiating long term supply contracts; this would encourage suppliers to proceed with plans for new production capacity and to search for the additional reserves needed to satisfy future needs. In this way mismatching of supply and demand could be avoided. Whether or not enough uranium will be found in time, the report seems reluctant to predict.

NEW WORLD

Rashness that may Pay Off

by our Washington Correspondent

JUST as the rubella vaccination campaign in the United States is reaching its full momentum, critics are repeating their earlier fears that the programme is based on a shaky strategy and could even do more harm than good. The root of the controversy is the classical dilemma of whether to act on the basis of incomplete knowledge to try to forestall a certain tragedy. In this instance the decision has been to act now in the hope of preventing the rubella epidemic that is expected to break out this winter. But although no qualitatively new evidence has come to light since the decision to proceed was taken a year ago, the doubts about the basic strategy of the campaign have been accumulating. Meanwhile the Department of Health, Education and Welfare's Center for Disease Control in Atlanta, Georgia, continues undeflected in its aim of vaccinating between 40 and 60 million children before the next epidemic begins.

Rubella, or German measles, is a harmless enough disease in people, but the virus can cause death or malformity in the foetus if contracted by the mother at a certain stage of pregnancy. In the last rubella epidemic in the United States, in 1964, there were some 30,000 foetal deaths and 20,000 children born with congenital abnormalities. So far some $41 million has been allocated to the present vaccination campaign, which has already reached 16 million children between the age of one year and puberty, or about a quarter of the total target population.

The campaign is modelled on the successful vaccination programmes conducted against polio and measles but it differs in the indirectness of its approach; the immediate beneficiaries are not the children who are vaccinated but the susceptible women in the community for whom the children are the commonest source of infection in an epidemic. With the live attenuated virus that is the basis of the present vaccines, the risks of vaccinating susceptible women directly seemed unacceptable—some of the vaccinees might unknowingly be pregnant and the effects of the attenuated virus on the foetus are unknown. Instead, it was decided to try and immunize enough of the children in the population to prevent an epidemic from starting.

This so called "barrier" strategy has been successful with measles and with polio, but several surveys of which the most recent was reported this month by Horstmann and colleagues at the Yale University School of Medicine*, have shown that at least in the special conditions of military camps the virus can still reach all the susceptible victims even though more than 8 men out of 10 have a natural resistance to the disease. Unless the vaccination programme can reach more than the 80 to 85 per cent of the population which is naturally resistant to rubella, some critics argue, the barrier it throws up will not be sufficient to halt the epidemic.

Another criticism is that the present vaccines provide a smaller degree of immunity to rubella than does natural infection, with the result that vaccinees are often reinfected when exposed to the wild virus. (In the survey reported by Horstmann and her colleagues, for example, 80 per cent of the vaccinated soldiers became reinfected during the epidemic.) Even though the infection in these cases is almost always clinically inapparent, being detectable only through a rise in the circulating antibodies, there is the possibility that the reinfected vaccinees may transmit the virus to others. The Public Health Service Advisory Committee on Immunization Practices said in a report in August that the probability of such spread is "exceedingly low". Others are not so sure. The epidemiologists at Yale University, for example, conclude that the question is far from settled although they agree that risk of contagion from reinfected persons is greatly reduced.

Another source of uncertainty is the duration of the immunity conferred by vaccination. Will a girl vaccinated against rubella at the age of 6 still be immune to the virus by the time she starts to bear children? The Advisory Committee on Immunization Practices bases its view that long term protection is likely, on the evidence that antibody levels have declined very little during the four years of observation of the children who were the first to be vaccinated. But others believe that a substantial proportion of vaccinees may lose their immunity after ten years or more.

A different question is whether a mother who has been vaccinated but is reinfected runs the same risk as a susceptible woman of bearing a rubella baby. Malformations are known to occur even when a susceptible mother has suffered from rubella in a clinically inapparent form; the clinically inapparent form of the disease with which vaccinees become reinfected could in theory also be teratogenic. However, although this possibility cannot yet be ruled out, no one has yet detected the virus in the bloodstream of reinfected vaccinees, which suggests that it is unlikely to cross the placenta in these cases.

A more theoretical worry concerns the quality of immunity to rubella in subsequent generations, should the wild virus be eliminated by the vaccination programme. Since the vaccine provokes a smaller degree of immunity than does exposure to the wild virus, it could be that generations which have to rely on vaccination for their immunity will be less strongly protected against the virus.

Defenders of the vaccination programme reply that none of these criticisms is new, and all were fully considered before the programme was started. It is true there are uncertainties in the knowledge of how the vaccine will work, but to wait for more complete knowledge whilst suffering the toll of the rubella babies born in the approaching and later epidemics would be absurd, especially when a viable rubella vaccine is in existence. The two crucial questions are whether a reinfected vaccinee can participate in the chain of transmission and whether, if pregnant, she can transmit the virus to her foetus. While these possibilities cannot be ruled out, they seemed at the time, and still seem, sufficiently small to justify the present use of the vaccine. Defenders of the programme argue that the spread of the virus in a military camp, as reported by

* *New England Journal of Medicine* (**283**, 771; 1970).

Horstmann, should not be construed as evidence that the barrier strategy is mistaken, since for several diseases the progress of transmission in these conditions is known to be quite different from that among the civilian population.

The severer critics of the present campaign believe that the Division of Biologics Standards of the National Institutes of Health, which is responsible for recommending licences for the vaccine, should have allowed more research data to accumulate before giving the programme its blessing. As it happens the attenuated virus strain on which two of the three vaccines are based was developed by two scientists in the Division of Biologics Standards, Drs H. M. Meyer and Dr P. D. Parkman. In deciding to recommend licences for the rubella vaccines the director of the CAP D division, Dr Roderick Murray, took advice from all people concerned, not excluding Drs Meyer and Parkman. But to avoid any conflict of interest Dr Murray specifically requested that no member of the Biologics Standards Division should also have a voting position on the board responsible for developing the rubella vaccines, the Vaccine Development Committee of the National Institute of Allergy and Infectious Diseases. Dr Meyer was one of the non-voting liaison members of this committee but, with his exception, no member of the Division of Biologics Standards sat on this or either of the two other committees involved, the Surgeon General's Advisory Committee on Immunization Practices and the Immunization Committee of the American Academy of Pediatrics. The latter two committees issued a joint statement at the time the rubella vaccines were licensed recommending their routine use on children.

A more moderate view of the vaccination programme is taken by the Nobel laureate Dr John Enders of the Boston Children's Hospital. In a judiciously balanced editorial article in the *New England Journal of Medicine* he said that the "accumulating doubts" about the long term effectiveness of the programme "should not for the present be allowed to interfere with its continuation. But in the meantime they may usefully encourage a reconsideration of other, more direct procedures, such as the vaccination of susceptible parturient women or of adolescent girls".

Though it is far too early to assess how the vaccination is working, those involved with the programme have the impression that in areas where there has been heavy vaccination there is less rubella around than usual. Even should the campaign not succeed, there are many who will say it was worth the gamble.

AIR POLLUTION

Academy to Take on Detroit Oil Men

by our Washington Correspondent

THE National Academy of Sciences is a rarity among learned societies in that it is required by charter to tender practical advice, when requested by government, on the issues of the day. Unlike the British Royal Society, for example, whose only purpose in life is self-perpetuation, the National Academy dares to put the talents of its members to practical use, though with the ever present risk of offending powerful interest groups or agencies of government. The academy now seems likely to be charged with a task as awesome politically as any that it has yet faced, that of monitoring progress in meeting Senator Muskie's clean air bill which states, among other things, that all cars manufactured after January 1, 1975, will emit 90 per cent less pollutants than present models. The academy may thus be brought into conflict with the automobile manufacturers, if it finds them dragging their feet, and maybe with the producers of gasoline as well, or with the Congress should it find the legislated standards technologically impossible to meet.

The standards demanded by the Senate for 1975 model cars have not yet reached the statute book but have every chance of doing so now that they have been agreed to at a meeting this month between Senate and House conferees. What the House and Senate have yet to agree upon is the precise role to be played by the National Academy in seeing that the legislation is fulfilled. It appears that the academy will not be asked, as at one time seemed likely, to say at this moment whether the 1975 deadline for reduced emissions is technologically feasible. At the meeting between Senate and House conferees on October 8, it was agreed that the academy should prepare reports at six-monthly intervals, the first being due next July, on the progress made by the manufacturers towards meeting the deadline. But the academy may also be required to comment in its six-monthly reports on the progress made in light of what is technologically feasible at the time—in other words, on whether the car-makers are trying hard enough. In assessing what is technologically feasible the academy will not be asked to consider price as a factor.

One point at which the academy's advice will clearly be crucial is in deciding the option, allowed for in the bill, of postponing the deadline by one year should the manufacturers be able to prove to a federal court that it is too harsh. The precise description of the Academy's role will be decided when the conferees from the Senate and House meet again next month. The Academy is said to have refused government requests for advice only half a dozen times in its existence and is unlikely to pass up this one, however great the temptation.

ANTARCTICA

NSF declared Sole Heir

by our Washington Correspondent

THE National Science Foundation will become the most puissant power in Antarctica, following President Nixon's decision last week that the foundation should be the sole channel for funding United States work in the continent. The budget of the NSF will be increased by $25 million when the transfer of programmes from the Department of Defense and the Coast Guard is complete. But the changeover will not necessarily mean more money for Antarctic research, since the programmes to be transferred are concerned almost wholly with providing logistical support to existing research efforts.

This year the foundation is spending $7·5 million on all forms of Antarctic research, which at the height of the season, during the austral summer, brings some 200 scientists and technicians to the four year-round bases the United States maintains at Byrd, McMurdo, Palmer and the Amundsen-Scott South Pole station. The eleven major projects being supported this year include a balloon study of cosmic rays under J. Barcus at the University of Denver, continued exploration by

Ohio State University of the rich fossil fields excavated last year, and a study of the plasmapause under J. Katsufrakis at Stanford University.

The US Army Cold Region Research and Engineering Laboratory, which has the distinction of having drilled cores down to bedrock through both the Antarctic and Greenland icecaps, is not venturing forth on the ice this summer. The intriguing record of climatic history that is stored in these cores—the ratio of oxygen isotopes in ice samples at various depths gives a measure of the temperature prevailing when the snow was formed—is unfortunately very expensive to extract. The core drilled at Byrd station in the summer of 1968–69 cost some $250,000 and the determination of the $^{18}O/^{16}O$ ratio costs $50 a sample, although this part of the research, conducted under W. Dansgaard at the University of Copenhagen, is supported by the Danish government.

The ice at the bottom of the Byrd station core is about 70,000 years old, whereas that in the Camp Century core from Greenland is nearer 100,000 years. There are plans to drill another core through the Antarctic ice cap, probably as part of an international glaciological programme in which the Soviet Union, Britain and France would participate. A second core would hopefully extend the climatic record further back into the Pleistocene as well as providing a fuller comparison with the thousand century temperature chart extracted from Greenland.

MALNUTRITION

New York Children lack Vitamin A

by our New York Correspondent

A WIDESPREAD deficiency of vitamin A among children in New York City, particularly those from lower-income homes, was reported last week by Dr Robert Newman, director of the National Nutritional Survey of New York City, at a meeting of the New York Academy of Sciences. Dr Newman noted that there is still no agreement as to what constitutes malnutrition, each scientist defining it according to his own frame of reference. But he hoped that the New York survey, along with those being conducted in ten other states, would enable present definitions and techniques to be re-evaluated.

The New York study figures released last week are based only on laboratory analyses, so that correlation of dietary deficiencies with specific symptoms or illnesses must wait until the clinical examination results have been tabulated. Deficiency of vitamin A is known to contribute to a loss of vision in poor light, but it is not known how great the deficiency must be before sight is affected. There is also great disagreement over what constitutes the "minimal daily requirements" of nutrients. For example, in Britain 20 mg is considered an adequate daily amount of vitamin C, while in the United States the common figure is 70 mg. The National Survey originally defined the requirement as 60 mg but dropped this level in the course of the survey to 30 mg. The distinction must also be made between nutritional levels and "good eating habits". Dr Newman pointed out that the reason why so few people were found with vitamin C deficiencies might well be because it is added to many sodas and soft drinks. "These drinks are still frowned upon and not considered a desirable source for this nutrient," he said.

Forty-six per cent of children under seven years old in lower income families were found to have vitamin A deficiency, compared with 18 per cent of children of that age in upper income families. Between the ages of seven and twelve the figures were 27 per cent for the lower-income and 25 per cent for the upper. Ten per cent of the low-income children between seven and twelve were deficient in vitamin B, riboflavin, compared with six per cent of the upper-income children of that age group. For purposes of the study, the dividing line between lower and upper income families was placed at an annual income of $4,156 for a family of four.

COMMUNICATIONS

Beware the Polluted Spectrum

IT is admirable that the National Academy of Engineering should be aware of the electromagnetic spectrum as a natural resource that is in as much danger of pollution as any river, but the latest report by the panel on spectrum value is a crashing disappointment*. The lengthy report now published could almost stand as a deliberate example of how words can be a pollutant. That itself does not auger well for the spectrum. The aim of course is to devise a sensible way of deciding how to parcel out the finite band of the electromagnetic spectrum that can be used for such activities as communications, radar, aircraft control and so on. Part of the reason for the continuing importance of this topic is that parts of the spectrum at shorter wavelengths than used to be impracticable to use are now being opened up through the development of new equipment and the pressure on the conventional wavebands. What the panel has been trying to do without much luck is to think up some social and economic criteria that can be applied to the judgments that have to be made about the purposes to which unused parts of the spectrum are to be applied. To begin with the report expresses surprise that up to now things have gone as well as they have, in the United States at least, with a system of spectral management which the report criticizes. For example, the panel finds that the Federal Communications Commission is slow at coming to decisions, usually hears evidence only from those directly involved in a contest over a particular band, and has inadequate technical advice. What the panel would like to see is more representation for the general public above that which the officials of the FCC themselves provide, and a better backing staff to provide the technical background and speed up the negotiations. The reason these deficiencies have not made themselves felt more strongly earlier, the report says, is that technical advances have tended to cover up where mistakes have been made. The panel makes no secret that what it would really like is a formula to express the social and economic value of a given application of part of the spectrum as an index. Reluctantly the panel concludes that no satisfactory formula is likely to be devised. All that the panel can suggest then is to strengthen the present methods of allocation. What this boils down to is that the people who have to make the decisions about the use of the spectrum should be backed by better advisory teams, and it is a shame that this lukewarm recommendation is all that the panel can find to say.

* *The Application of Social and Economic Values to Spectrum Management*, available from the Committee on Telecommunications, National Academy of Engineering, Washington DC.

SOUTH AFRICA

Public Support for Science

THE government of South Africa has a creditable record in the support of scientific research, chiefly through the agency of the Council of Scientific and Industrial Research, which has just been celebrating its twenty-fifth birthday. The organization was established by Dr Basil Schonland, who has in his time served as director of the Atomic Energy Research Establishment at Harwell. Over the years, the council has grown until total expenditure is Rd80 million (£1 = Rd1·7). This represents an increase by a factor of 2·5 in the past decade, during which time the council has also produced by fission the Medical Research Council of South Africa, established a year ago and still from all appearances learning how to find its administrative feet. The chances are that the CSIR is directly responsible for roughly one half of expenditure on basic research and applied research in South Africa—substantial sums are also spent by the Atomic Energy Board and by other government departments.

As a vehicle for the public support of scientific research and development, the council is an interesting variant on the theme of a research council. At the beginning, it was modelled on the National Research Council of Canada, but care has been taken to ensure that funds intended for the support of university research cannot dribble away into government laboratories.

The president of the CSIR, Dr S. M. Naudé, explains that the funds intended for university research, Rd1·34 million in 1968–69, are administered entirely separately from the budgets for the several research institutes which make up the CSIR campus at Pretoria and which are also scattered elsewhere about the country. Dr C. E. M. Brink, who administers this money, explains that the task is carried out much in the way now familiar in Western Europe and the United States—a series of seven interlocking advisory committees drawn from the academic world serves at once to provide advice on how to spend the funds available and also as a kind of lightning conductor to assure universities that their rights are well looked after. One innovation is that the academic awards committees are built up by selecting suitable members of the academic staffs of universities in strict rotation. Another, which administrators elsewhere will no doubt envy, is that there is a built-in growth factor of 7·5 per cent applicable to both halves of the budgets.

In the balance between extramural and internal research, there are grounds for thinking that the council has been less than generous to the universities. Excellent though much of the university research may be, there is no doubt that academic research is spread too thin. A part of the trouble is the shortage of research students, itself a function of the rapid attrition of the entering university population with progress towards an honours degree (see page 312). Another seems to be the difficulty of persuading universities which are inordinately jealous of their independence from government direction that sensible concentration on particular fields of activity may be appropriate. The council has nevertheless been able to establish in the past few years research units at universities which are responsible for diverse programmes of research—chromatography (Pretoria), cosmic rays (Potchefstroom), geochemistry (Cape Town), marine research (Durban), natural products (Cape Town), oceanography (Cape Town), palynology (Bloemfontein), polyenes (Stellenbosch) and solid state physics (Witwatersrand). The objective of these units is to concentrate the efforts of a full-time staff on particular problems, and in the process, toughen the fibre of university research. There is some way to go before the influence of the several units will be fully apparent.

Like other research councils, the CSIR is prepared to support students with bursaries for further study. People staying on for an honours degree can hope to pick up Rd600 a year; the stipend increases to between Rd700 and Rd1,000 a year (with a maximum of four years) for postgraduate students, while there is a system of postdoctoral stipends (not particularly effective so far) amounting to Rd 1,400 a year but with a possibility of supplementation by means of fees for university teaching. The council is at present also dickering with a scheme for providing three "prestigious bursaries" of between Rd2,500 and Rd3,000 a year for periods of three years but, for an organization seeking to tempt back emigrés and to attract people from overseas, this looks like small beer. In the battle against the brain drain, however, there is more in the scheme for tempting South African nationals back to the Republic by sharing the cost of a person's salary

South Africa

THE haunting dilemma of the Republic of South Africa is that no question can be thoroughly divorced from the central issue of South African politics—*apartheid*. The accompanying account, based on observations during a visit to South Africa sponsored by the Council for Scientific and Industrial Research, is an attempt to describe the present state of scientific research and of the institutions related to it. For many people in South Africa, that will be sufficient, and indeed there is a great deal to be learned from cold-blooded comparisons. Many South Africans will also be puzzled to know why their present policies should cause such deep resentment eleswhere, which is why this survey should be read in conjunction with the leading article on page 301.

between the CSIR and the government up to a maximum of Rd,6000 a year for a period which may be as long as two years—this device seems already to have brought back several good people.

What are the principles on which the national research council of a small country should operate? From the beginning, the CSIR has made no bones about its interest in the full exploitation of national resources. The result is that the bulk of its expenditure goes on the support of fifteen research institutes, most of them in Pretoria. The directors of the individual establishments echo the views of the president of the council as a whole in his insistence that the operation of a successful research establishment requires that applied research should be leavened with an admixture of more fundamental work, and this is the spirit in which laboratories such as the National Physical Research Laboratory and the National Chemical Research Laboratory, to name two, devote a substantial part of their energy to work that could well be carried out in universities. In practice, the research institutes seem also to have been successful in achieving one of Mr Wedgwood Benn's old ambitions for British government establishments—a measure of success in supporting the work done by means of contracts from outside. On the face of things, no less than Rd5·45 million of the Rd14 million spent on research institutes in 1970–71 came from sources other than the parliamentary grant, but Rd1·85 million consists of a payment by the United States National Aeronautics and Space Administration for the operation of the space tracking station at Hartebeesthoek. Elsewhere in the council's empire, substantial sums are provided by contracts with other government departments—the work carried out by the National Chemical Research Laboratory on the improvement of what is patronisingly known as bantu beer is, for example, financed by means of a levy on the 151 million gallons of this beverage sold each year by municipalities in South Africa. (A part of the justification for this enterprise is that the particular product of a two-stage fomentation of maize which yields the regional mildly alcoholic drink is also an important source of protein for diets that may otherwise be unbalanced.)

The insistence on a modicum of basic research in the research institutes is also a valuable means of keeping the staff concerned in touch with scientific developments elsewhere. In the past few years, the CSIR has been vigorous in supporting research conferences and symposia in South Africa. During the same period, it has helped to let its scientific employees feel at liberty to travel overseas at frequent intervals and has encouraged the same optimism among its pensioners in the universities. Those in charge of these operations say that this policy is necessary to compensate for the geographical isolation of South Africa. Most people insist that there have been no signs so far of political isolation, although there are individual and occasional tales to be coaxed out of unfriendly receptions overseas or of difficulties in attracting scientists of precisely the right kind to South Africa. As in the universities, so in the government establishments of the CSIR, however, there seems to be general agreement that the flow of visitors in both directions has become more free in the past three or four years. The newly created Medical Research Council has an explicit declaration of its willingness to encourage foreign travel.

The ecumenical influence of the CSIR is also seen in the way in which the council has been able to mix up Afrikaans and English speakers. In many other fields, the two communities of separate European origin are almost as carefully separated from each other as white people are from those with black or coloured skins. One of the most serious defects of the educational system in South Africa is, for example, the requirement that primary and secondary public education should be carried out in what is called the mother tongue—the result is that the distance between the English and the Afrikaans population which is in many ways responsible for the political unreality of South Africa is perpetuated and even intensified.

The work at the council's institutes has an interest that often extends beyond the severely practical. Thus there is immense potential interest in a research programme being carried out by the National Institute for Nutritional Diseases, until recently one half of the National Nutrition Research Institute of the CSIR and now a dependant of the Medical Research Council.

The objective is to investigate possible relationships between the occurrence of liver cancer among the native Africans—one of the diseases frequently occurring among migrant workers in South African gold mines. Demography has shown that the highest incidence of liver cancer is to be found in northern Mozambique and the object of the investigation by the National Institute for Nutrititional Diseases (in collaboration with a Portuguese group) is to investigate the possibility that liver cancer is caused by mycotoxins such as, for example, the aflatoxins. So far, the surveys carried out have shown that the incidence of the disease is in many places one hundred times that found elsewhere, but so far there has been no obvious link with the fungi cultured from the local diet. A similar project of potential regional benefit and international interest is an investigation of the aetiology of oesophageal cancer among the black native population of the Transkei—one of the regions of South Africa now set aside as a "homeland" for the native population and already blessed with a measure of independence.

The National Institute for Building Research has made its name by the development of a cheap and easily constructed house for black Africans. One product of this work is the stark uniformity of the African townships which are to be found at distances of between three and twenty miles from the large cities in which large amounts of native labour are employed. The original research was based on the result of a careful survey of the needs and habits of the black population of South Africa in the late fifties. Then, it seems, the needs of the typical black labourer could be most adequately met by a simple four-roomed house, without internal doors and without a ceiling. In the past few years, houses on this pattern have been constructed in several African townships, sometimes by the would-be residents themselves and sometimes on a production line basis by comparatively unskilled labour. Now, however, the National Institute for Building Research has embarked on a new survey of the needs of contemporary Africans. By all accounts, it is almost certain to emerge that urbanization has brought with it increased expectations and increased capacity to pay among black Africans. The institute is also deeply

concerned to find ways of planning African townships so as to make them seem less stark. The work now under way could, in other words, have a powerful influence on African society in the seventies.

Similarly far-reaching work is under way at the National Institute for Personnel Research, just off the campus at Witwatersrand. The institute's reputation stems from its work in the late forties in the development of a simple test for estimating the capacity of would-be mine workers (black) to carry out the tasks expected of them. Over the years, the test has become so well established that rural parts of Africa are now said to provide coaching in the assessment test for those about to seek employment in the mines. Thus the institute is bringing its assessment procedure up to date. In the process, it is seeking evidence to show how, over a span of two decades, urbanization, modestly increased prosperity and an awareness of the modern world may have made would-be mine workers more skilful in western ways.

The institute is beginning to ask questions about the way in which black people and white people are influenced by changes in their environment. The reputation of the institute's people is high enough to ensure that they will tell the truth, however unpalatable it may be, and for whom.

In the past year, arrangements have been made to extend the scope of the South African Government's influence on scientific research and development, chiefly by the creation of a Scientific Advisory Council, providing advice both for the Prime Minister, the Minister of Planning (formally responsible for the CSIR) and the government departments with an interest in scientific research. It remains to be seen how deep the influence of this body will be.

In general, however, there is a sharp contrast between the success with which the CSIR and other bodies have been able to develop their research programmes and the apparent lack of objective criteria for deciding how the balance should be struck between competing claims. In such a situation, there is at least a danger that the work that gets done is the work most easily done. And why should the funds available for university research be such a modest proportion of the government's total expenditure. Elsewhere, the money spent in this way has been linked with the output or the desired output of trained scientists. South Africa is more conscious than most countries of this need and thus would seem a natural place for the application of the doctrine that university research expenditure is a necessary component of higher education.

Universities Between Millstones

THE problems of higher education in South Africa seem to be determined largely by the quality of secondary school education, of which most university teachers complain, by the heavy teaching load which most of them carry and by the problems occasioned by the government's policy of separate development. In the past few years, there seems to have been a generous increase in the funds available for university development as well as for research, and everybody agrees that the government has been fair in its allocation of funds to universities considered loyal, chiefly those that teach in Afrikaans, and those which make no secret of their opposition to separate development, chiefly the University of Witwatersrand and the University of Cape Town. Research funds, at least when they are provided by the CSIR, are said to be administered efficiently and fairly; the chief complaint is that time for research has to be squeezed out of a timetable overcrowded with teaching.

The growth of the universities whose existence is justified by the doctrine of separate development is perhaps of the most immediate interest. By now, there are four universities for the Bantu (blacks), one for coloured people (in western Cape Province) and one for Indians (soon to be constituted in Natal). Until July last year, the first four of these universities were constituent colleges of the University of South Africa which still has 25,000 students on its books, most of them following correspondence courses. The philosophy underlying the setting up of the non-white universities is that each "nation" in the Republic of South Africa should have its own university to act as a focus for its own characteristic cultural development. Quite apart from the question whether such a policy is meaningful, there are practical questions of whether the universities are doing the job for which they are intended and which their students expect of them.

In the ten years of its existence, the University of the North at Terfloop, 200 miles north of Johannesburg, has grown to a total of 800 students. As with the white universities in South Africa, the undergraduate course consists of three years of study, with the option of a fourth year for those who wish to obtain an honours degree. The assistant registrar at Terfloop, Mr L. Coetsee, explained some days ago that the university is planning for between two and three thousand students by 1980. Many of the students at Terfloop, all of whom are black, come from as far away as South-West Africa, Rhodesia and even Malawi. Mr Coetsee expects that it will be possible to accept between 200 and 250 of those who have applied for admission for next year (beginning in January). The average age of the students is 24 and more than a third of those now in residence are thought to pay their own way, although others survive on grants which may range up to Rd600 a year (compared with fees of about Rd250 a year), usually—as in white universities—provided in the form of loans by government departments or private companies wishing to stake a claim in advance on a student's services.

At Terfloop, the standard language of instruction is Afrikaans and the staff for the time being is also largely white. Mr Coetsee estimates that some thirty of the 100 people on the staff at present are black. One of the complications of the situation, stemming not so much from the doctrine of separate development as from the older prejudice that white men do not take orders from black men, is that the black members of staff are either

junior people or nominally at least the heads of separate departments such as "history of education". The assistant registrar, Mr Coetsee, says that there is no difficulty in recruiting staff to the university, which is after all "a part of the university system", and which, in spite of the deserted plain in which it is sited, "is only 200 miles from Johannesburg".

Professor D. J. Fourie, dean of the faculty of mathematics and natural sciences, says, however, that one of his chief difficulties is that of recruiting staff, many of whom are prepared to come for short periods while finishing off a thesis. One result is that a splendid array of equipment for the investigation of surfaces and physical structure of solid materials remains under-used because the two junior members of the physics department this year are nuclear physicists and not solid state physicists. Professor Fourie is also more sceptical than Mr Coetsee about the speed with which it will be possible to recruit a teaching staff which is entirely black.

Everybody seems to agree that there are serious problems in preparing students in mathematics, but those who blame poor teaching in the schools are matched in numbers by those who say that there may be more fundamental causes. As a practical expedient to help students along with mathematics, two parallel courses are being provided which are expected to carry a student to the point of school-leaving mathematics after two years at the university, and this is only one of the reasons for thinking that, in spite of its name, the University of the North is still very much a high school. The most fierce critics of the system will of course agree that ten years from start to finish is a short spell in the lifetime of a university, and there is every chance that growth will bring simplification—at Terfloop as at the Western Cape University for coloured students, people complain that in small classes the chance is small of finding a handful of stimulating students. Professor E. P. Lekhela, from the department of history of education, agrees with Mr Coetsee that separate development applied to universities is worthwhile—"you work better for your own kind". The Western Cape University does, however, have a dash of the mission about it. The principal, Professor N. Sieberhagen, says that "we would not be here if we were not missionaries".

In the year just finishing, more than 900 students have been enrolled and the university is expected to grow to between 2,500 and 3,000 by 1980. Eventually there may be a second university for coloured students, but only when the population of the Western Cape University has grown to 6,000 or more, possibly by 1990. At present, the university is not residential but, rather, dependent on the nearby coloured communities of Cape Town for lodgings. As at Terfloop, there is a great deal of headshaking about the quality of the schools from which the students come but everybody insists that academic standards must not be allowed to drop. One result is that there are only two coloured members of the staff of seventy and—given the insistence on standards of academic achievement and the likelihood that the university will have to train most of its own staff—there is very little prospect that this ratio will rapidly increase.

Another consequence of the insistence on high academic standards and the poor preparation that the schools provide for higher education is that the drop-out rate is often extremely high. In chemistry, for example, more than half the students are expected to fail their first year examinations even after many of them have been prevented from competing by advance testing. Among the students at Western Cape, science seems to be a popular option—of the sixty-one degrees awarded in 1969, twenty were BScs and seventeen were BAs. (In the same year, there were three honours degrees in science and four in arts, while the university as a whole awarded fifty-six diplomas indicating training in teaching and social work.) The dilemma of the non-white universities is evidently that of knowing how best to satisfy the needs of students without so markedly adjusting the curriculum to suit them that students may complain of being given an inferior education. Another is that of striking a balance on the staff—many teachers at the non-white universities are gifted people with the highest ideals, but others are plainly much less well endowed. The problems of how to recruit a teaching staff which is racially identical with the students is still more daunting. So too is that of improving standards of teaching in the schools. One of the problems peculiar to the Western Cape University is that many of the brighter students never find their way there because of the temptation to register for medicine or engineering at one of the white universities willing to take in non-white students—a procedure which, with government permission, can still be followed when non-white universities have no suitable courses available. (One calculation at Western Cape University is that there are 450 coloured students registered at Cape Town and Witwatersrand and 500 at the University of South Africa. The staff seems much more constant than at Terfloop.)

The problems of inadequate preparation at school, particularly in scientific subjects and their ancillaries, seems constantly to plague the white universities as well as those set up to provide non-whites with higher education. Entrance to South African universities is by exemption from matriculation. At Stellenbosch, for example, more than 60 per cent of the matriculation examination provides more or less automatic admission. As elsewhere, the attrition through the years is rapid—one estimate is that 200 first year students intending to specialize in chemistry will be whittled down to 120 in the second year and will produce sixty graduates at the end of their third year. The number of students staying on for an honours degree is usually about 20 per cent of the first degree class. Witwatersrand and Cape Town, both English-speaking, seem to be able to be a little more selective, as is the new Afrikaans University of the Rand (established three years ago at Johannesburg).

There is a good deal of talk about curriculum development in the schools but very little interest among the university establishments in reforms of the higher education system itself, except that there is now something of a tussle under way at Stellenbosch, with younger members of the faculty urging that the diversity of its students predicates a need for a broader education than the classical pattern based—especially at the Afrikaans-speaking universities—on what is called in South Africa the continental pattern. (The word European is of course preempted.) The Afrikaans University of the Rand, with only a few hundred students to boast of, is also hoping to break new ground by relying on open-ended teaching patterns and on a modified tutorial system.

Research, when there is time for it, is as imaginative

and excellent as anybody could ask. Pretoria has made a name for itself, for example, in chromatography and other methods of chemical separation; Stellenbosch has a strong line in the ecology of desert animals; Western Cape is pursuing the study of indigenous snake venoms with distinction; Cape Town has geochemistry and marine ecology to boast of, as well as the study of insect pheromones, and is also the possessor of Moon rock samples; Witwatersrand has a phytotron and a splendid programme in geophysics. One difficulty in estimating how much research work is carried out in universities stems from the way in which South African universities are encouraged by the government to buy new equipment by raising loans from outside sources repayable over forty years. Even the most casual inspection shows, however, that university departments are almost lavishly equipped (even if the oceanographers at Cape Town now wish they had a larger boat in which to go to sea). The most acute shortage is that of time in which to pursue research. Research grants as such usually come from the CSIR, and tend to be at once rather small in amount and uncoordinated—a pattern which is as much a consequence of the jealous independence of the universities as of niggardliness by the CSIR. Dr C. E. M. Brink, the deputy director of the CSIR and the man responsible for administering university research, has made a reputation for himself by his diligence in interviewing potential grant recipients.

People in the universities say that it is comparatively easy to keep in touch with scientific developments elsewhere. In the past three years at least, universities seem to have made conscious attempts to provide members of staff with opportunities to travel abroad. Good research students are encouraged to seek research experience overseas before settling down to academic life in South Africa—a practice begun by the English-speaking universities and now being copied by the others.

There seems some confusion about the rate at which people going abroad for study are lost to South Africa—in the early sixties, it seems that 70 per cent of those going abroad failed to come back again but now the ratio is more like 20 per cent. Academics and administrators agree that in the past few years there has been a tendency for people from abroad, especially Western Europe and the United States, to seek openings at South African universities. Part of the explanation seems to be that academic salaries (in contrast with those to be earned in school teaching) are comparatively high, that South Africa abounds with interesting problems to be solved and that, in any case, positions in the United States are now much harder to find than in the past.

University Politics

FROM outside South Africa, it is hard to appreciate how strongly some of the universities, but especially Witwatersrand and Cape Town, dissent from government policy on *apartheid* or, as it is now called, separate development. Both universities have commemorated their protests in 1958 against the decision by the government that non-white students should not register at white universities except by government consent by plaques spelling out their devotion to the cause of academic freedom. Two weeks ago, the students at Witwatersrand surprised themselves and the authorities with the orderliness of a march through Johannesburg to protest against the banning (i.e., isolation) of seventeen alleged terrorists acquitted in the previous week of the government's allegations against them. At both universities, members of staff and students alike—dissenters, if any, go undeclared—talk of their universities as "liberal", but it may be significant that this attitude is not usually accompanied by a willingness to embrace modern causes such as student representation.

At other universities, members of the teaching staff are usually less outspoken. The key question is whether, if there were no laws, the admission of non-white students to white universities would be welcomed. Even before the formal declaration of *apartheid*, only the Universities of the Witwatersrand, Cape Town and Rhodes (Grahamstown) chose to be "open". It is therefore remarkable how many members of the academic staffs at Afrikaans-speaking universities will now admit that the admission of non-white students would be desirable—at one university, it was estimated that 80 per cent of the staff was so minded—and one distinguished dean surprised himself and his small audience in conversation two weeks ago when, under pressure, he said that the introduction of the formal regulations of *apartheid* had probably been mistaken.

In the event, both Cape Town and Witwatersrand have quite large numbers of coloured (but not black) students on the books, usually in schools of medicine and engineering where there are at present no corresponding courses in the non-white universities. One estimate is that nearly a third of the first year class in the medical school at Cape Town consists of coloured students, and that the corresponding percentage at Witwatersrand is 25 per cent.

There is of course no way of knowing how representative university opinions may be of those of the rest of the population, but the chances are that in Africa as elsewhere they are more enlightened. In the sciences, moreover, there is no evidence at all that the politics of a university help to determine the scale on which government support is provided. To be sure, in more contentious subjects such as the social sciences, there is some disquiet over cases such as that in which a sociologist at the University of the Witwatersrand has this year been prosecuted for alleged indecorum in a study of the comparative incidence of the application of the death penalty to the black and white communities—the judgment (an acquittal) implied that the author of this research would have been guilty of contempt of court if he had been made aware in advance of the derogatory implications of his work. To scholars of all persuasions, this is a cloud much larger than a man's hand.

Should Palaeoanthropology be Big Science ?

THE natural flora and the ancient rocks of southern Africa have given South Africa a compelling interest, but the attractions of the terrain for palaeoanthropologists are even more striking. Indeed, the valley to the west of Johannesburg, in which the two caves of Swartkrans and Sterkfontein confront each other from the sides of two low hills a mere mile apart, suggests that so far palaeontologists have scratched only the surface of southern Africa. And even so, there are signs that the materials being excavated from these sites may soon outstrip the efforts being made to record and interpret them.

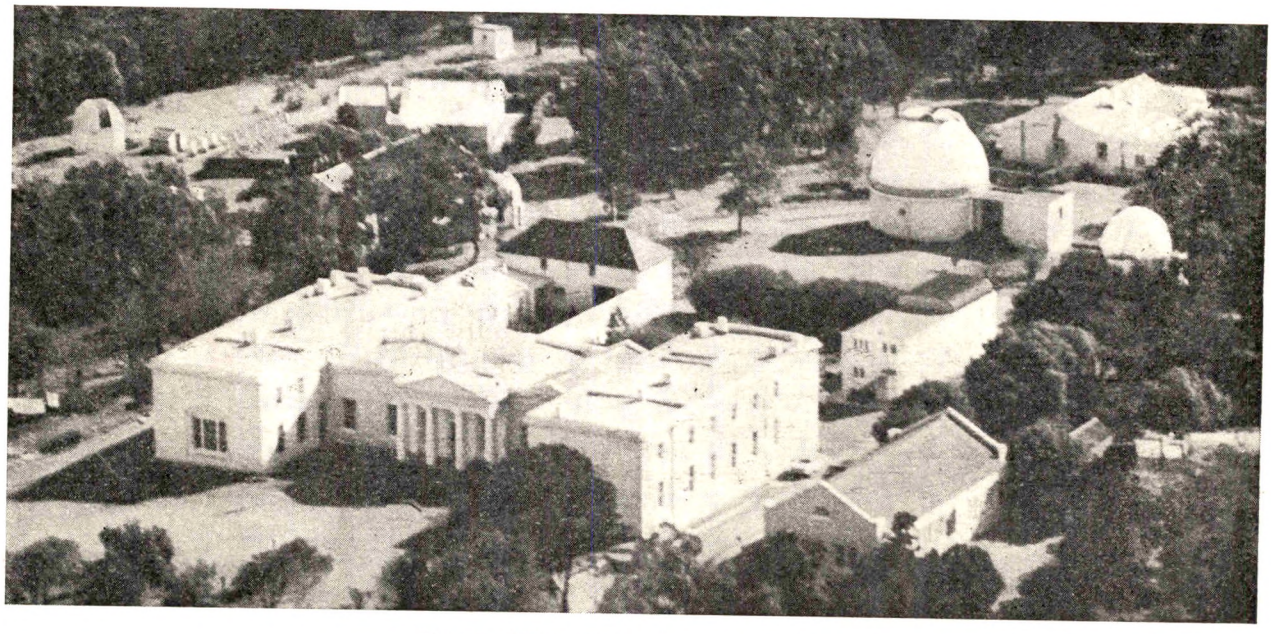
In the past year or so, the activities at Swartkrans directed by Dr C. K. Brain, the director of the Transvaal Museum at Pretoria, have been the most spectacular (see *Nature*, **225**, 1112; 1970). Although the cave has been known since 1948, when it was first investigated by Dr Robert Broom and Dr J. T. Robinson, work in the past few years has helped to resolve several important questions about the development of hominid creatures in South Africa and their relationship to similar processes of evolution in East Africa.

The interest of the excavations at Swartkrans is that they have thrown new light on the coexistence of two types of hominids—the robust type (*Paranthropus robustus*) and the gracile creatures now thought to lie more directly on the line of descent to modern man. But Swartkrans has also yielded evidence of the use of tools of a primitive character by these early creatures and a rich store of mammalian fossils by means of which it is possible to relate the ages of the South African fossils to those being found in East Africa, where dating by radioactive methods is possible. Dr Brain has also extracted from Swartkrans a vast collection of fossils of small rodents, presumably killed by predatory birds—one half of a plastic bucket in the Transvaal Museum is filled with such remains and may yet yield a sensitive understanding of the ecology of Swartkrans in the late Pliocene. Across the valley at Sterkfontein, the pace of excavation has also been increased in recent years. At both sites, a dolomite cave has been filled with breccia. Swartkrans seems to have been connected with the surface of the hillside by a vertical chimney channelling remains to the underground site. Sterkfontein was once a cave inhabited by Pliocene creatures and excavations by Professor P. V. Tobias have now shown that the cave is perhaps three times as great in horizontal extent as originally thought when it was first excavated by Professor Dart. Here, too, there are vast stocks of tiny rodent bones as well as the remains of larger mammals and Australopithecines. A large galvanized hut is used as a storeroom for fossils recovered from the breccia, and systematic attempts are being made to catalogue and to classify hominid and mammalian fossils—baboons, for example. Professor Tobias says that the work would be faster if more people were available.

At the other end of the South African Republic, in Cape Town, Mr Q. B. Hendey seems to be confronted by an even more daunting collection of fossils—the marine deposits at Langebaanweg on the coast in the south-western Cape Province. Although there have so far been no traces of hominid remains, the site has yielded one of the richest collections of vertebrate remains in the whole of Africa. As well as more than sixty distinct types of mammals belonging to eleven different orders, fish, amphibians, reptiles and birds are also represented as fossils. One of the hazards of the work is that the fossils are recovered from a mixture of sand and phosphates in which they are embedded only with the connivance of the mining company extracting phosphates from the region. The result is that much of the vast collection of material at the South African Museum at Cape Town consists of broken pieces of bones. Nevertheless, there seems no doubt that in due course the site at Langebaanweg will eventually be made to yield a good understanding of the fauna of South Africa in the early Pleistocene and before. One interesting find, for example, is that of the first late Pliocene bear to have been found south of the Sahara. Outside observers cannot fail to be impressed with the disparity between the richness of the fossil store and the resources of the people concerned with it. Everybody speaks highly of the willingness of the CSIR to help with money, although the amounts involved are comparatively small—Rd20,000 is considered handsome. Although the work at Swartkrans and Sterkfontein is going ahead quickly, moreover, the shortage of trained people does limit the extent to which other sites can be explored. Yet a comparison between Sterkfontein and Swartkrans has already yielded an understanding of human evolution which could not have been obtained by the detailed exploration of one of them alone—this comparison, for example, is one of the reasons for excluding the hypothesis that the difference between the heavily built and the lighter forms of hominid creatures from two million years ago is an example of sexual dimorphism—why should one site yield females only and the other predominantly males ? From this point of view, there is probably a great deal to be said for a more thorough search for cave sites in the dolo-

Lateral view of the facial skeleton of the Swartkrans hominid articulated with a robust australopithecine jaw bone.

mites of South Africa, but everybody seems to shudder a little at the prospect of how to describe and interpret what material might be found. Is it possible that the unique character of the palaeoanthropological sites in South Africa—five of them have so far produced material of great importance—is a sign that something should be done to conduct this enterprise on a scale that would not be justified elsewhere ?



Good Cheer for Astronomers

THE reorganization of the Royal Observatory at the Cape and the Union Observatory of the South African Council for Scientific and Industrial Research into a single operating agency is likely to be a great boon for South African astronomers as well as for those in Britain and elsewhere in the northern hemisphere for whom South Africa is a convenient vantage point south of the equator. After two years of planning, the point seems now to have been reached at which there is a clear plan for the next few years. To begin with, the 40-inch reflector at the Royal Observatory will be moved at the beginning of 1972 to a site at Sutherland, 200 miles north of Cape Town and sufficiently far on the leeside of the western escarpment to be comparatively free from cloud. Work has already begun on the roadworks around the site, which seems to have been chosen both for its accessibility and for its good seeing. Although there will eventually be a landing strip for light aircraft, astronomers at the Cape will be able to reach the site in four hours of reasonable driving on a good clean road, but those who will have to commute from Johannesburg will have farther to travel and are less keen on the choice of Sutherland. They are also somewhat discontented with what they consider the loss of their identity in the joint venture.

In the development of the joint observatory, which will be financed by the CSIR in South Africa and the Science Research Council in Britain, the willingness of Sir Richard van der Riet Woolley to become the director of the new organization seems to have played a crucial part. "A name to conjure with" is what one administrator said, and it is not every decade that the retiring Astronomer Royal has a passion for building telescopes and an origin in South Africa as well (Sir Richard graduated from Cape Town in 1929). The first phase of the work at Sutherland, consisting of site development and the building of a housing for the 40-inch telescope, is intended to be completed by the end of 1971. By that time, plans will have been completed for dismantling the instrument and for moving it, in pieces as large as possible, to the new site.

The 40-inch telescope is intended only as the first instalment of the project, which will be completed later in the seventies by the addition of a larger telescope. Approaches have apparently been made to the trustees of the Radcliffe Observatory in Pretoria, where the 74-inch reflector which has been operating since 1948 and which has contributed valuably to the study of the southern skies in the past two decades, is supported by a contract with the British Science Research Council which expires in 1974.

The Radcliffe instrument has suffered less than the Cape Town instrument from the problems of city lighting systems, but the suburbs of Pretoria have now crept a long way up the hill on which the Radcliffe Observatory stands. In the past few years, it has been necessary to restrict the use of the telescope for photometric work, but spectroscopic observations are still entirely feasible. In the past few weeks, the telescope has been fitted with one of the image intensifiers developed by Professor J. D. McGee at Imperial College, London, and the director of the observatory, Dr A. D. Thackeray, hopes that the new equipment will provide not merely greater sensitivity but also a

The Royal Observatory, Cape of Good Hope.

measure of convenience. No doubt the fate of the telescope will ultimately be determined not merely by the desirability of moving it to Sutherland but by the feasibility of such an undertaking, and much will depend on whether it is considered that the driving mechanism would need to be replaced.

Observing conditions at the Cape have for several years required that observation should be confined to the brighter objects in the sky. The Cape Observatory, built in a way that shows quite clearly its Victorian naval origins, will remain in use as a base for observers working at Sutherland as well as an experimental station for the department of astronomy on which the University of Cape Town has set its heart. The university is clearly anxious to exploit in every way it can the opportunities which the new arrangements will provide, and it has already begun to scour the world for just the right man to fill the chair.

The Republic Observatory in Johannesburg has also fallen a victim to city light, but Johannesburg is more than three times as far away as is the Cape from Sutherland. Moreover, it must have been plain for several years to those in charge that the future for an observatory in or near Johannesburg would always be restricted and indeed the observatory has been without a permanent director for some time.

The joint observatory at Sutherland is only one of several smaller observatories maintained by other organizations from outside South Africa. The site of the Republic Observatory's annexe 40 miles north of Johannesburg also houses a southern station maintained by the Leiden Observatory, there is a 60-inch reflector at the Boyden Observatory maintained by the Harvard College Observatory near Bloemfontein as well as a 36-inch Baker–Schmidt telescope and a 27-inch refractor maintained by the University of Michigan at another site in Bloemfontein. In the past few years there has also been some useful development in radio astronomy, partly stimulated by the construction of the NASA tracking station at Hartebeesthoek (which is used in its spare time for radio astronomy), while a number of universities such as Rhodes University, Grahamstown, have established useful experimental groups in this field. South Africa nevertheless must still regret the decision of the consortium of European nations operating the European Southern Observatory to settle not in South Africa but in Chile.

NUCLEAR FUEL

Enrichment Up the Sleeve

THE announcement in June this year by the Prime Minister of South Africa that the Atomic Energy Board is developing a novel technique for the enrichment of uranium has left a great many scientists in South Africa as puzzled as their colleagues abroad about the potential of the claim. Some are openly sceptical. What follows is an account, culled from authoritative sources, of what has been happening.

First, the enrichment process, whatever it is, is based on the use of gaseous UF6. The project has been under way since 1959, when the Atomic Energy Board first set out to investigate what seemed a potentially promising alternative to the then standard method of enriching uranium—the building of a diffusion plant. By their own accounts, the people concerned seem at first to have been unwilling to believe their good luck in having found such a promising route to enriched uranium, and now regret the wasted years from 1963 to 1966 when it would have been possible to launch a more intensive study of the process. Since then, however, experimental studies have been carried out which have justified the decision to build a pilot plant.

The year 1966 is held to be significant, for then the Atomic Energy Board announced the abandonment of work on the reactor concept which had until then been its chief public pride and joy—a reactor operating with natural uranium (of which South Africa has plenty) and liquid sodium as coolant. In retrospect, this decision is said to be a necessary redeployment of skilled labour. But as things are, however, the scale of activity at the main research establishment at Pelindaba has grown slowly over the years (and cost Rd 5·28 million in 1969). The study of sodium loops continues, and there are some who hold that the new enrichment process will make it economical to return once more to the PELINDUNA reactor concept, for the inconveniently large power output of the original concept may now be avoidable.

The development of the enrichment process, whatever it is, is rigorously separated both geographically and financially from the public work of the Atomic Energy Board. One of the reasons given for the decision to make public the existence of the pilot plant is the fear that the growing scale of activity associated with it would soon inevitably leak out. Although the Prime Minister said that "under South African conditions, a large-scale plant can be competitive with existing plants in the West", it does also appear that the expected saving of cost is likely to be a comparatively small fraction and certainly less than 50 per cent of the current American price for enrichment—at present rather less than $30 per unit of separated work. In short, it looks very much as if there is a good idea on which the builders of the pilot plant can chew, but that development has not yet reached the point at which the production costs can be accurately predicted, which in turn implies that the operation may yet be frustrated by economics if not by technology.

One of the obvious advantages of a process for enriching uranium indigenously is that South African uranium suppliers would enjoy a larger slice of the profits to be obtained from nuclear power. The political leverage provided by a supply of enriched uranium is also evident. One of the difficulties with which the government of South Africa is now faced, however, is that of knowing how to exploit the process without also making it available to potential competitors. By all accounts, the process, whatever it is, could be replicated in a comparatively short time by any comparable organization worth its salt.

But what is the process? The statement that the South African process "is unique in its concept" is held to exclude the use of centrifuges. For what it is worth, Dr A. J. A. Roux, the chairman of the board, accepted a bet of £5 that chromatography is somehow involved with such alacrity that attempts are now being made to hedge the bet with an investment in one other frequently mentioned process—a combination of a cyclone and gas diffusion.

NEWS AND VIEWS

Accelerating Somatic Cell Genetics

THE standard technique for detecting linkage between human genes and assigning them to particular chromosomes involves correlating the chromosomal make-up with the biochemical properties of interspecific hybrid cells. This approach to somatic cell genetics stems, of course, from the pioneering work of Watkins and Harris. They found not only that inactivated Sendai virus mediates cell fusion and, in Harris's words, converted "cell hybridization from an exercise in the exploitation of chance events to a method of general applicability", but also that when mouse and human cells are fused the hybrids preferentially lose most of their human chromosomes. If a normal human cell is fused with a mouse cell carrying some mutant biochemical marker and the hybrids are grown in conditions which do not support the growth of either parental cell, the hybrid should retain the human chromosome which carries the human gene that compensates for the defective murine function. A series of independently isolated clones of such hybrids should always have one human chromosome in common, that which carries the compensating gene. Once this has been established the hybrid cells can be analysed for a wide range of other human enzyme activities to see if any of these are always present and therefore carried on the same chromosome as the compensating gene. Using this basic approach Bodmer and his colleagues and Ruddle's group, for example, have established that the human genes specifying lactate dehydrogenase B and peptidase B are linked (*Nature*, **227**, 248; 1970), while Weiss, Green and Basilico have established that the thymidine kinase gene is probably located on a human chromosome of group *E*.

This mouse–human system, however, has its disadvantages. The hybrids emerge only slowly, and so experiments are protracted; the number of available genetic markers for the mouse cells is limited and the mouse cells in culture have as many as sixty chromosomes, which makes the identification of individual chromosomes in the hybrids extremely tedious. It will be no surprise therefore if in future the use of Chinese hamster cells, as described on page 329 by Kao and Puck, becomes widespread. Kao and Puck find that when these cells, which have only twenty chromosomes, are fused with normal human cells, the loss of human chromosomes is very rapid. Only a week after the fusion many of the hybrid cells have about twenty chromosomes and, moreover, eleven different auxotrophic markers of Chinese hamsters cell have already been isolated.

Kao and Puck have used three of these in an experiment which failed to establish any new linkage groups but proves beyond doubt the feasibility of their approach. They took Chinese hamster cells which were dependent for growth on the supply of either proline and glycine or proline and inositol, and fused them with normal human fibroblasts. The hybrid cells were grown in calf serum which does not support the growth of the human parental cells and in the presence of proline, but in the absence of either glycine or inositol. This condition selects, of course, for the retention of the human chromosomes which carry genes for the biosynthesis of glycine and inositol respectively. Once the hybrids had been isolated they were tested for the capacity to grow in the absence of proline. If the gene specifying the ability to make proline is on the same chromosome as either the glycine or inositol genes the hybrids should invariably grow in a medium lacking proline. In fact Kao and Puck found the proline requirement of their hybrids to be very variable. Out of fifteen hybrid clones able to grow in the absence of glycine only five could also grow in the absence of proline, while only seven of the forty-two clones able to grow without inositol could also grow without proline. Clearly there is no linkage between these genes in human cells, moreover the human lactate and malate dehydrogenase genes do not seem to be linked to the inositol gene.

It is disappointing that no new linkage groups have been detected but the technique of using doubly marked Chinese hamster cells and normal human cells holds great promise for the future. It means that possible linkage between two genes can be tested for directly, and there are eleven genes corresponding to the eleven auxotrophic markers of Chinese hamster cells that can immediately be studied by this approach. Kao and Puck's experiments have also thrown some light on the process of chromosome shedding. It seems that when cells with such disparate generation times as those of Chinese hamster cells, which divide every twelve hours, and human cells, which divide every twenty-two hours, are fused the condensation of the two sets of chromosomes becomes asynchronous. The faster growing partner seems to dominate the heterokaryon, and this leads by one or more mechanisms to the loss of the chromosomes of the laggard. From observations of individual cells Kao and Puck suggest that chromosome pulverization and the clumping of human chromosomes is related to the mechanisms of shedding and it seems likely that many of the human chromosomes are lost as groups rather than individually.

No Support for Gravitational Waves

MUCH can be learnt about the methods of science from situations in which discoveries of a rather contentious nature are made by one scientist or group, and are then searched for by other interested workers, often without success. During the past year or two there seems to have been a rash of examples. In 1968, cosmic ray physicists at the University of Utah announced that a rather well established behavioural pattern of the intensity of cosmic ray muons with zenith angle had been found to break down at energies above several hundred GeV (*Phys. Rev. Lett.*, **19**, 1487; 1967). Their results seemed entirely convincing, yet nobody else has been able to reproduce them, either with similar experiments or by approaching the problem from a different standpoint. Professor C. B. McCusker's triumphal announcement to the last international cosmic ray conference that he had found the elusive quark hiding in the cores of extensive air showers has likewise received no corroboration (*Phys. Rev. Lett.*, **23**, 658; 1969). The latest candidate for addition to the list of unsubstantiated discoveries is gravitational radiation—but the problems entailed in proving or disproving it are immense.

In 1969 Professor J. Weber reported that he had detected gravitational waves (*Phys. Rev. Lett.*, **22**, 1320; 1969). This was the culmination of years of patient work on two rather carefully designed detectors situated 1,000 km apart at the Argonne National Laboratory and the University of Maryland. The vibrations of two large metal cylinders with natural frequencies about 1,660 Hz are measured by piezoelectric instruments and coincidences between the two signals are taken to indicate the existence of gravitational waves. But where is the supporting evidence? Weber continues to find coincidences between his detectors and has even recently suggested that the greater part of the gravitational radiation he detects comes from the galactic centre.

In this issue (page 346), thirteen workers from five laboratories in Great Britain report attempts to confirm Weber's findings by searching for the small amount of radio frequency energy almost certainly accompanying gravitational waves. At each of five sites (Cambridge, Dublin, Glasgow, Harwell and Jodrell Bank), a pair of dipole aerials was set up to detect radiation arriving within a frequency band of 1 MHz about 151 MHz from almost anywhere in the sky. A number of coincidences between two of the stations were found, but tests have shown that it is unlikely that they are attributable to gravitational waves. Five coincidences were observed between three of the stations, but none of these was consistent with emission from a distant source. No coincidences, however, have been observed between four or all five of the stations. The outputs of the stations have also been examined. Since Weber's suggestion that the galactic centre may be a source of gravitational waves, the collaborators in the radio waves have put a directional detector in Malta and have replaced four of the original five detectors with directional types. It is possible with this array to observe the galactic centre and look for radio pulses which could be compared in time with the coincidences observed by Weber with his own apparatus. This could, however, pose difficulties because of the separation of the two experiments on the Earth's surface and the small probability of the two sets of apparatus observing the galactic centre at the same time.

Negative results from their experiment do not by any means invalidate Weber's original claims. There could be many reasons why radio pulses associated with gravitational waves may not be observable. The radio waves could be absorbed between their source and the Earth or, indeed, there may be no radio emission associated with gravitational waves. This, however, seems unlikely, for the violent conditions necessary to emit the enormous amounts of energy in the form of gravitational waves are almost certain to provide also the ideal source for radio signals.

LIQUIDS

Electrical Switching in Alloys

by our Solid State Physics Correspondent

THE disclosure by G. Busch, H. J. Guentherodt, H. U. Kuenzi and A. Schweiger (*Phys. Lett.*, **33**, 64; 1970) that a liquid alloy of tellurium and selenium has the electrical properties of a switch comes very much as a bonus in the search for a non-crystalline version of this important circuit element. So far little headway has been made in explaining the switching behaviour in amorphous solids discovered by Ovshinsky two years ago, and liquids are always one degree harder to understand. But the common features in the disordered structures of liquids and amorphous solids offer the chance to pick out some fresh clues as to why the electrical resistance of these materials should dive so sharply on a small change of voltage, and may help to point to the type of amorphous substance which can perform this function most efficiently.

Busch *et al.* found a sharp transition between resistive and conductive state in various alloys of both tellurium and selenium and tellurium and sulphur. They observed switching behaviour up to 200° C above the melting point with the samples held between graphite or platinum electrodes. The property was apparent from the sharp breaks in the current voltage characteristic.

In the simplest form of switch the resistance changes reversibly as the voltage is altered. It is, however, possible to obtain bistable switching action in which the device remains indefinitely in the desired "on" or "off" state until specifically switched out of it. The understanding of solid state switching is still too insecure for anybody to be sure whether the latter type of memory switch is related to the former variety or if it arises from an essentially different electronic process.

Busch *et al.* believe that they have witnessed a memory or threshold type of action, but they confess to being eager to publish their first results of switching in a liquid alloy before embarking on what must necessarily be a highly speculative assay on the theory.

METAL VAPOURS

New Way of Synthesis

from our Inorganic Chemistry Correspondent

SINCE Skell and Westcott (*J. Amer. Chem. Soc.*, **85**, 1023; 1963) first described the production and reactions of carbon atoms in the gas phase, the use of high temperatures and low pressures to produce unstable gaseous atoms and molecules, which can be rapidly reacted with stable molecules to produce new compounds has been of increasing importance.

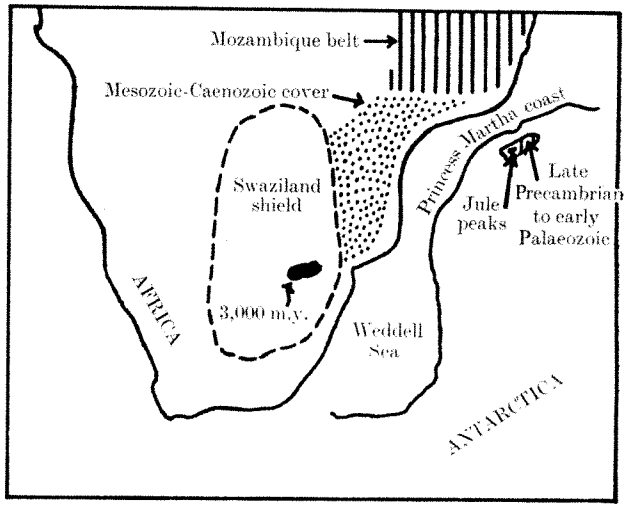
Recently P. L. Timms (*Chemical Communications*, 1033, 1969; *J. Chem. Soc.*, A, 2526; 1970) has extended this technique to the production of vapours of transition metal atoms at very low pressures ($\sim 10^{-5}$ Torr) and has shown that these vapours can be reacted with gaseous compounds such as trifluorophosphine, PF_3. The reactions proceed cleanly and give good yields in gram quantities of several unusual compounds which are either unknown or difficult to prepare by other methods.

For example, when chromium vapour is reacted with PF_3 the compound $Cr(PF_3)_6$ is produced in 60 per cent yield on the metal. If benzene vapour is used instead of PF_3, chromium dibenzene, $(C_6H_6)_2Cr$, is produced.

When iron vapour and trifluorophosphine are used, two volatile products are isolated; the first is the already known compound $Fe(PF_3)_5$, and the second has the molecular formula $Fe_2P_8F_{22}$, and seems to have the structure $(PF_3)_3Fe(PF_2)_2Fe(PF_3)_3$. With cyclopentadiene iron vapour gives ferrocene, $(C_5H_5)_2Fe$. With benzene, however, iron vapour forms a compound which explodes on warming to $-50°$ C; this may be $(C_6H_6)_2Fe$.

Cobalt, nickel and palladium vapours give with trifluorophosphine respectively $[Co(PF_3)_4]_x$, $Ni(PF_3)_4$ and $Pd(PF_3)_4$. The palladium compound is fairly unstable and decomposes back to metallic palladium and trifluorophosphine. Oddly enough no compounds are formed with manganese or copper vapours.

Timms has also shown that the transition metal vapours can be reacted with mixtures of volatile compounds to give compounds containing mixed ligands. Thus when vapour is reacted with a mixture of phosphine, PH_3, and trifluorophosphine, PF_3, both $Ni(PF_3)_4$ and $Ni(PF_3)_3PH_3$ are formed.



It is very likely that transition metal vapour reactions will prove useful in the synthesis of a wide range of new transition metal compounds of low oxidation state, and may in many cases provide an easier synthetic route to already known compounds.

CONTINENTAL DRIFT

Dating the Fit

from our Geomagnetism Correspondent

THE matching of discrete geochronological zones across the boundaries of continents thought to be adjacent before the onset of continental drift does not, in itself, prove that drift has occurred, but it is strong supporting evidence. The correlations across the boundary between South America and Africa are particularly impressive because they are based on many dated rocks. Other pre-drift configurations have not been so well documented geochronologically, however; and the fit of Antarctica with southern Africa has hardly been examined at all in this way. But Halpern (*Science*, **169**, 9771; 1970) has obtained a rubidium–strontium age of 3,060 ± 80 million years from a single sample of biotite granite from Jule Peaks, Antarctica. This is comparable with the age of the granites of the Swaziland shield (see map). He suggests that this supports the continental reconstruction of Dietz and Sproll (*Science*, **167**, 1612; 1970) in which the Princess Martha coast of Antarctica fits against the coast of southern Africa—as long as the Swaziland shield extends north-eastwards below the observed Mesozoic–Caenozoic cover.

One swallow does not, of course, make a summer; but to support his claim, Halpern has also collected information on the stratigraphy of the relevant coasts and finds some general correlations. Thus the early Palaeozoic to late Precambrian granitic rocks of the Mozambique belt (about 440 to 800 million years) correspond in age to sedimentary and crystalline rocks in Antarctica. Precambrian sedimentary rocks in the age range 1,400 to 1,800 million years are also found in both regions, as are late Palaeozoic to Jurassic volcanics. To these must be added the new Precambrian correlation, although many more ages are required to make it really convincing. Incidentally, Halpern's biotite granite is the oldest Antarctic rock reported so far.

RAMAN SPECTROSCOPY

Impact of the Laser

from our Inorganic Chemistry Correspondent

LASERS have wrought a transformation in Raman spectroscopy through their use as sources of illumination. The recent rapid growth of interest was evident at the international conference on Raman spectroscopy, held in Oxford from September 13 to 17. Whereas a few years ago it was difficult and sometimes impossible to

obtain a Raman spectrum from a powdered sample, even when several grams were available, spectra are now routinely obtained on a few milligrams of powdered sample. Raman spectra can also now be obtained from single crystals of quite modest size because of the small cross-sectional area of the illuminating laser beam, and some results of work with small single crystals were reported by Dr D. M. Adams and co-workers (University of Leicester). The Raman spectra of matrix isolated species, previously only studied by infrared spectroscopy, have also been obtained; both from alkali halide matrices by Drs D. B. Fitchen, A. R. Evans and C. Sawicki (Cornell University), and from noble gas matrices by Drs G. E. Levi, D. O'Hare and D. Hatzenbulher (Michigan State University).

The high coherence and narrow band width of laser light mean that it is possible to obtain Raman spectra of higher resolution than before, and also that very low frequency Raman shifts can readily be measured. The improved resolution possible in laser Raman spectroscopy is beginning to approach that possible with the most highly developed infrared techniques. One of the most interesting developments reported at the conference was the use of interferometric techniques for studying pure-rotation and rotation-vibration spectra of gases by Raman spectroscopy, reported by Drs J. J. Barrett (Perkin–Elmer Corporation) and W. J. Jones (University of Cambridge).

Another feature of laser illumination, if a pulsed laser is used, is the great intensity of the oscillating electric field that is incident on the sample. The induced polarization, P, is related to this electric field, E, by the equation

$$P = \alpha E + \beta E^2 + \text{etc.}$$

The αs are the well known coefficients of the polarizability tensor and their magnitudes are responsible for the intensities of Raman lines. The βs are so small that normally the term in E^2 can be ignored, but when the light intensity is sufficiently high, as it is in a powerful pulsed laser, this term becomes important and hyper-Raman lines due to it can be seen. The selection rules for hyper-Raman lines are quite different from those for conventional Raman activity. For example, the torsional oscillation of the ammonium, NH_4^+, ion in a crystal lattice is hyper-Raman active. Successful detection of the hyper-Raman effect in various systems, using a pulsed laser and a multichannel photon counting detector, was reported by Dr P. D. Maker (Ford Motor Company, Dearborn, USA).

PROTEINS

Gelatin to Collagen

from our Molecular Biology Correspondent

THERE are, of course, people who place collagen in the outer darkness of molecular biology—a dreary protein with no function to fire the imagination. This is a pity, for collagen has engaged the attention of some of the most accomplished practitioners of the day in the fields of sequencing, X-ray analysis and physical chemistry. Apart from the potential utility of deeper structural and chemical knowledge about collagen, lessons of the broadest relevance to protein chemistry are often to be drawn. An example is in the nature of the refolding process, when the randomly coiled gelatin chains revert to ordered collagen forms. Earlier studies of the process left an uncomfortable residuum of unexplained and often paradoxical observations, and many of these have now been assimilated into a generalized scheme by Harrington and his co-workers.

In the first of five articles of intimidating thoroughness, Rao and Harrington (*Biochemistry*, **9**, 3714; 1970) re-examine the renaturation kinetics of homogeneous chains—that is to say, separated α_1 or α_2 chains, which differ from each other in sequence. Optical rotation was used to follow the change. The first objective was to resolve conflicting reports on the order of the reaction, which in the event was found to be a function of the concentration. Only at very low protein concentrations was the reaction first-order; with increasing concentration, the order of reaction rose rapidly. The simplest explanation is that the triple-helical native structure can be generated intramolecularly by antiparallel folding—which according to model-building studies is a feasible way of achieving a collagen fold. This conclusion was borne out by molecular weight measurements. The temperature-dependence of the renaturation reflects the slow formation of longer helices near the melting temperature, for only these are stable in this range. This mechanism leads to a high degree of order, whereas by contrast at low temperatures short helices are rapidly produced. Regeneration of three-chain structures, as opposed to the intramolecular triple helix, is thus expected at high concentrations (where the order of reaction approaches three), and at the highest workable temperatures. The intramolecular folding rate for a series of collagens is also apparently related to the sizes of proline clusters in the chain, which most probably act as the primary nuclei for helix initiation.

To analyse the temperature effect further, Harrington and Karr (*ibid.*, 3725) have extended the working range downwards below 0° C, by adding glycol to the aqueous solutions. Working with *Ascaris* (invertebrate) collagen, in which the disulphide cross-links peculiar to this species have been broken, they find that the refolding rate has a maximum at a temperature about 46° C below that of melting. Two or more processes differing in their temperature dependence are therefore at work, and become rate-determining in different temperature ranges. In the upper region the kinetics are as expected for a reaction limited by a nucleation rate, the growth of the helix from the nuclei being rapid. At low temperatures, on the other hand, it is the growth of the helix, by incorporation of residues one at a time, that evidently becomes rate-determining. This kind of situation, in which the two types of mechanism become dominant in turn, could, one might suppose, be widely relevant in refolding and assembly processes.

When the cross-links in *Ascaris* collagen are preserved, or when cross-links are chemically introduced into uncross-linked collagen species, refolding is rapid and essentially complete, for the three chains are then always in register. The remaining three articles, by Hauschka and Harrington, are concerned with the characterization of the refolding mechanism, especially in relation to the cross-linked molecules. They relate *p*H effects on renaturation rate (*ibid.*, 3734) to evidence about the distribution of charged groups in the two types of collagen, and they consider (*ibid.*, 3745) the cooperativity of the refolding reaction, which is acutely temperature-dependent, and they also derived

the lengths of helical nuclei which seem to be common to all collagens. They show (*ibid.*, 3754) that the kinetics of renaturation of cross-linked chains bear out all the predictions of theory for three independent first-order processes—nucleation, helix growth and a slow annealing process. In *Ascaris* collagen, the native state is a disulphide-linked lattice of single chains, each folded on itself into a triple-helix.

FLUORESCENT LABELLING

Getting a Grip on tRNA

from a Correspondent

ONE of the most favoured techniques for disentangling the structure of transfer RNA is to label certain of its bases. But it is difficult to know just what goes where in the molecule. Labelling the bases by chemical modification, for example, is far from straightforward because several bases may be affected by any particular chemical agent. A more elegant handle to approach this problem is provided by a built-in label in the phenylalanine tRNAs of yeast, wheat and rat liver, all of which have a fluorescent base, "Y", adjacent to the anticodon loop.

Earlier this year, by measuring the energy transfer between the Y base and a chromophore attached to the 3′ end, Beardsley and Cantor (*Proc. US Nat. Acad. Sci.*, **65**, 39; 1970) showed that the distance from the anticodon to the 3′ end, where the amino-acid would be attached, is 24–30 Å. Two recent reports from Cantor's laboratory (*Biochemistry*, **9**, 3514, 3524; 1970) continue the exploration of the structure of yeast phenylalanyl tRNA through various measurements based on the fluorescence properties of Y and a bound dye, ethidium bromide, which also fluoresces.

They report that the fluorescence intensity of the phenylalanyl tRNA is enhanced two and a half times when magnesium is added to a solution containing the tRNA at 320 nm. This change is accompanied by a 5 per cent drop in the extinction coefficient of the tRNA at 260 nm, simultaneously with a similar change in the magnitude of the principal positive circular dichroism band. The fluorescence intensity of Y, as in the case of many fluorescent molecules, increases in nonpolar solvents. Thus the enhanced intensity as a function of the magnesium concentration is interpreted as a conformational change that tucks Y into a hydrophobic region of the tRNA molecule. That such a large change occurs in the fluorescence intensity compared with absorption or circular dichroism, makes the Y base a very sensitive probe for studying the conformation around the anticodon loop of this tRNA. Beardsley and Cantor have shown that this change is not due to the interaction of the magnesium ions with Y itself, for there are no such changes in its fluorescence when the tRNA molecule is digested with nuclease. There is a further decrease in fluorescence as a consequence of the increased contact of Y with water molecules.

This natural fluorescent probe has also been used to demonstrate directly that there is a specific interaction with polyuridylic acid in a solution free of ribosomes (Eisinger *et al.*, *Proc. US Nat. Acad. Sci.*, **65**, 638; 1970). They found a small blueshift in the fluorescence spectrum as well as a drop in the fluorescence intensity in the presence of U_5 as well as poly U, but not in the presence of poly C.

Further information can be obtained by observation of the nanosecond depolarization in the fluorescence of Y. Because the molecule is tumbling freely in solution, the rotational diffusion coefficients can be estimated by measuring the randomization of the fluorescence induced by polarized light at the excitation frequency. The interesting result is that Y is rotating faster than the whole tRNA molecule. It is not possible to deduce whether this is due to free rotation of the fluorescent group itself or to a relatively flexible attachment of the anticodon loop to the rest of the tRNA. There is, however, greater fluorescence anisotropy than expected for a completely freely rotating chromophore, indicating some hindrance in the motion of Y.

In their second report in *Biochemistry*, Cantor *et al.* report that the dye, ethidium bromide, which intercalates into DNA, binds to tRNA chiefly at one site in the presence of a low concentration of magnesium. From a consideration of the quenching effect that this dye molecule has on Y, they conclude that it is probably bound in the double helical region adjacent to the anticodon loop. From nanosecond depolarization measurements, they conclude that the data are consistent with a tRNA molecule that changes from a prolate ellipsoid with an axial ratio of 2–3 in the presence of magnesium to one with an axial ratio of 4–5 when magnesium is removed. An interesting incidental observation is that the tRNA can still be activated by the activating enzyme with the bound dye present.

NUCLEOTIDES

Fragments and Factors

from our Nucleic Acids Correspondent

SOMETIMES experiments are elegant and interesting even if they do not lead to entirely unambiguous conclusions. Two pieces of work recently reported in the *Journal of Biological Chemistry* display these symptoms markedly. Siddiqui and Ofengand (*J. Biol. Chem.*, **245**, 4409; 1970) have attempted to study the function of the modified nucleotide pseudouridylic acid (Ψ) in tRNA. They chose to examine the formylmethionine tRNA from *E. coli*, because it only contains a single Ψ residue (occurring in the common sequence GTΨC). Unlike most other nucleotides, Ψ can be cyanoethylated with the aid of the reagent acrylonitrile, affording a way to probe its function in the tRNA. Unluckily, this tRNA also contains the modified nucleotide 4-thiouridylic acid, which also reacts with acrylonitrile to yield the S-cyanoethyl derivative. Siddiqui and Ofengand circumvented this problem using large fragments of the tRNA obtained by digesting it with T_1 ribonuclease. The fragments were fractionated by chromatography on columns of DEAE-cellulose. In this way they partially purified a piece encompassing about a quarter of the tRNA molecule (from the 5′ end) containing the 4-thioU residue, and also a fragment—the remaining three-quarters of the tRNA—containing the Ψ. The two pieces could "stick" together, and subsequently accepted methionine in the normal way.

It was therefore possible to effect the cyanoethylation of each of the fragments separately, and assess the amino-acid-accepting activity of such modified fragments when recombined with the complementary unaltered pieces. When 4-thioU alone was cyano-

ethylated, accepting activity was virtually unchanged. Cyanoethylation of the Ψ residue, however, decreased accepting activity considerably. Regrettably, the elusive conclusion slips from their grasp at this point. It cannot definitely be said that Ψ is specifically involved in forming a complex with the activating enzyme and that this complex cannot form when the Ψ is modified, for the effect of the cyanoethyl group can be to distort the tertiary structure of the tRNA molecule. This might be the true reason for the lack of activity. The second reason is likely to be correct because others have shown that the excision of the TΨCG or the replacement of Ψ by 5-fluorouridine does not lead to loss of acceptor activity.

Bernardi and Leder (*J. Biol. Chem.*, **245**, 4263; 1970) describe the purification and characterization of a mutant G (elongation) factor from *E. coli*. This protein φ is involved in the translocation of the peptidyl-tRNA from the recognition site to the holding site on the ribosome, and surprisingly comprises more than 2 per cent of the soluble protein of the cell. A steroid antibiotic, fusidic acid, inhibits the activity of G factor, as well as the equivalent factor in mammalian cells.

Bernardi and Leder examined five strains of *E. coli* which were resistant to fusidic acid, but found that the G factor of only one of them resisted the effect of the acid on *in vitro* protein synthesis. They purified the mutant factor and also the sensitive factor from the parent strain to apparent homogeneity by chromatography on DEAE-'Sephadex' and DEAE-cellulose. The factors could not be distinguished by chromatography or electrophoresis on polyacrylamide gel or even by immunological reaction. There must be a definite difference between them, however, presumably as a result of a single mutational event, for their properties are indubitably distinct. The specific activity of the G factor from the sensitive strain was roughly twice that of the resistant factor throughout purification. Furthermore, the Michaelis constant for the hydrolysis of GTP by the resistant factor together with ribosomes was twice that of the sensitive factor. Normally GTP hydrolysis is concomitant with peptide chain elongation and is also inhibited by fusidic acid.

These findings could be explained in two ways, and it is not possible to distinguish between them. On the one hand, the mutation causing fusidic acid resistance might directly alter the binding site or catalytic site of the G factor for GTP, if the G factor contains such a site. On the other hand, the GTP might be hydrolysed in a site on the ribosome with the required presence of the factor, and the mutation would alter the interaction of the factor with the ribosome, and indirectly the ribosomal GTPase site. A long term aim of these studies will be to exploit this mutation in an important component of the protein-synthesizing system in genetic studies, now that a firm biochemical basis has been established. In a note added in proof, the authors claim that the fusidic acid resistance mutation lies close to the streptomycin resistance marker.

FISH

Exclusive Diet of Mullet

from our Marine Vertebrate Correspondent

THREE species of grey mullet are found in English waters but none are so abundant as to be of great importance to the fishing industry. There is, however, a small fishery for them chiefly in the south-west, which has recently produced about twenty tons of fish per year. Probably because they have only a marginal economic value the biology of grey mullet has never been investigated by fisheries workers in Britain, and knowledge of these fish is sketchy. They do have some value to anglers and, largely because of this, such recent work as has been undertaken has been in the capable hands of the Irish Inland Fishery Trust's staff (see for example, M. Kennedy and P. Fitzmaurice, *J. Mar. Biol. Assoc. UK*, **49**, 683; 1969).

A recent study of the natural history of the English grey mullets by C. F. Hickling (*J. Mar. Biol. Assoc. UK*, **50**, 609; 1970) goes a long way towards redressing the past neglect of these fish. Hickling has paid particular attention to the food and feeding of the mullets, especially the thick-lipped mullet (*Crenimugil labrosus*), although also dealing with aspects of the growth rate, maturity, spawning and fecundity in this and the other species.

The mullet has three ways of obtaining its food. In the first, and probably the least important, large edible items are ingested by a sudden extension of the protrusible mouth into a circular sucker, and simultaneously a powerful pumping of water through the gills creates a suction current whisking food with a cloud of mud into the mouth. Another feeding process involves scraping, with the hard-edged lower lip used as a scoop to skim off fine algal growth or bottom living diatoms. Grey mullet can often be seen browsing in this way up and down vertical surfaces or over rocks. Finally, they can stir up a cloud of mud and swim into it filtering the mud vigorously through the gill complex.

Mullet have long been notable among fishes for their gizzard-like pyloric stomach and for the extreme length of their gut, which has usually been attributed to their presumed herbivorous diet. Hickling confirms that in large *Crenimugil labrosus* the gut may be five times the length of the body, but he suggests that the long gut is not a result of herbivorous diet but is correlated with the large quantities of indigestible inorganic matter in their diet. Combustion of the cardiac stomach contents of fifty-four fish revealed that only two had more than 30 per cent organic matter, and prior examination showed that much of this was woody matter and chitin. It seems, however, that grey mullet are selective feeders and do not simply suck in mud and food fortuitously, because the stomach contents contain a notably higher percentage of organic matter than the sediment in which they are feeding.

Evidently these fish use their gill rakers to strain off the minute animals such as harpacticoid copepods and free-living nematodes which form their principal animal diet. Mullet fed in an aquarium on cod roe (which contained only 8 per cent inorganic matter) were later found to have 82 per cent of inorganic matter in their stomachs, and this tends to confirm earlier suggestions that the mineral matter in the muscular pyloric stomach is an essential grinding paste, and that this organ is in effect a gizzard.

Grey mullet are thus of singular interest, both for their adaptation to this diet and because few other fish can live on such poor food material. They seem to have evolved a feeding regimen in which they suffer no competition from other fishes.

British High Flux Beam Reactor

by

P. A. EGELSTAFF*

Atomic Energy Research Establishment, Harwell

The neutron scattering technique has become an accepted method for the study of condensed matter. Because of the great scientific and technical value of neutron experiments and the growing body of users, several proposals have been made during the past decade for a nuclear reactor devoted primarily to this technique. This article reviews the reasons for and history behind these proposals.

SLOW neutrons have been used widely in condensed matter physics, for many problems in chemistry and for industrial experiments. They represent a powerful tool of considerable versatility for several reasons. First, neutron wavelengths are about equal to the spacing between atoms in condensed matter while the corresponding energies are about equal to the spacing of the energy levels that determine chemical and physical properties of the material. The scattering by an isolated nucleus is isotropic and elastic so that there are no complications due to form factors, selection rules or competing cross-sections. Diffraction effects from neutrons scattered by nearby nuclei will show up atomic structure, and energy exchange between the neutron and matter gives a new determination of energy levels; simultaneous analysis provides new information.

Second, neutrons penetrate matter in bulk, having mean free paths of about 1 cm, so that surface effects can be neglected and a sample can be measured inside a furnace, cryostat or pressure container. Third, because neutron cross-sections are distributed virtually at random, both throughout the periodic table and between isotopes, light elements can be studied in the presence of heavy elements and the scattering properties of a sample can be changed by changing the isotopes without altering the chemistry of the sample. In addition the scattering of differently oriented but otherwise identical nuclei is different: for example, hydrogen with its two possible spin orientations scatters with a weak mean scattering amplitude and a strong random value. The incoherent scattering arising from such random effects contains no structural information, but makes possible the study of essentially "one-atom" dynamical effects.

Fourth, neutrons possess a magnetic moment so that magnetic atoms scatter neutrons through an effect which allows the structure and the dynamics of the electron spins, and hence of certain chemical bonds, to be studied. Finally, the range of wavelengths available extends from 0·3 to 10 Å and (by varying scattering angles) spacings or particle sizes between 0·1 Å and 20,000 Å can be measured.

This range of useful properties led to a wide usage of the technique once satisfactory neutron spectrometers became available. In many experiments it is possible to measure the strength, position and width of some peak in the dependence of scattering intensity on angle of scatter or on energy change of the neutron. Where such a well defined peak exists the interpretation is usually unique and quantitative in an absolute way. Experiments of this type are listed here as i–v. Some of the most exciting new applications, such as vi–x, however, arise where the scattering is not organized into well defined peaks, for example, the study of liquids, amorphous substances and disordered crystals. It is possible often to prepare samples that differ only in one feature, and a comparison of these samples allows the scattering by that feature to be studied, as in experiments xi and xii. Clearly neutron scattering experiments have an unparalleled richness, variety and depth, and touch on most of the problems connected with the several forms of condensed matter. Although neutron fluxes are low by comparison with, for example, X-ray or light fluxes the experiments are powerful. It is to extend the range and power of these experiments that the building of a high flux beam reactor (HFBR) is being considered. Extensive descriptions of the results of neutron experiments have been published[1,2], and I shall describe some of them briefly.

EXPERIMENTS IN WHICH NEUTRON SCATTERING HAS PROVED USEFUL

(i) Atomic structure of crystals deduced from Bragg reflexions in a way analogous to X-ray work.

(ii) Magnetization distribution in crystals deduced similarly; no alternative technique is available.

(iii) Frequency, wavelength, amplitude and polarization of crystal thermal vibrations, deduced from energy and momentum changes of neutrons; no alternative technique is available.

(iv) Thermally excited oscillations of magnetization in magnetic crystals, deduced similarly; no alternative technique is available.

(v) Energy of thermally excited molecular oscillations and rotations in crystals, liquids or gases—analogous to infrared spectroscopy but frequently specific to proton motions and applicable to symmetrical molecules which are otherwise inaccessible.

(vi) Static pair and triplet distributions of atoms in a liquid (including the partial distribution functions in a binary system).

(vii) Time-dependent pair distribution in a liquid, which is related to the cooperative modes of motion.

(viii) Self diffusion of atoms on atomic distance and time-scales (related to small angle incoherent scattering).

(ix) Time-dependent correlations of magnetization near and above the magnetic critical point.

(x) States of electrons in conducting substances (related to the magnetic scattering).

(xi) Distribution of atomic or magnetic distortion around atomic scale defects in crystals has been measured.

(xii) Dynamics of different molecular groups in one molecule has been measured by the proton/deuteron substitution technique.

Atomic Distributions in Crystals

The determination of the positions of light atoms in structures and the differentiation of atoms of similar atomic number are possible with neutrons. This has removed serious restrictions on X-ray work which have held up studies of hydrogen bonding, hindered rotations of ions, hydride structures, heavy element oxides, carbides and nitrides, and studies of ordering in many interesting metallic systems.

Samples with linear dimensions of about 1 mm are used and through the use of automatic diffractometers the reciprocal lattice can be explored in three dimensions in a reasonable time. Recent work has not only resulted in a greatly increased accuracy of parameter determination (for example, a standard deviation of ± 0·008 Å is claimed for the location of the hydrogen atoms in hexamethylene

* Present address: Department of Physics, College of Physical Science, University of Guelph, Guelph, Ontario, Canada.

tetramine) but has provided general conclusions on groups and series of compounds, simply because of the greatly increased output of information. For example, the high accuracy of hydrogen location which neutron beams permit has made it possible to examine accurately the problem of random and rigid body motion in relatively simple molecules which can be studied theoretically by quantum chemists. Thus naphthalene, resorcinol, salicylic acid and hexamethylene tetramine have been studied in detail by university groups at Harwell. In the case of hexamethylene tetramine it has also been demonstrated that a concurrent refinement of X-ray and neutron data produces a more satisfactory result than the use of either set of data separately.

Magnetization Distributions and Liquid Structure

Although the close connexion between strong magnetic properties and the anti-symmetry condition for electron wave functions was recognized by Heisenberg in 1926, it is still impossible to predict the magnetic structures of matter. Even for technologically important materials, such as ferrites and garnets, there is only a skeleton empirical knowledge of the facts, provided mostly by neutron techniques. The magnetic electrons are the outer electrons and are interesting for chemical as well as physical reasons.

Scattering of polarized neutrons from unsymmetrical antiferromagnets, for example, MnF_2, shows the transfer or sharing of spin between "magnetic" ions (M_n^{++}) and "non-magnetic" ions (F^-). This is the most direct evidence of covalency available and is in a form suitable for direct comparison with theory.

The detailed understanding of the liquid state remains one of the outstanding problems of condensed matter physics. Measurements of the liquid structure factor for monatomic liquids can be made to higher accuracy than with X-rays and good data can be obtained with the samples inside a cryostat, furnace or pressure containers. This makes it possible to measure pressure and temperature derivatives which, in addition to providing data on the pair distribution function, allows the triplet and higher order distributions to be studied. Thus a new insight into liquid structure is being achieved.

Of special interest are studies on binary (A–B) systems (for example, alloys or fused salts) where by isotopic substitution three or four separate diffraction patterns can be obtained for a single system. From these data the three pair distribution functions (AA, BB and AB) can be obtained and which transform treatment of binary systems from "primitive guesswork" into a "scientific subject". Examples are provided by the resistivity of a binary alloy (CuSu) and the interaction potential in a fused salt (CuCl).

Crystal Lattice Vibrations

Neutrons are unique in that their energies are thermal when their wavelengths are atomic. This makes possible precisely defined experiments on phonons and spin waves, which have led to a new understanding of interatomic forces.

The first vibrational studies to be completed in detail (at Chalk River in Canada) showed that although some of the forces between atoms in a metal were best thought of as comparatively local, some are of very long range, and probably represent forces derived from the electron gas in some way. In ionic and covalent crystals the phonon frequencies showed some unpredicted effects, now regarded as evidence for polarization by deformation. A study of lead has shown anomalies which are due to the interaction between the electron Fermi surface and the phonons—the interaction which is the basis of the current explanation of superconductivity. Solid helium has been investigated in a range of temperature and pressure and the phonon dispersion relations for argon at 4 K have been determined.

Inelastic scattering of neutrons also provides a means of studying directly fluctuations in the magnetization of crystals (spin waves), for example, in ferromagnets, antiferromagnets and ferrimagnets. Again this is the only available method for work on bulk substances (there is a resonance technique available for thin films of ferromagnets). In metallic systems the inadequacies in the original theoretical formulation of the problem are now clearly exhibited for the first time.

Liquid Dynamics

Inelastic scattering from liquids facilitates study of the dynamics of atoms or molecules. In the study of diffusion it is possible to examine the details of a single diffusive step on a time scale of about 10^{-12} s. The scattered neutron spectrum can be compared with the predictions of diffusion theories, and it can be shown, for example, whether the diffusion process consists of atoms jumping from site to site, as in a solid, or of combined movements of groups of atoms, analogous to Brownian motion, or, as actually occurs, the process is a combination of several mechanisms. The significance of this knowledge in the study of chemical reactions has been realized, but the accuracy of individual experiments, and the throughput of different compounds, is severely limited by present fluxes and facilities.

The discussion of the short wavelength collective motion in liquids is complicated because these modes are heavily damped due to their strong interaction with one another. Their behaviour is described by current–current correlation functions which can be measured only by the neutron scattering technique. This area is stimulating theoretical work on many body systems, and this in turn leads to more exacting neutron inelastic scattering studies of simple liquids. Such work is relevant also to the study of the dynamics of amorphous materials. Here the problems are usually greater, for molecular materials are being examined, and work so far (on SiO_2, for example) has produced results on a limited number of modes only.

Molecular Dynamics

A major growth point has been the application of neutron techniques to the study of molecular spectroscopy in gases, liquids and solids of interest to chemists. The studies include work on small molecules, on synthetic and natural macromolecules and on molecules absorbed on surfaces, and they complement infrared and Raman spectroscopic techniques. The special features of the neutron technique include the removal of the restrictions imposed by optical selection rules and very different (often simpler) intensity relationships. The intensity of a vibrational band is simply related to the amplitudes of nuclear displacement in the normal mode. Particular use is made of the abnormally high scattering cross-section of the proton; substitution of ^2H for ^1H greatly reduces the

scattering cross-section and provides an important diagnostic tool. Recent applications include studies of (i) torsional modes in $CH_3{\cdot}CH_3$, $CH_3{\cdot}CF_3$ and $CH_3{\cdot}CCl_3$, (ii) the dynamics of polymer main-chains, side-chains and crystal lattices to obtain information relevant to structure–property relations in polymers, and (iii) direct observation of hydrogen bonds.

Defect and Domain Scattering

Long wavelength neutrons can be scattered from crystals only if deviations from the crystal perfection are present, so that the scattering of neutrons of 4–10 Å gives a powerful method of studying defects on a size scale of 2–20 Å. This is just below the resolution of the electron microscope and there is considerable promise in this method for the study of crystal damage caused by, for example, radiation.

An important recent development is the investigation of diffuse scattering by non-stoichiometric compounds and solid solutions. It is already clear that the technique has great potential for providing information about clustering and short range ordering of atoms in various solids.

High Flux Reactor Proposal

The justification of a large neutron beam facility lies in the overall impact made by neutron experiments on the study of condensed matter. Generally a neutron experiment is so definitive that it is used as the basic experiment in a field, and the interpretation of the data obtained by other methods is greatly improved through the use of reliable molecular knowledge. Thus neutron scattering has a central role, well illustrated by the examples of magnetic structure and crystal lattice dynamics given here. In these cases the entire field rests on the neutron data, which are used by theoreticians and experimentalists for further interpretations and extensions of knowledge. Thus the important ideas in a discussion of neutron beam facilities are those involving the broader implications of neutron work, the strengthening or weakening of entire fields of study and the basic significance of the study of condensed matter in the life of mankind.

The gradual development of neutron scattering techniques through the 1950s had led by 1960 to a relatively sophisticated programme for the study of condensed matter. This was recognized by the International Atomic Energy Agency (IAEA) which started in 1960 a series of conferences on the inelastic scattering of neutrons in solids and liquids. Four such conferences have been held. In the United Kingdom the main team doing this work was concentrated at Harwell, but other groups (chiefly at Cambridge) were involved. Thus in 1960 the future heralded the expansion and development of a new and very powerful technique. Many very important problems, concerned with the study of condensed matter and with significant practical applications, were waiting to be investigated, and many scientists both within the Atomic Energy Authority (AEA) and in universities were anxious to help.

But the reactors used until this time had been designed for other purposes—primarily the irradiation of materials of significance to the reactor power programme: the Harwell reactors DIDO and PLUTO are called materials testing reactors for this reason. As a result they had three basic disadvantages for thermal neutron scattering experiments. These concerned the shield, the building and the flux. First, the shield of a materials testing reactor is arranged to be just thick enough to reduce the radiation to a safe biological level. But this level produces a very high background in thermal neutron scattering experiments and a substantially thicker and more efficient shield is required in a purpose built reactor. Second, the building which houses DIDO and PLUTO is too small to contain much of the sophisticated neutron scattering equipment. When a reactor is used to irradiate materials there is little need for horizontal space: most of the specimens are loaded in vertical rigs and headroom above the reactor is the major requirement. Horizontal space is needed only for coffins to accept active materials from the horizontal holes. For this reason the containment buildings of the DIDO and PLUTO reactors are very small, and when the neutron scattering apparatus was installed both the design and operation of the spectrometers were restricted. Third, the flux available from these reactors is not optimized for neutron beam experiments. The fuel elements are spaced at distances which allow samples to be placed between them, and the thermal neutron flux then peaks at the irradiated specimens. Unfortunately, neutron beam tubes are placed at the ouside of the core and are therefore not in the region of maximum flux. In the design of a thermal neutron beam reactor, the fuel elements are placed as close together as possible so that the core has a very high flux of fast neutrons. These fast neutrons enter the heavy water around the core and are thermalized, producing a peak in the thermal flux at approximately the position of the neutron beam tubes. This design advantage together with a higher power level will give the HFBR a factor of 15 advantage in flux over DIDO and PLUTO.

Table 1. RESEARCH REACTOR COMPARISONS

Country	Reactor	Date	Relative flux for typical beam user
UK	DIDO	1956	1
UK	PLUTO	1957	1·5
UK	HERALD	1960	0·3
USA	HFBR	1966	10
USA	HFIR	1967	15
Germany/France	HFBR	1971	20
Holland	HFR	1962	1·5
Belgium	BR2	1961	1·5
Sweden	R2	1960	1·5

During the 1960s, the horizontal holes of DIDO and PLUTO at Harwell and HERALD at Aldermaston were progressively taken over by the neutron beam programme until now they are almost all used for neutron spectrometers. Because of the low neutron fluxes, very substantial efforts were made to maximize the efficiency of the neutron spectrometers and of the detecting and data handling systems. In addition the number of university users increased during this period from six to approximately 100: thus the development anticipated in 1960 took place in spite of the restrictions in the use of the existing reactors. This, of course, demonstrates the attraction of the neutron scattering technique for the study of condensed matter.

A comparison of research reactors available or under construction in various countries is shown in Table 1 (the Germany/France figure is an estimate). It shows that the DIDO and PLUTO reactors are old compared with the reactors in other countries and the newer reactors in the USA and Europe have a significant flux advantage

(as well as more modern experimental facilities). Until 1960 the reactors at Harwell had kept in step with developments in other countries, but we have now fallen materially behind.

It was in anticipation of these developments that a group of reactor designers and neutron beam experimentalists proposed in 1960 that a new HFBR be built at Harwell. A design study was made of this project and in 1961 a proposal was ready.

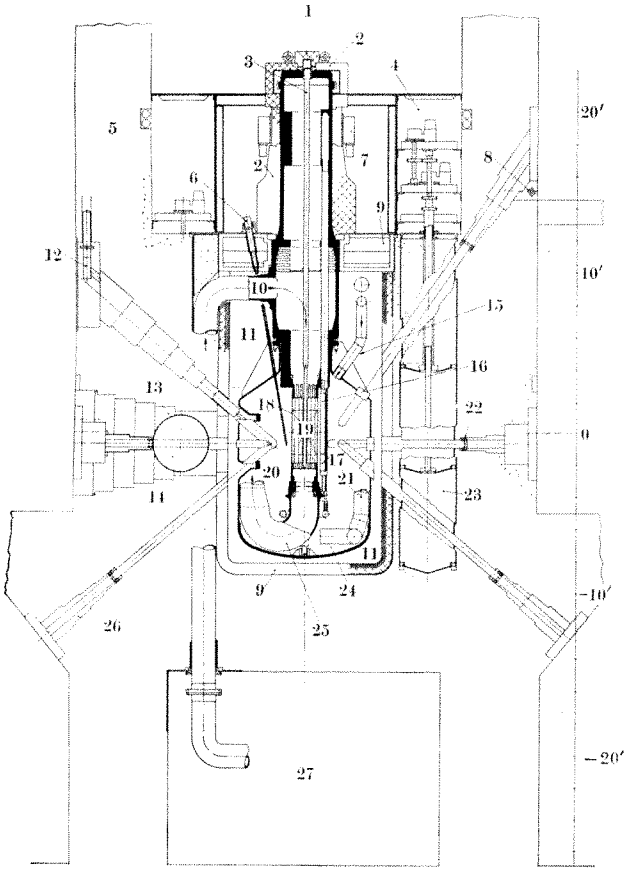

Fig. 1. Cross-section of the proposed high flux beam reactor. 1, Fuel element handling room; 2, shielding; 3, in-core rig; 4, beam shutter drives; 5, high density concrete biological shielding; 6, irradiation facility; 7, control rod drives; 8, removable shield block; 9, thermal shield; 10, core D_2O inlet; 11, CO_2 void; 12, cold source services; 13, removable shield; 14, cartwheel beam shutter; 15, reflector inlet; 16, upper control rods; 17, lower control rods; 18, zirc II pressure barrel; 19, core; 20, core D_2O outlet; 21, reflector D_2O outlet; 22, aluminium windows; 23, split rotating beam-shutter; 24, reflector tank-D_2O at atmosphere pressure; 25, core circuit-D_2O at 400 pounds/inch^2; 26, low angled beam hole; 27, sub-pile D_2O plant room.

This design was discussed later as the possible basis for a European international project, but no agreement was reached on various aspects of siting and finance, so that the project was shelved. In 1967 the French and German Governments set up a bilateral agreement to construct such a reactor at Grenoble, and this is now being built. The general outline design for a reactor suitable for the range of experiments appropriate to the United Kingdom has been completed, and there is strong user support for its construction. The proper channels of funding such a project of both technological and scientific promise involve more than one government department. The considerable expenditure involved (the Franco-German project budget is £11 million), naturally comes under close scrutiny when the national scientific budget is under great pressure, and the matter is still *sub judice*.

Matters singled out for careful study include the relative merits of a continuous reactor and a pulsed neutron source. The comparison is complicated because the continuous source techniques are better developed than the pulsed source techniques, and the two techniques are not equally applicable to all classes of experiments. The continuous beam reactor is clearly superior in experiments which require a continuous neutron beam and experiments based on long wavelength neutrons (greater than 4 Å). On the other hand, for some neutron time of flight experiments (for example, with relaxed collimation and for short neutron wavelengths) the pulsed neutron source will be superior. In the former category are most of the experiments with crystals, including the study of structure and dynamics using both the nuclear and the magnetic scattering processes. The long wavelength field includes studies of defects and many transient phenomena in liquids and polymers on a long time scale. On the other hand, in the category of time of flight experiments (with $\lambda < 3$ Å), concern is chiefly with inelastic scattering processes on a short time scale, particularly for the study of liquids, polymers and molecular spectroscopy. Experiments of this type are less detailed in interpretation at present, though they include significant work in a rapidly developing scientific area. Thus the decision between these sources rested on the balance of user interest. Because time of flight experiments of high quality can be done on the reactor, the larger number of users in the former category persuaded the minority in the latter category to accept the HFBR as the preferred source. This choice also satisfies the requirement that it is possible to prosecute a balanced programme on any major neutron source.

The HFBR project is ten years old and the present design is not far removed from the design of 1960, so that it might be asked whether the reactor is obsolete ? There are several reasons why this is not so. First, the reactor field is reaching a plateau in its development determined by the heat removal rates from the fuel elements (which in the HFBR are approximately 1 kW/5 cm of fuel element or 100 MW in 0·16 m^3). It is difficult to increase the heat rating and hence the flux without making major, and very expensive, changes in the design amounting to the development of a new reactor system. These changes might include very high flow rates of cooling water through the use of very high pressures or might involve the use of a liquid fuel rather than a standard metallic fuel element, but do not offer obvious advantage at a reasonable cost. Nevertheless, the 1970 design does include improvements in the design of the reactor components which have occurred during the intervening ten years. Second, a more significant factor is the balance between the different types of user or, in other words, the overall scientific programme. Special Science Research Council (SRC) committees have confirmed that the outcome of the discussions on the type of source to be preferred, held during the 1960s, is still valid, and therefore the basic decision on the type of source is still valid.

SRC Neutron Beam Programme

The SRC makes use of neutron beam time on three reactors owned by the AEA: these are the HERALD reactor at Aldermaston and the DIDO and PLUTO

reactors at Harwell. The flux available at the beam holes of HERALD is about one-third of that available at the DIDO and PLUTO reactors, but because many users cannot be accommodated on the Harwell reactors it is necessary to use this reactor as well. This programme is managed by the SRC Neutron Beam Committee which reports annually on progress. Its scientific reports cover the fields in which predictions of neutron beam interest have been made during the past few years and university scientists are translating into successful experiments many of the approaches which have been claimed to be practicable.

The value of neutrons to chemists as well as physicists is clearly evident in the scope of the reports on chemistry submitted by the Neutron Beam Committee. Approximately half of the scientists using the neutron beam facilities are from university chemistry departments. Some of the areas they cover were listed earlier in this article. Some proposals have been made and initial experiments conducted on biological problems with neutrons, but this field is in its infancy. It is anticipated, however, that it would expand rapidly through the improvements provided by the HFBR. An analysis of the present programme into categories of use is given in Table 2.

Table 2. DISTRIBUTION OF UNIVERSITY USERS OF AEA REACTORS

Field	No. of users
Chemical crystallography	30
Magnetic crystallography	18
Inelastic excitation of solids	21
Liquids	11
Defects in solids	13
Properties of neutrons	2
Total	95

Each physical technique seems to follow a general pattern of development. First, it is developed by the physicists concerned; in this case the nuclear physicists. It is then taken over by other physicists for use in basic research; in this case the condensed matter physicists. Subsequently other scientists become interested (in this case chemists and biologists) and use the technique. If as a result the technique is shown to have a wide scientific application it is used increasingly for applied problems in many industries. This pattern of development can be seen, for example, in X-rays, in infrared absorption, nuclear magnetic resonance and so on.

It seems likely that neutron scattering is following this general pattern, and is entering the final phase of its application to applied and industrial problems. The number of industrial scientists using the neutron spectrometers at Harwell and Aldermaston is small but increasing: their scientific and technical interest covers the same general field as the SRC scientists, though the motivation of their companies is industrial development. Although their work includes the structure and the dynamics of condensed matter, in many cases the samples are complex. This is partly because they are a mixture of many species and partly because large molecules are involved. Thus as the neutron scattering technique is developed for chemical and biological purposes we may expect parallel development in its use for applied and industrial applications. In some areas this is aided by the high efficiency of modern neutron spectrometers and the fact that they operate continuously and on a routine basis.

Present Proposal

Fig. 1 shows the cross-section of the proposed HFBR. Twelve horizontal beam holes are fed by different neutron sources. Several observe the ambient neutron spectrum in the heavy water while others are connected to the cold neutron source for long wavelength experiments and a group is connected to the hot neutron source for short wavelength experiments. In addition to these horizontal holes several inclined holes (both upwards and downwards) have been included. The flux viewed by these holes is lower than that seen by the horizontal holes but is still higher than that available on existing reactors. Also shown in the figure are the multi-hole arrangements for the cold and hot neutron sources. A limited number of irradiation facilities are provided also. It is proposed to operate the reactor at 100 MW and the maximum flux available would be $1{\cdot}5 \times 10^{15}$ neutrons/cm^2 s. The fuel is an Al/U alloy cooled by heavy water under a pressure of $28{\cdot}2 \times 10^4$ kg/m^2.

It is anticipated that after the project has been approved it will take five years to reactor criticality, and all twenty or so experiments should be in full swing after two more years. Because the neutron spectrometers could be constructed while the reactor is being built the experimental programme could commence as soon as the reactor is operating continuously at full power. At present it is proposed that the new spectrometers should include all the major types in use at Harwell: but the position will be reviewed at stages so that new techniques can be included in the instruments for the HFBR. Present proposals include the provision of several time of flight spectrometers, several three-axis neutron spectrometers as well as diffractometers for single crystal analysis. Other specialized instruments for long wavelength work and defect studies are proposed, making in all twenty-seven different spectrometers.

The higher flux may be used in various ways, for example; smaller specimens may be examined, higher resolution in energy and/or momentum may be used, the wavelength range may be extended to higher or lower limits, the statistical accuracy of the data may be improved, the study of weak scattering processes in the presence of strong ones may be improved and so on. The choice between these alternatives is open to the scientist concerned, for neutron spectrometers can be designed with flexibility in mind. Once again the neutron beam work is characterized by its breadth, and when transferring to a new reactor the neutron beam scientist reconsiders his experimental programme and makes use of the higher flux in one (or more) of the six or so ways open to him.

With a reactor of the type proposed the university teams would be able to consolidate their neutron beam programmes and to maintain the lead the United Kingdom has given in the field of condensed matter science.

I thank Dr W. M. Lomer for helpful suggestions and Professor E. W. J. Mitchell for permission to use some material from his SRC report on the scientific case for the HFBR.

Genetics of Somatic Mammalian Cells: Linkage Studies with Human–Chinese Hamster Cell Hybrids

by
FA-TEN KÁO
THEODORE T. PUCK
University of Colorado Medical Center,
Department of Biophysics,
Denver, Colorado 80220

Linkage relationships between human genes have been determined by following chromosome losses from human–Chinese hamster hybrid cells.

GENES can be located on the chromosomes of mammalian cells by taking advantage of the extensive chromosome loss which occurs in certain inter-specific hybrids after cell fusion *in vitro*. Normal human cells have been fused with mouse cells which contain a specific genetic defect affecting growth, and hybrids selected in conditions which fail to support the growth of either parental cell alone. These are cultured until there is maximum loss of their human chromosomes. Any human chromosome which is uniquely common to all the surviving clones is presumed to carry the normal gene which compensates for the defect in the mouse cell.

This system has shown that the thymidine kinase gene is probably located on a human chromosome or group E[1–3]. But experimental difficulties exist: it may be difficult to identify unequivocally the human chromosomes in the hybrid karyotype; there may be chromosomal breaks and rearrangements; the number of human chromosomes is not always reduced sufficiently, and only a limited number of usable genetic markers are available in the mouse culture. Moreover, because cell growth and loss of chromosomes occur slowly, these experiments take a long time.

We have described previously[4–6] a Chinese hamster cell system which offers advantages for this purpose. First, its generation time (T_g) in defined media is 12 h or less. This represents a greater difference from that of the human cell (T_g about 22 h) than does that of the mouse (T_g about 16–20 h). Cell hybrids presumably grow slowly initially[3], but if extensive loss of chromosomes of the slower parent occurs, they approach the growth rate of the faster parent. An automatic selection advantage should therefore be established for rapid isolation of human–Chinese hamster hybrids which have lost the maximum number of human chromosomes. Second, this standard Chinese hamster cell has only 20 chromosomes instead of approximately 60 as does the mouse L cell. Third, we have already isolated eleven different auxotrophic markers, so that simple linkage experiments can be performed in this system.

Thus a Chinese hamster cell with two auxotrophic deficiencies can be fused with a normal human cell and chromosome loss of the hybrids allowed to take place in the presence of only one of the critical metabolites. If the resultant clones are always simultaneously relieved of both deficiencies, both genes must be carried on the same chromosome (provided that the different clones contain only one human chromosome in common). But if there is random loss of the unselected marker, the two genes must be unlinked, and in this case, detailed chromosome analysis is not necessary. We report here the dynamics of chromosome loss from human–Chinese hamster hybrid cells and linkage determinations between selected genes.

The auxotrophic mutants of the CHO-K1 Chinese hamster cells have been described in previous publications[4–7]. These cells are cultivated in medium F12 (ref. 8) supplemented with 10 per cent foetal calf serum. Single cell plating was carried out in F12 from which specific omissions were made as required, and which was supplemented by the macromolecular fraction of foetal calf serum in an amount sufficient to support maximum growth of the cells[4]. The human fibroblasts originated in a skin biopsy from a newborn, normal male and were routinely cultured in F12 supplemented with 13 per cent human cord serum and 5 per cent foetal calf serum. The generation time of the CHO-K1 cells is approximately 12 h whereas that of the human fibroblasts is approximately 22 h in the present conditions. We used human cells which had previously undergone 20–25 generations of growth in culture.

Cell fusion was carried out as described[9] by mixing 2×10^5 cells of each type with 200 units of ultraviolet irradiated Sendai virus and incubating for 15 min at 4° C and then for another 15 min at 37° C. The cells were then placed in Petri dishes containing the respective selection media. These were prepared to permit growth of colonies only from hybrid cells formed by fusion of the Chinese hamster mutants with the normal human fibroblasts.

Chinese hamster cell mutants doubly deficient for inositol and proline (ino⁻pro⁻) and for glycine and proline (gly⁻pro⁻) were used. Different gly⁻ mutants, A, B, C, and D (ref. 6), were used in various experiments. Each mutant grows with a plating efficiency nearly 100 per cent in complete F12 supplemented with the macromolecular fraction of foetal calf serum and with zero plating efficiency if its specific auxotrophic requirement is omitted[5]. Single cells of normal human fibroblasts do not grow in F12 supplemented with the macromolecular fraction of foetal calf serum but do produce colonies if the corresponding fraction of human cord serum is supplied (Table 1); thus, by plating fused cells in a medium containing the macromolecular fraction from foetal calf

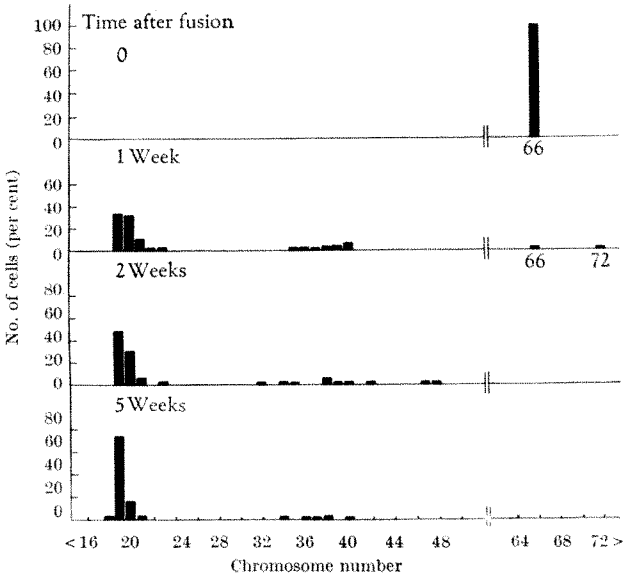

Fig. 1. Distribution of chromosome numbers in uncloned cultures of human–Chinese hamster cell hybrids, at various periods of incubation following fusion of the cells. Mitotic cells were collected after treatment with velban for 3 h.

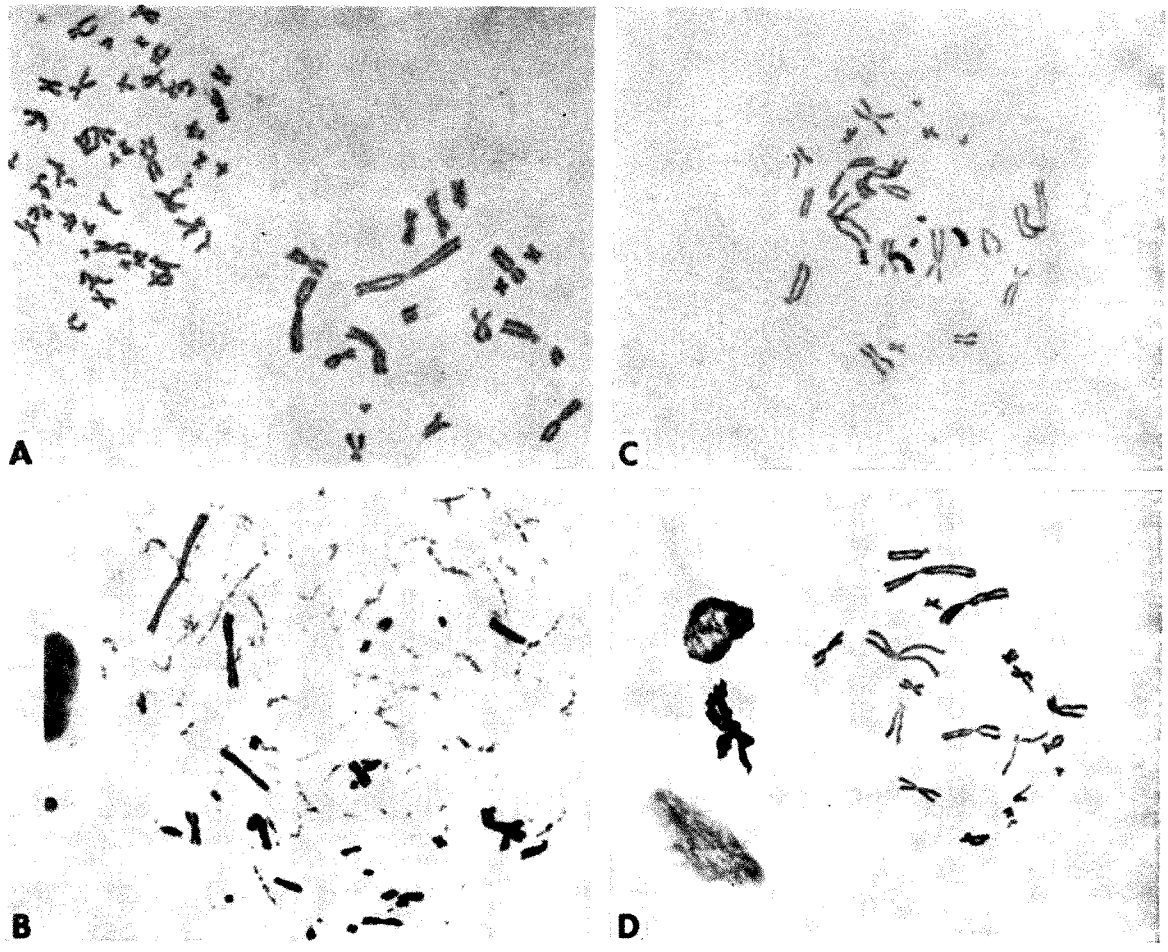

Fig. 2. Mitotic chromosomal patterns observed in a random culture of human–Chinese hamster cell hybrids sampled after 2 days of growth following fusion. *A*, A complete set of mitotic chromosomes from each parental cell is present in synchrony. *B*, All or most of the Chinese hamster and approximately ten presumed human chromosomes are mitotic. The remaining chromosomes display a "pulverized" appearance reminiscent of that obtained when a mitotic cell is fused with a cell in S. *C*, All or most of the Chinese hamster chromosomes but only about five of the human chromosomes are present. The two kinds of chromosomes have achieved synchrony, for all are in mitosis, although the presumed human ones seem more highly condensed and therefore more deeply staining. *D*, This cell is like *C*, except that the presumed human chromosomes are clustered together in a compact mass.

serum only, and lacking the specific auxotrophic requirements of the parental Chinese hamster mutant, colonies result only from hybridization of cells from the two animal species.

Chromosomal examination of mitotic cells from a fused cell mixture in a medium supporting growth only of the interspecific hybrids was carried out by standard methods[10] at various periods after fusion, and the distribution of chromosomal numbers was determined. Hybrid clones were grown from single cells plated two weeks after fusion and grown up in a selection medium containing proline, but not the other nutrient (glycine or inositol respectively). These hybrid clones were then tested by single cell plating to see whether they had retained their requirement for proline.

Examination for the presence of isozymes of lactate and malate dehydrogenases was carried out by acrylamide gel disc electrophoresis as described in Fig. 4.

Table 1. DEMONSTRATION THAT SINGLE HUMAN CELLS GROW WELL IN F12 SUPPLEMENTED WITH THE MACROMOLECULAR FRACTION OF HUMAN CORD SERUM, BUT NOT AT ALL IF SUPPLEMENTED ONLY WITH THE MACROMOLECULAR FRACTION OF FOETAL CALF SERUM

Concentration of macro human cord serum (per cent)	Concentration of macro foetal calf serum (per cent)	Plating efficiency (per cent)	Generation time (h)
10	0	13·0	25·0±1·7

0	15	0	—

Concentrations are indicated relative to the normal serum content of the respective macromolecular component.

Chromosomal Loss in Human–Chinese Hamster Cell Hybrids

Extensive loss of human chromosomes begins almost immediately. Fig. 1 shows the results of chromosomal counts made on a human–ino⁻ hybrid culture at 1, 2 and 5 weeks after fusion. Within 1 week, the chromosome number has fallen to a point close to and sometimes even less than that of the original CHO-K1 cell. Similar results were obtained in the fusion of normal human fibroblasts with the following CHO-K1 mutants: gly⁻A pro⁻, gly⁻B pro⁻, gly⁻C pro⁻, and gly⁻D pro⁻.

In the first several days of growth after fusion, the cell size is highly heterogeneous, presumably reflecting the heterogeneity of chromosome numbers during the early period of chromosome loss. The stabilized hybrids are much more uniform. The generation time of the stable hybrids is approximately 15–17 h, a value intermediate between the two parental cells. The hybrid which no longer requires inositol for colony formation grows with the same rate regardless of the presence or absence of inositol in the medium.

During the early growth period of the hybrid cell, the human and Chinese hamster chromosomes often are morphologically distinct because of a slight difference in the degree of condensation, a phenomenon also noted in other inter-specific hybridizations[11,12]. In addition we have observed that groups of human chromosomes cluster together. In Fig. 2 are shown three different patterns occurring in a random culture sampled two

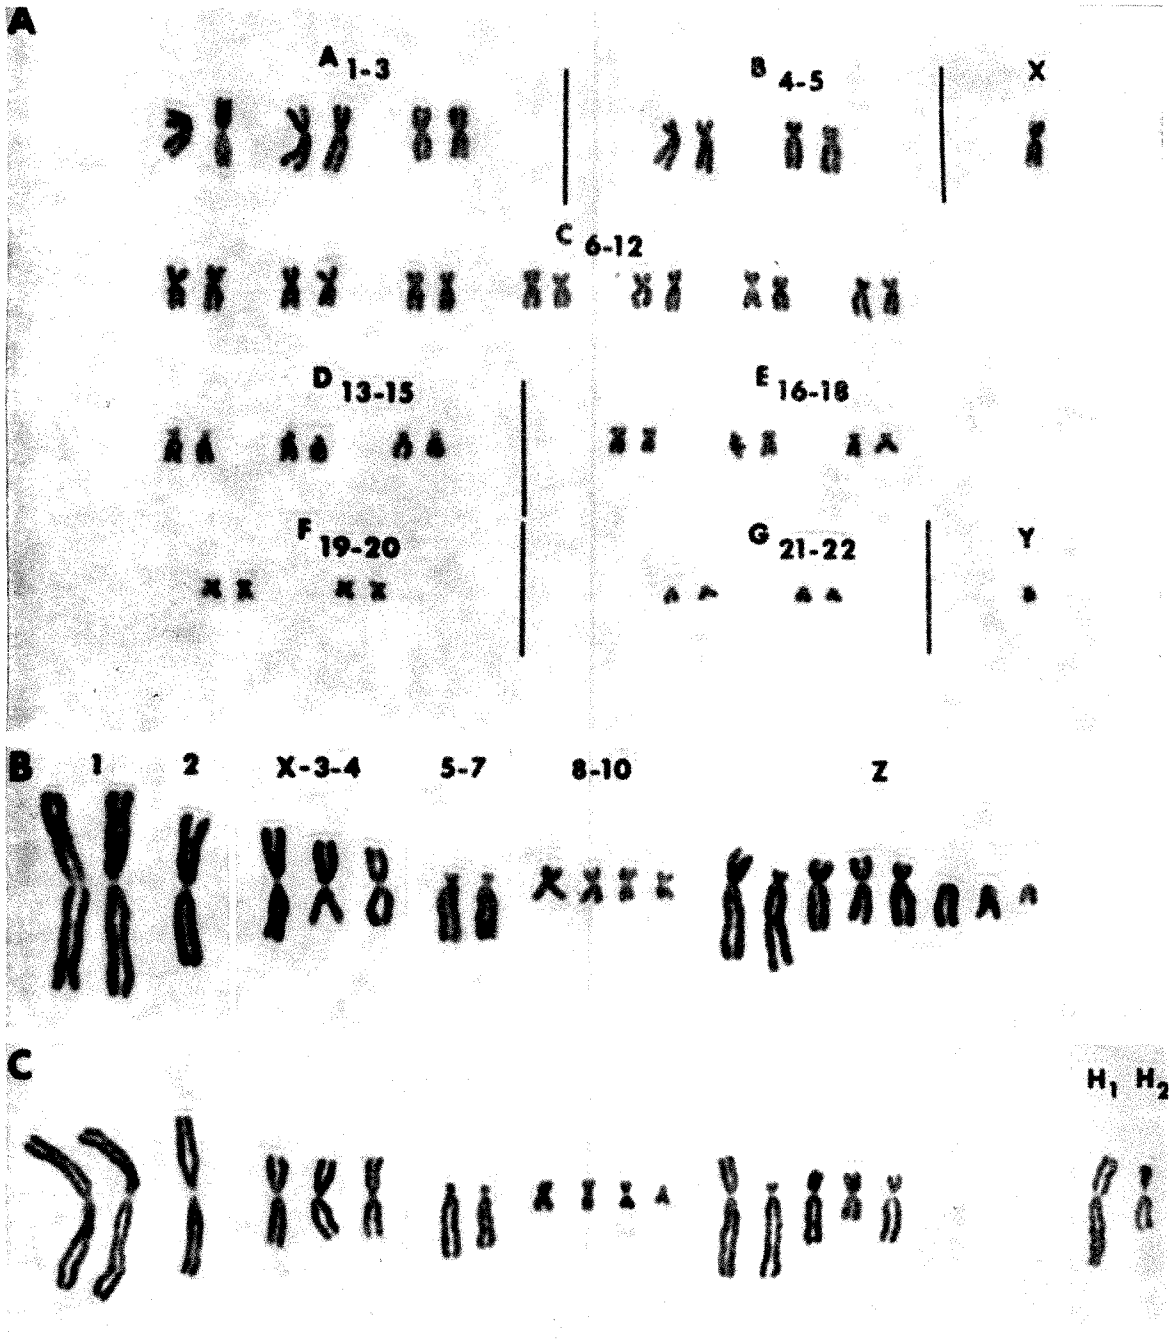

Fig. 3. *A*, The karyotype of the human fibroblast used in these fusion experiments. *B*, The karyotype of the CHO-K1 cell. *C*, Karyotype of the ino⁻pro⁻ hybrid produced by fusion of the cells of *A* and *B* and subsequent growth in medium lacking inositol but containing proline.

days after fusion. Fig. 2*A* presents a cell in which a complete set of chromosomes of each type is present and in which synchrony has been achieved so that both sets are in mitosis. Fig. 2*B* demonstrates a cell in which all or most of the Chinese hamster and about nine or ten presumed human chromosomes are mitotic. The remaining chromosomes have a "pulverized" appearance, and would probably be lost from the cell as a group. In Fig. 2*C* and *D* are displayed mitotic figures of cells which have retained all of their CHO-K1 chromosomes but only a few of the human ones. Synchrony seems to be achieved although it may not be perfect, because in Fig. 2*C* the several presumed human chromosomes appear more highly condensed and therefore more densely stained than the others. In Fig. 2*D* the chromosomes which seem to be clustered together are presumed to be of human origin and might also tend to be lost as a group by some non-disjunctive process. These figures illustrate that one or more processes may operate to cause simultaneous and extensive loss of chromosomes of one species.

The chromosomes lost from the human–ino⁻ hybrids are not always exclusively human. A few Chinese hamster chromosomes are also lost occasionally, and such losses are most frequent among the telocentric members of group Z of CHO-K1 (ref. 7).

Gene Linkages

Fusions of normal human fibroblasts and the doubly deficient CHO-K1 mutants, ino⁻pro⁻ and gly⁻A pro⁻, respectively, were carried out. In each case the hybrid cells were grown up in the presence of proline but in the absence of the other nutrient, inositol or glycine respec-

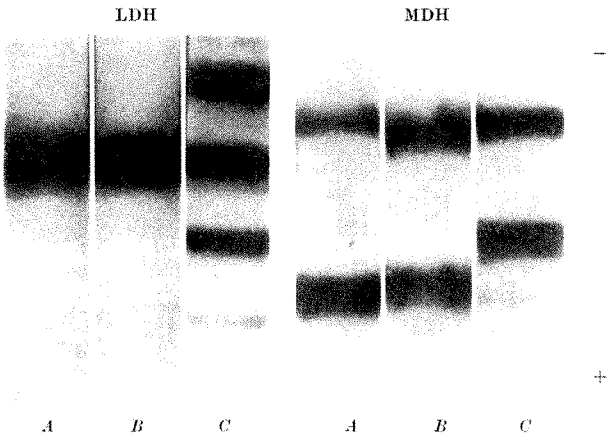

Fig. 4. Gel electrophoretograms of lactate dehydrogenase (LDH) and malate dehydrogenase (MDH) obtained from extracts of (*A*) the CHO-K1 cell; (*B*) the ino$^+$ pro$^-$ hybrid; and (*C*) the normal human fibroblast. In each case, 10 μl. of an extract from approximately 2×10^5 cells for LDH or 10^6 cells for MDH, to which was added an equal volume of 40 per cent sucrose, was layered over a 5·5 per cent polymerized acrylamide gel without use of a stacking gel. Electrophoresis was carried out for 45 min with a current of 2·5 mA per tube at 4° C in a Tris-glycine buffer (*p*H 8·3). Thereafter the gels were stained for LDH and MDH activities using appropriate substrates. In each case the pattern of the hybrid is indistinguishable from that of the CHO-K1 cell.

tively. After 2 weeks of growth in the partially deficient media, at which time maximum chromosome loss had occurred and the hybrids had achieved stable karyotypes, hybrid cells were plated, the resulting clones selected, and their nutritional requirements determined. As expected, all the clones could grow in the absence of inositol in the one case or glycine in the other. But, as shown in Table 2, the proline requirement of the original Chinese hamster cells was found to be variable. Thus absence of linkage between the pro$^-$ locus and either of the ino$^-$ and gly$^-$A loci is demonstrated.

Confirmation of the absence of linkage between the inositol and proline genes is afforded by a separate fusion experiment in which the converse selection medium was used. Thus the human–ino$^-$pro$^-$ hybrid cells were grown up in the presence of proline, but not inositol. Four clones were picked and tested: of these, three were ino$^+$pro$^-$ and one was ino$^+$pro$^+$.

Preliminary Chromosomal Analysis

Although karyotype analysis of these stabilized hybrid clones requires more than morphological methods of identification of the chromosomes particularly if errors from visually undetectable rearrangement are to be avoided, some preliminary conclusions are possible. Sixteen different human–CHO-K1 hybrid clones of the ino$^+$pro$^-$ type were picked from single cells grown in inositol-free F12 for 2 weeks after fusion. All had similar karyotypes. Fig. 3 presents a comparison of the karyotypes of (*A*) the normal human cell; (*B*) the original Chinese hamster cell (ino$^-$pro$^-$); and (*C*) a typical stabilized hybrid clone (ino$^+$pro$^-$), containing two chromosomes designated H_1 and H_2, which seem to be human. The stabilized hybrid cell contains only nineteen chromosomes, one less than the number in the original Chinese hamster cell. Seventeen of these seem to be chromosomes of the original CHO-K1. These include the twelve —presumably normal Chinese hamster chromosomes of the CHO-K1—and five of the eight abnormal ones which we previously designated as the *Z* group[7]. The three missing chromosomes of this group are the small telocentric ones.

The two sub-metacentric chromosomes which are present (designated H_1, H_2) presumably are of human origin. Measurement from more than twenty good metaphase spreads, of the arm lengths of these two presumed human chromosomes and their ratios (1·82 and 1·72 for the larger and smaller one respectively) suggests that the larger of the foreign chromosomes could be No. 2 and the smaller one could be either No. 6 or *X* of the human karyotype.

Table 2. TEST FOR LINKAGE BETWEEN THE INOSITOL AND PROLINE AND BETWEEN THE GLYCINE AND PROLINE GENES IN THE HUMAN CHROMOSOMES OF STABLE HYBRIDS

Parental genotypes		Growth media for hybrids	No. of hybrid clones isolated with the indicated genotypes
Human fibroblast	CHO		
ino$^+$pro$^+$	ino$^-$pro$^-$	Inositol-free proline present	ino$^+$pro$^-$ 35 ino$^+$pro$^+$ 7
gly$^+$pro$^+$	gly$^-$pro$^-$	Glycine-free proline present	gly$^+$pro$^-$ 10 gly$^+$pro$^+$ 5

Linkage of Dehydrogenase Genes with the Inositol Gene

Acrylamide gel electrophoresis of extracts of cells from CHO-K1, normal human fibroblasts, and the ino$^+$pro$^-$ hybrid with two presumed human chromosomes as shown in Fig. 3, was performed, and the resulting gels were stained to reveal the distribution of the lactate and malate dehydrogenase enzymes. The isozyme patterns of the Chinese hamster and human cells are distinct, and the hybrid patterns are indistinguishable from that of the CHO-K1 cell. The simplest interpretation of these results is that in the human genome the genes for these two enzymes are not linked to the inositol gene.

Our experiments show that human–Chinese hamster cell hybrids lose human chromosomes rapidly and extensively, so expediting genetic analysis. The rapidity of this process may in large part be determined by the disparity in growth rate of the two parental cells which would operate in two ways. First, because the two cells have widely different rates of traverse of their respective life cycles, asynchrony in the two chromosomal complements is to be expected in a large fraction of the initial fused population. Johnson and Rao[13] have shown that a set of mitotic chromosomes in a hybrid cell can induce premature condensation in a set of interphase chromosomes. When the latter are in G1 or S their condensation results in abnormal chromosomal structures, some of which resemble the pulverized chromosomes of Fig. 2*B*. Such chromosomes might be lost in relatively large groups. Second, because the Chinese hamster cells grow more rapidly than the human ones, a selective advantage is granted to the hybrid cells which lose the maximum number of human chromosomes. These considerations suggest that for optimal results, cells with the largest possible difference in growth rate be used, and that the slowly growing cell be the one from which chromosome loss is desired. Studies analysing the life cycles of such fused cells should illuminate this process.

The rapidity with which unnecessary chromosomes seem to be lost from the human–Chinese hamster hybrid cell commends it as a particularly useful system for gene linkage studies. By the use of appropriate auxotrophic mutants of the Chinese hamster cells and of accumulating knowledge of the chromosomal location of various human genes it should become possible to design conditions from which stable hybrids of Chinese hamster cells with particular human chromosomes will result.

We thank Dr Carol Jones for the gel electrophoretic isozyme analyses and Miss Judy Hartz for technical assistance. This investigation was aided by a US PHS grant from the National Institute of Child Health and Human Development.

Electron Microscopic Evidence for Chloroplast Fusion in Zygotes of *Chlamydomonas reinhardii*

by
T. CAVALIER-SMITH
Department of Biophysics,
University of London King's College,
26-29 Drury Lane, London WC2

In *Chlamydomonas reinhardii* zygotes the two chloroplasts contributed by the two gametes fuse, as do nuclei, to form a single zygotic chloroplast; this would enable non-Mendelian genes residing in the chloroplast to undergo recombination.

CHLOROPLASTS are currently believed to be formed only by the division of existing plastids[1], and there is much evidence that certain chloroplast defects are inherited as if controlled by non-Mendelian genes residing in the chloroplast itself[1]. Because chloroplasts have been shown to contain DNA[1,2], several authors[1,3-5] have suggested that these non-Mendelian genes are in fact chloroplast DNA. The non-Mendelian genes of the single-celled alga *Chlamydomonas reinhardii* have received intensive study by Sager[4] and by Gillham[5] who have shown that they are "particulate" and that linkage and recombination can occur between certain of them. Recently Margulis[6] has questioned the belief[3-5] that this recombination is the result of recombination within organelles (which she calls "intraorganellar recombination") and proposes instead that it simply results from the assortment of whole but phenotypically distinguishable organelles.

If genuine "intraorganellar recombination" does occur, as recent genetic evidence strongly indicates[4], one would expect it to be preceded by the fusion of the organelles derived from the two parents. So far as I am aware, such organelle fusion has not previously been convincingly demonstrated in any organism either in the case of chloroplasts or of mitochondria.

In this article I present electron microscopic evidence that in *Chlamydomonas* the two chloroplasts contributed by the two parents actually do fuse together to form a single "zygotic" chloroplast, in a similar way and at approximately the same time as the two parent nuclei fuse to form a diploid zygotic nucleus (see Figs. 1 and 2). I also outline a model for the behaviour of the non-Mendelian genes.

In most organisms it is difficult to observe the fate of chloroplasts in the zygote by electron microscopy because of the large number of indistinguishable chloroplasts and the difficulty of studying every stage. *Chlamydomonas*, however, has only one chloroplast per cell, which contains one distinct pyrenoid and one eyespot; these features make it possible to show unambiguously that chloroplast fusion does occur in the zygotes.

Gametes of both mating types (32C and 32D, Cambridge culture collection) of *C. reinhardii* were prepared[3,7] and mixed together to allow mating to occur. The resulting cell suspension was observed by light microscopy and fixed for electron microscopy at various intervals of time after mixing. Fixation was in 1 per cent glutaraldehyde in 0·02 M sodium phosphate buffer (*p*H 7·4) followed by a wash in phosphate buffer and post fixation in 1 per cent OsO_4 in phosphate buffer. After araldite embedding the sections were stained in uranyl acetate followed by lead citrate.

Observations of Chloroplast Fusion

One can obtain some information on the behaviour of the chloroplasts in the zygote by observing living cells by phase contrast microscopy. Newly formed zygotes (Fig. 1; 2 min) have four flagella and contain two nuclei and two discrete green chloroplasts; each chloroplast contains one orange birefringent eyespot and one small (1 μm) spherical pyrenoid. The two chloroplasts are cup-shaped and lie side by side (separated by a thin layer of colourless cytoplasm) at the base of the cell with the open ends of the cups towards the flagella. Three to four hours later the chloroplast bases, containing the pyrenoids, have moved so close together as to appear to be touching. Those inner parts of the two chloroplasts' "rims" which were earlier side by side have disappeared, so that each chloroplast is no longer cup-shaped, but the two together form one large green cup. One eyespot persists in each of the two remaining outer chloroplast rims and there are still two discrete pyrenoids. An hour or two later still there seems to be only one large chloroplast with two eyespots and two pyrenoids. By 10·5 h after mixing the gametes most zygotes contain only one pyrenoid. Zygotes at 12 h still contain two eyespots, but these are only about one-quarter the size of those of vegetative cells or gametes. Thereafter eyespots can generally not be seen in zygotes 1–6 days old; occasionally one very small one is present at the limits of visibility. The single chloroplast and its single pyrenoid at 12 h have both much more than twice the volume of those of gametes. By 24 h the chloroplast fills most of the cell which has also grown larger. In one mating, quadriflagellate zygotes were spherical and about

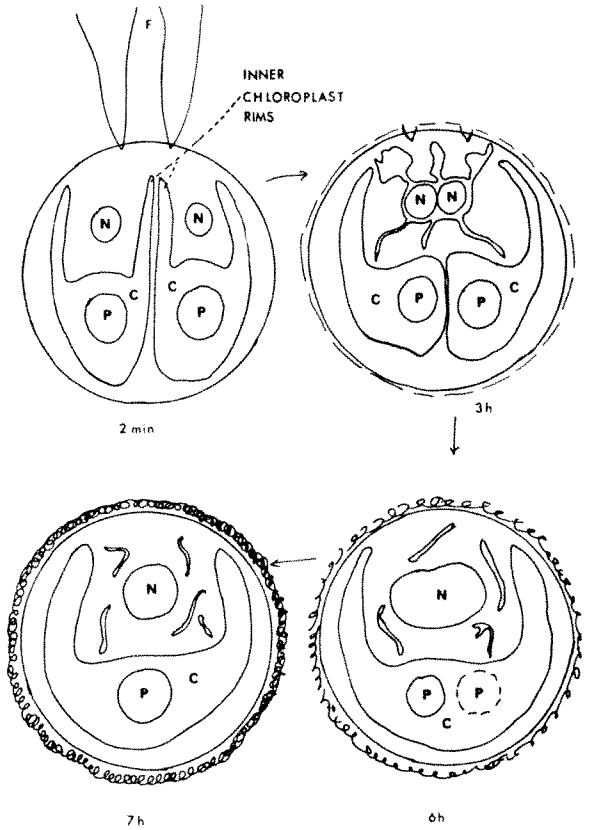

Fig. 1. Diagrammatic summary of the major events (approximate times indicated) during the first 7 h after cell fusion in *Chlamydomonas*, showing fusion of nuclei (N), chloroplast (C) fusion, regression of flagella (F) and basal bodies, loss of one pyrenoid (P), proliferation of the endoplasmic reticulum from the outer membrane of the nuclear envelope, and formation of part of the fibrous layer of the zygospore wall.

Fig. 2. 5·5 h old zygote in which the two nuclei (N) and the two chloroplasts (each containing a distinct pyrenoid, P) are in the early stages of fusion. In both cases both the inner and outer membranes of the envelopes have already fused. Note the large, interconnected, inflated rough endoplasmic reticulum cisternae connected to the outer membranes of the nuclear envelope. The outer fibrous layer of the zygospore wall is partly laid down. ×10,500.

8·8 μm across. Twenty four hours later zygotes were 15·8 μm across: this represents an 8·8-fold increase in volume. In the same time the remaining pyrenoids increased from 1 μm to 4·4 μm in diameter. The pyrenoid can usually be seen using both phase and bright field microscopy. Using the latter and iodine staining they are conspicuous, at all stages up to 12 h after mixing, as deep brown spheres standing out from the pale yellow-brown cytoplasm.

These observations with the light microscope suggest that chloroplast fusion may occur, but they cannot be regarded as conclusive, for the resolution is insufficient to distinguish two closely adjacent chloroplasts. Nonetheless they clearly show that, within 12 h of mixing the gametes, the zygotes contain only one greatly enlarged pyrenoid instead of the two small ones contributed by the gametes. This could come about in one of three ways: (1) the two chloroplasts fuse, in which case the two pyrenoids might fuse, one might degenerate or both might do so and one new one be formed; (2) the chloroplast from one mating type degenerates, the other persists; (3) both degenerate, and one new one is formed.

The changes in shape of the two chloroplast cups before the formation of the "single" cup suggest that fusion is the most likely explanation, but the resolution of the light microscope is insufficient to establish this. Because sections through a single branched chloroplast may reveal an interconnected system or several apparently distinct "chloroplasts", depending on their orientation, electron microscopy would also be inadequate without very extensive serial sectioning but for the fact that the pyrenoid (and also the eyespot) may be used as a chloroplast label or marker. Chloroplast fusion could be established by showing that two pyrenoids become enclosed by a common chloroplast envelope, provided one makes sure that one is observing zygotes and not gametes or vegetative cells, a small proportion of which might conceivably be in the predivision state when chloroplasts normally contain two pyrenoids[3]. This is easy to do, for at the critical times (2 h 15 min to 5 h 30 min after mixing) the zygote wall is beginning to be laid down—which distinguishes them from naked gametes—but is still thinner than and distinguishable from that of vegetative cells (see Fig. 3)[3]. At 4 h 40 min and 5 h 30 min I have often seen two pyrenoids enclosed in a common chloroplast envelope, which establishes chloroplast fusion as a fact (Figs. 2–4).

Chloroplast fusion begins by the formation of slender bridges between the basal regions of the two chloroplasts, often in more than one place (Fig. 4). Before this happens inner parts of the two chloroplast rims have usually regressed as also seen by light microscopy (see above) and the basal, pyrenoid-containing regions of the two chloroplasts have moved very close together. Most of the bridges are traversed by disk membranes (Figs. 2–4) which suggests that this happens soon after their formation. During fusion the remaining chloroplast rims are often elongated and sometimes branched, but by 5 h 30 min many cells have a single chloroplast with a fairly normal morphology which contains two pyrenoids in its basal region. Sometimes one of these shows signs of degeneration; its dense core may be almost absent and the tubular membranes swollen and disorganized. By 6 h 30 min sections of chloroplasts showing two pyrenoids are rare: most contain only one (Fig. 1; 7 h) and possibly the remains of a second. From 9 h onwards only one chloroplast with one pyrenoid (and no trace of a second) is normally present in each zygote. These observations suggest that the core material of one pyrenoid is degraded or dispersed, but do not establish whether the tubule membranes are broken down or reorganized, possibly as disk membranes or through incorporation into the remaining pyrenoid. My observations do not entirely rule out fusion of the two pyrenoid cores or some combination of lysis and fusion: sometimes, indeed, pyrenoids are seen partly intact and partly apparently degraded; occasionally a lobed pyrenoid is found which might conceivably be interpreted as a stage in fusion. These observations are summarized in Fig. 1.

Chloroplast Fusion and Non-Mendelian Heredity

There is no firm evidence as to the chemical nature or the location in the cell of the various non-Mendelian genes of *Chlamydomonas*. It is a reasonable working hypothesis that the DNA present in both mitochondria and chloroplasts of *C. reinhardii* has a genetic role and that some non-Mendelian genes will prove to be borne on chloroplast DNA and some on mitochondrial DNA. Mutations in the acetate genes presumably cause defects in photosynthesis, so it seems likely that these genes and those linked to them[4] reside in the chloroplast. The fusion of the two chloroplasts as described here brings together the chloroplast DNA from the mating type plus and minus parents into a common chloroplast matrix and therefore makes the recombination of non-Mendelian genes by the

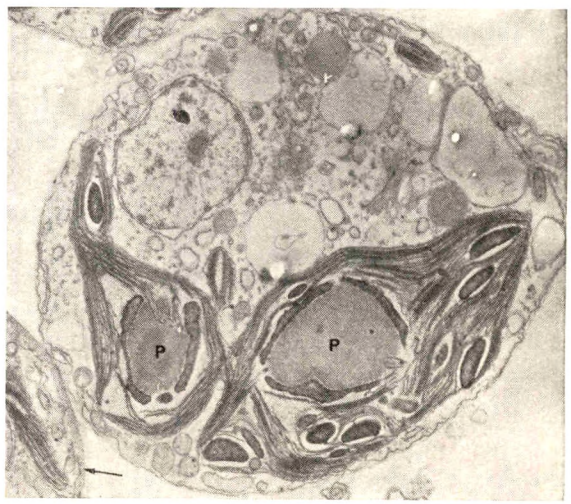

Fig. 3. Fusing chloroplasts in 4 h 40 min zygote, showing two pyrenoids (P) within a single chloroplast envelope. The chromatin clumps in the single nucleus are characteristic of a diploid zygotic nucleus. The fibrous layer of the zygospore wall is still very tenuous and clearly distinct from that of the vegetative cell in the lower left corner (arrow). ×6,000.

physical exchange of pieces of DNA a very attractive hypothesis. I have suggested[3] that chloroplast DNA is the bearer of at least some of the non-Mendelian genes studied by Sager and Gillham, and have put forward the following model to account for some of their detailed results.

First, during the early part of maturation the DNA from the minus parent is entirely broken down but that of the plus parent remains. This explains the normal uniparental inheritance of non-Mendelian genes.

Second, in a certain proportion of cases the degradation mechanism fails and both plus and minus DNA persist. Cells in which this happens would be the "exceptional zygotes".

Third, in exceptional zygotes both plus and minus DNA are replicated during and after maturation and are segregated at subsequent chloroplast divisions during and following germination. The time at which this occurred would depend on the number of copies of each DNA molecule present at each chloroplast division. If no process comparable with meiotic pairing between homologous chromosomes occurs, this segregation would be largely postmeiotic, even if each gamete originally contained only one copy of each molecule and only two replications[8] occurred before the first chloroplast division during germination.

Fourth, recombination[4,5] would result from the physical exchange of parts of the plus and minus DNA molecules after chloroplast fusion.

I suggested[3] that the most direct test of the proposed model would be to mate gametes of one sex, produced on a ^{15}N medium, with those of the opposite sex from a ^{14}N medium and to determine the fate of heavy and light chloroplast DNA during zygote maturation.

Preliminary results by Sager and Lane[9] using this method indicate that the minus DNA is either lost, as predicted by this hypothesis, or at least not replicated. Chiang's evidence[10], using ^{14}C and ^{3}H-adenine as labels for the two mating types, indicates that minus chloroplast DNA is conserved. If alternative explanations for his results (for example, the very efficient re-use of nucleotides derived from degraded minus chloroplast DNA) can be ruled out by future work, then a different explanation for uniparental transmission would have to be considered, for example, the restricted replication or transcription of minus chloroplast DNA in the normal maternal zygotes. The full publication of Sager and Lane's results ought to clarify this issue.

Whatever the exact mechanism of uniparental transmission, four features of this model would remain: (1) the equivalence of chloroplast DNA and certain non-Mendelian genes; (2) the selective "inactivation" of minus non-Mendelian genes in normal maternal zygotes and the failure of this inactivation process in exceptional biparental zygotes; (3) the segregation of non-Mendelian genes as a result of the segregation of chloroplast DNA; (4) the recombination of non-Mendelian genes as a result of physical exchange between plus and minus chloroplast DNA in the single zygotic chloroplast.

Detailed investigation of the behaviour of plus and minus chloroplast DNA, using both density and radioactive labels, not only in normal maternal zygotes but also in populations consisting predominantly of biparental or of paternal zygotes should confirm or disprove this model and also reveal the mechanism of inactivation.

My observations on chloroplast fusion clearly do not prove that recombination of non-Mendelian genes occurs within the single zygotic chloroplast, but they do refute the postulate of Margulis that in *Chlamydomonas reinhardii* uniparental inheritance can be mediated by the transmission of only the female chloroplasts through the zygotes. In addition, her simple model seems unable to explain satisfactorily the various degrees of linkage between the different non-Mendelian genes[4].

In flowering plants the frequent (but not universal) uniparental inheritance of plastid characters has often led to the belief that this is the result of uniparental transmission of entire plastids[1], as Margulis has suggested for *Chlamydomonas*. Because this is clearly not the case in *Chlamydomonas*, the idea must therefore be open to question in other plants. There are, however, a number of classic instances[1,11] where light microscopists have observed the apparent breakdown of male chloroplasts in the zygotes of algae such as *Spirogyra* and *Zygnema*, and also indications in some other species (for example, the liverwort *Anthoceros*) that the male gamete may possess no plastid at all. If these observations are confirmed by electron microscopy it seems that uniparental inheritance of plastid characters can in some species result from the uniparental transmission of whole plastids. It would be very interesting to know how widespread the phenomenon of plastid fusion is in plant zygotes. Even in zygotes of other unicellular algae the fate of the chloroplasts is generally unknown[12]; a few light microscopists, notably Stein[13–15], have believed that chloroplast fusion occurs, but electron microscope studies are needed to confirm this.

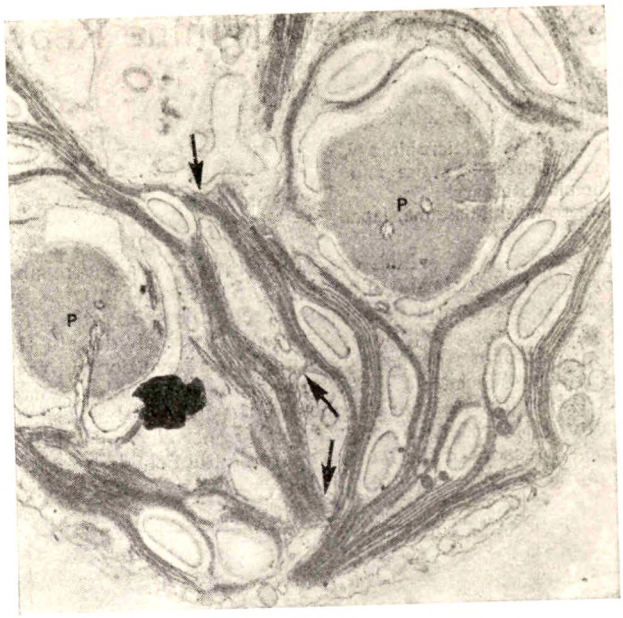

Fig. 4. 5·5 h zygote showing two chloroplasts whose envelopes have fused in three places (arrows). The pyrenoids (P) of both chloroplasts are intact. ×14,400.

It would clearly be of great interest to determine whether mitochondria, as well as chloroplasts, fuse in zygotes of *Chlamydomonas*, or indeed in any organism. Unfortunately the large number of indistinguishable mitochondria in each cell makes this difficult.

I thank Sir John Randall for support and encouragement.

NATURE VOL. 228 OCTOBER 24 1970

Isolation of the Arginine Repressor in *Escherichia coli*

by
SHIGEZO UDAKA
Department of Microbiology,
The Institute of Physical and
Chemical Research,
Yamato-machi, Saitama, Japan

The repressor produced by the *argR* gene of *E. coli* K-12 has been isolated. This protein seems to repress several separate operators.

THE eight genes which code for the enzymes responsible for the biosynthesis of arginine in *E. coli* map in five separate groups on the chromosome. Their expression is controlled by a regulator gene, *argR*, which directs the synthesis of a repressor exerting a negative control over enzyme synthesis[1,2]. This repressor must somehow control all the eight structural genes of the system because, in spite of their separation, they are controlled in parallel. The repressors of the lactose operon and of the lysogenized lambda phage are proteins which seem to block transcription by binding directly to DNA[4,5]. That the arginine repressor is also a protein is suggested by *in vivo* experiment[6] and by the existence of *argR* mutants whose repressibility is sensitive to high temperature (*argR*^{ts})[2,3] and to amber suppression[2].

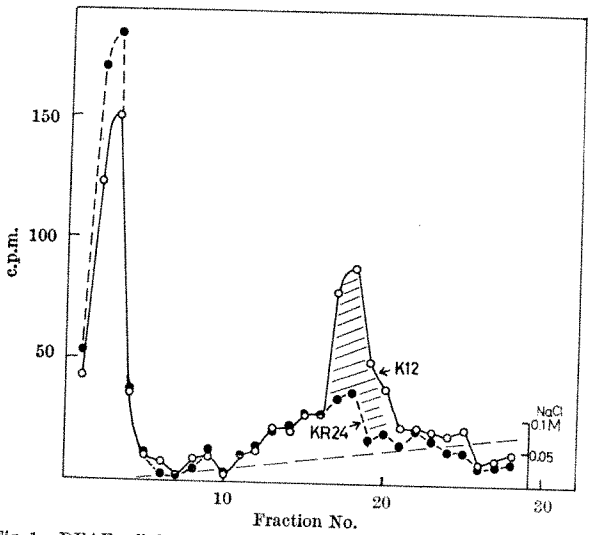

Fig. 1. DEAE-cellulose elution profiles of a mixture of fractions derived from the ribosomes of the wild type and an *argR*⁻ mutant, KR 24. The cells were grown in an M9 medium supplemented with 0·03 per cent yeast extract and nineteen amino-acids (not including lysine) (20 μg/ml. each). Fifty μCi of ^{3}H-lysine (○) was added to the wild type culture and 20 μCi of ^{14}C-lysine (●) to the KR 24 culture. The bacteria were labelled for three generations at 37° C and then mixed. Cell extracts were prepared by alumina grinding in 1·5 ml. of 0·01 M Tris (*p*H 7·4) and 0·1 mM magnesium acetate, and centrifuged on a sucrose density gradient and fractionated by the conventional method. The supernatant, 30S and 50S ribosome fractions were pooled separately. The 30S fraction was dialysed against 5 mM Tris (*p*H 7·4), and then incubated in 10 mM Tris (*p*H 8·5)–10 mM magnesium acetate–60 mM NH_4Cl at 25° C for 1 h. This fraction was passed through a DEAE-cellulose column (1 × 10 cm) which was equilibrated with the same buffer. The effluent was collected, dialysed against 5 mM Tris (*p*H 7·5), and applied to another DEAE-cellulose column (0·5 × 15 cm) equilibrated with 5 mM Tris. Fractions were eluted with a 40 ml. linear gradient of NaCl (0–0·08 M) containing 5 mM Tris (*p*H 7·5). The flow rate was 1·5 ml./fraction/30 min. An aliquot of each fraction was added directly to Bray's solution[10] and counted on a scintillation spectrometer. All fractionations were done at 4° C. The counts were normalized by multiplying the measured ^{14}C values by the ^{3}H/^{14}C ratio of the sample applied to the column.

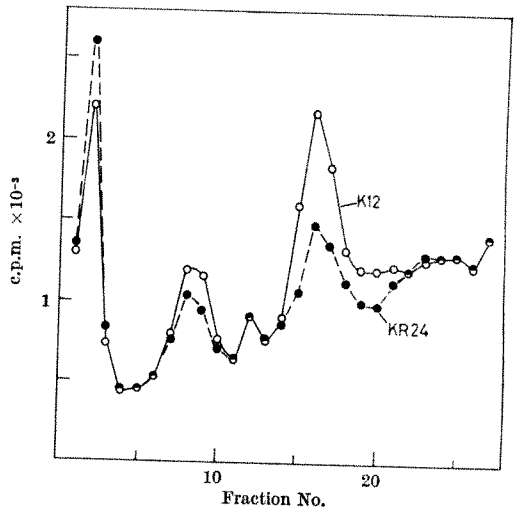

Fig. 2. Elution profiles of a mixture of crude extracts from the wild type and KR 24. The wild type was labelled with 4 μCi ^{3}H-lysine and KR 24 with 1 μCi ^{14}C-lysine. The labelling of cells and the preparation of crude extract were as described in Fig. 2, except that 5 mM Tris (*p*H 7·5) was used for extraction. The crude extract was dialysed against the same buffer, then applied to a DEAE-cellulose column (0·5 × 15 cm). Gradient elution and analysis of the effluent were as described for the second column chromatography of Fig. 1.

Isolation of the *argR* Product

Our previous work has suggested that the repressor protein might be involved in some way with the ribosome[7]. We have therefore examined the ribosomal proteins of *argR* mutants. Cells of wild type *E. coli* K-12 and an *argR* mutant were differentially labelled with ^{14}C- or ^{3}H-amino-acids, and ribosomal proteins analysed on carboxymethyl-cellulose columns by the method of Otaka *et al.*[8]. There was no significant difference between the principal ribosomal protein components, but comparison of the proteins of the 30S subunits showed a small but reproducible difference between the two bacterial strains.

One column fraction was rich in the radioactive label of the wild type. The detailed procedures used for its further purification are given in Fig. 1. We postulate that the

Cells of KR 18 and KR 24 were mutagenized with nitrosoguanidine[11]. The isolated colonies were tested for their enzyme levels[12]. The mutants selected were purified and subjected to further analysis. Possible contaminants in the mutagenized cells were eliminated by examining the colony morphology on EMB agar and sensitivity to phage T_4. The cells were grown in M9 medium containing 0·5 per cent casamino-acids and 100 μg/ml. L-arginine and their enzyme levels were determined as previously described[9]. The amounts of the fractions R and R′ were estimated from the area of each peak in the DEAE-cellulose elution profile obtained as in Fig. 2. Specific activities of enzymes are expressed as μmoles of reaction product formed per h per mg of protein. The amounts of the fractions R and R′ are shown relative to that of the fraction R of the wild type.

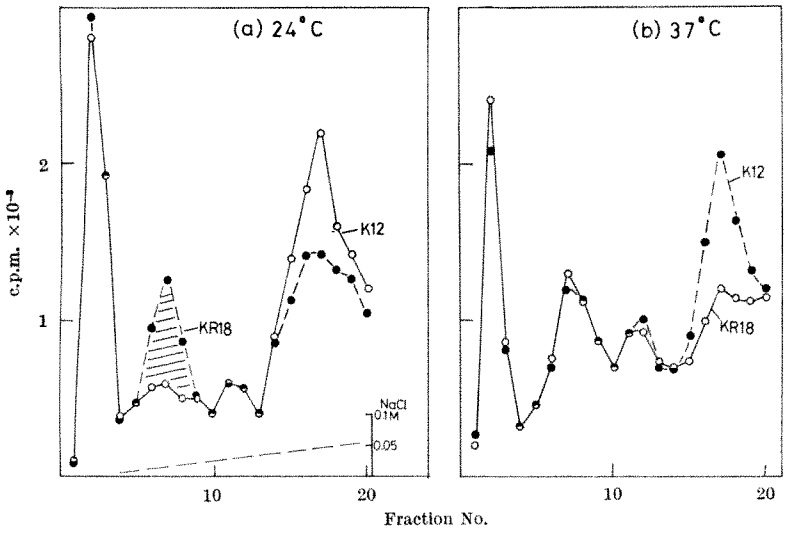

Fig. 3. Elution profiles of a mixture of crude extracts from the wild type and KR 18, grown at 24° C and 37° C. Cells were labelled either with ^{3}H-lysine or ^{14}C-lysine. The cells were labelled at 24° C and 37° C as indicated. All the analytical procedures were the same as in the legend of Fig. 2. (○), ^{3}H; (●), ^{14}C.

shaded area of this figure represents a protein fraction (termed fraction R) which is present only in the wild type cells and not in the *argR* mutant cells. The radioactivity of fraction R constituted only about 0·1 per cent of the total radioactivity of the 30S subunit. Cells of KR 18 (*argR*^{ts}) grown at 37° C yielded a profile similar to that of KR 24 (*argR*$^-$) shown in Fig. 1, thus also showing lack of fraction R. KR 18 cells labelled at 24° C, however, yielded a small extra peak in approximately 0·02 M NaCl eluate.

The amount of the repressor associated with the ribosome is only a small proportion of that found in the soluble fraction (see below) and the repressor fraction can easily be removed from ribosomes by buffers containing 0·06 M NH_4Cl. This suggests that its presence on the ribosome is fortuitous and results from a non-specific adsorption. Some *argR* mutants have ribosomes with altered sensitivities to streptomycin (unpublished observations); this suggests that such an adsorption may occur *in vivo* to cause some change in ribosome function, but its significance remains obscure.

An elution profile similar to that of Fig. 1 was obtained when a soluble fraction of the cell extract (the 100,000*g* supernatant) was applied to the DEAE-cellulose column by the procedure given in Fig. 1. The fraction R recovered from the supernatant or crude extract was much larger than that from the ribosome fraction. A chromatographic profile of the crude extract showing the presence of fraction R is indicated in Fig. 2. Double-label experiments conducted with reversibly labelled amino-acids (a "criss-cross" experiment) gave the same result, and experiments carried out with leucine and reconstituted protein hydrolysates gave similar profiles. Although radioactivity measurements were taken directly on the sample solution, counting on the 10 per cent trichloroacetic acid (TCA) precipitate heated to 95° C for 20 min gave essentially the same results. We estimate that fraction R is approximately 0·3 per cent of the soluble cellular protein.

As shown in Fig. 3, the crude extract of KR 18 exhibited a definite extra peak in eluates with lower concentration of NaCl when the bacteria had grown at 24° C. We again postulate that the shaded area of Fig. 3*a* represents a protein present only in the KR 18 cells which had grown at lower temperature (referred to as fraction R′). The elution profiles of *argR*$^-$ mutants lacking fraction R were similar to that of K-12 in eluates with lower concentration of NaCl when they had grown at 24° C, showing that fraction R′ is unique for KR 18.

The following evidence indicates that fraction R is the product of the *argR* gene and that fraction R′ is an altered form of the repressor. The fraction R present in the wild type K-12 strain has not been found in the *argR*^{ts} mutant, KR 18, or in some of the *argR*$^-$ mutants (four out of nine mutants tested). Other *argR*$^-$ mutants and another *argR*^{ts} mutant, KR 59, produce a protein fraction indistinguishable from fraction R. Only KR18 formed the fraction R′ at 24° C at which temperature enzyme synthesis was nearly repressed. We therefore assume that both the fractions R and R′ are able to repress the synthesis of arginine enzymes.

Fraction R was found in derepressed cells of wild type bacteria grown in medium lacking arginine which formed about 60 times more ornithine transcarbamylase than repressed cells. This suggests that there is no self-control over fraction R formation by the repression mechanism. To see if fraction R is deleted only in *argR* mutants, similar double-label experiments were done with mutants of other operons; *i*$^-$ and *trpR*$^-$ mutants, and their respective isogenic parental *E. coli* (supplied by Drs T. Horiuchi and T. Yura, respectively), were compared. No difference such as that shown in Fig. 2 was found between these mutants and their parents.

Table 1 demonstrates quantitative alterations of fractions R and R′ on further mutations of KR 18 and KR 24. The amounts of these fractions varied in accordance with the changes in the phenotypes of the mutants. Thus repressible revertants from KR 18 gave the same chromatographic profile as that of the wild type. Non-repressible derivatives of KR 18 lost the ability to form fraction R′ at 24° C as well as at 37° C. Strain 18-M-7, in which the enzymes are more repressed, produced fraction R′ even at 37° C while KR 18 formed little at this temperature. On the other hand, strain 24-M-49 seems to form some fraction R, for it is partially repressed.

The fraction R′, but not the fraction R, nearly disappeared when KR 18 cells were heated at 49° C for 20 min (Fig. 4). Heating for 15 min resulted in an intermediate

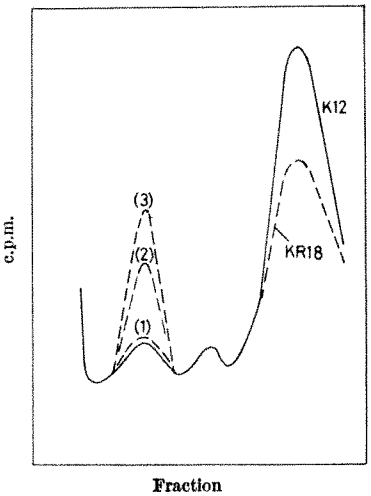

Fig. 4. Schematic elution profiles of the extracts from heated cells of KR 18. Labelling was performed as in Fig. 2. The labelled cultures were mixed, centrifuged, suspended in 1/20 volume of 0·01 M phosphate buffer (*p*H 7·1), and divided into several portions. One served as the unheated control. The other parts were heated at 49° C for 20 min with and without the addition of chemicals. Each sample was collected by centrifugation and ground with alumina. The subsequent analysis was as described in Fig. 2. Each curve represents schematically the summary of each analysis. The experiment was repeated two to four times. (1) Heated in absence or presence of 10^{-3} M D-arginine or of 10^{-3} M L-ornithine; (2) heated in presence of 10^{-3} M L-arginine; (3) unheated control.

disappearance of fraction R′. This figure also shows that L-arginine, but neither D-arginine nor L-ornithine, partially prevents the heat denaturation of fraction R′. The responses of fraction R′ to heat are consistent with the results of *in vivo* experiments with KR 18 (unpublished). When KR 18 cells grown at 24° C were heated in a buffer at 49° C for 10 min, a rapid enzyme synthesis ensued on return to 24° C. Addition of L-arginine to the buffer partially prevented the derepression by heat. We interpret these results to mean that the temperature-sensitive repressor is denatured by heat. The findings also provide evidence for the identity of fraction R′ as the altered repressor.

The approximate molecular weight of the repressor was estimated by gel filtration. The molecular weights of fractions R and R′ are about 45,000 and 25,000 respectively. Because the amounts of the two fractions are about equal, we might presume that fraction R is a dimer and that fraction R′ is a monomeric form of the wild type repressor. Disc electrophoresis of fraction R was carried out in a standard gel at *p*H 8·7 (ref. 9). Fraction R migrated toward the anode to about one-third of the distance between the origin and the dye front.

I thank Misses S. Ikawa and T. Akiyama for technical assistance, Dr Y. Ikeda for support and Drs B. D. Davis and L. Gorini for reading the manuscript. The work was partly aided by a grant from the Japanese Ministry of Education.

Localization of Acyl Carrier Protein in *Escherichia coli*

by
H. VAN DEN BOSCH*
JOSEPH R. WILLIAMSON

Departments of Biological Chemistry and Pathology,
Washington University School of Medicine,
St Louis, Missouri 63110

Acyl carrier protein has been localized in *Escherichia coli* by electron microscopy and autoradiography to a site just inside the cytoplasmic membrane.

Acyl carrier protein (ACP) functions as a carrier of acyl groups in the *de novo* biosynthesis of fatty acids. As such it plays an essential part in two kinds of fatty acid synthetases: multienzyme complexes and non-associated fatty acid synthetases.

In the fatty acid synthetase multienzyme complexes the individual enzymes participating in long chain acyl synthesis are present in a high molecular weight aggregate. This complex can be purified as a unit, but attempts to isolate the individual enzymes in an active form from this unit have been unsuccessful so far. Multienzyme complexes have been isolated from yeast[1], adipose tissue[2], liver[3] and *Mycobacterium phlei*[4]. Although protein-bound 4′-phosphopantetheine has been found in all of these, indicating the presence of an ACP-like component, only from the yeast synthetase has the ACP been isolated after disruption of the complex[5].

The non-associated fatty acid synthetases by definition fail to show any tendency to associate when studied *in vitro*. The individual soluble enzymes from these synthetases can be isolated by conventional protein separation techniques. By contrast with the multienzyme complexes, ACP in the non-associated fatty acid synthetases (as found in most bacterial[6,7] and plant extracts[8]) is present in the free state and can easily be separated from the enzymes involved in fatty acid biosynthesis. Yet in these fatty acid synthetases, as in the case of the multienzyme complexes, ACP must interact specifically and consecutively with acetyl-CoA-ACP transacylase, malonyl-CoA-ACP transacylase, β-ketoacyl-ACP synthase, β-ketoacyl-ACP reductase, β-hydroxyacyl-ACP dehydrase, and enoyl-ACP reductase[9]. In spite of this, the process of fatty acid biosynthesis in *E. coli* is apparently very efficient, for no free acyl-ACP intermediates are found in extracts made from cells grown in normal conditions. This observation led us to consider whether the synthetase from *E. coli* might exhibit some kind of structural organization *in vivo*. We therefore designed experiments which would localize ACP, a component of the fatty acid synthetase with a unique prosthetic group which facilitates detection, in the bacterial cell. We speculated that ACP might be lined up along the cytoplasmic membrane because recent studies from this and other laboratories have shown that acyl-ACP derivatives react not only with the soluble enzymes of the fatty acid synthetase but also with the membrane-bound enzymes involved in the biosynthesis of complex lipids[10–13].

To localize ACP in *E. coli* we used auxotrophs of this bacterium requiring either pantothenate or β-alanine. When these mutants are grown on limiting concentrations of radioactive pantothenate or β-alanine and allowed to remain in stationary phase for some time, the level of CoA drops dramatically and the pantothenate or β-alanine is present almost exclusively in ACP[14,15]. Thus by using β-^{3}H-alanine of high specific radioactivity we were able to label specifically one protein in the cell, ACP, and to localize it by electron microscopy and autoradiography.

Absence of ACP in Periplasmic Space

When *E. coli* Hfr 139, a pantothenate auxotroph, is grown on a limiting concentration of ^{14}C-pantothenate and allowed to remain in the stationary phase for several hours, the cells contain the incorporated ^{14}C-pantothenate almost exclusively in ACP. The cells used in the experiments of Table 1 contained 97 per cent of the radioactivity in ACP and 3 per cent in CoA. When these cells were subjected to the osmotic shock treatment described by Heppel[17], 92 per cent of the radioactivity (at least 90 per cent of the ACP) remained inside the shocked cells while 81 per cent of the 5′-nucleotidase activity was

* Present address: Laboratory of Biochemistry, Vondellaan 26, Utrecht.

Table 1. OSMOTIC SHOCK TREATMENT OF ^{14}C-ACP CELLS

Fraction	Total protein (mg)	Total radioactivity (c.p.m.)	5′-Nucleotidase (μmoles P_i/20 min)
Cells	115*	382,000	938*
Stage 1 fluid	—	5,100	7
Stage 2 fluid	4	8,690	720
Shocked cells	109*	350,200	165*

* Determined on sonicates.

E. coli Hfr 139 were grown at 37° C in a New Brunswick shaker, model G-25, in medium E (ref. 16) containing 0·4 per cent glycerol as carbon source and supplemented with a limiting concentration of pantothenate (0·05 μM, specific activity 3·5 μCi/μmole) and 1·7 μM thiamine. Cells were harvested 4 h after they reached stationary phase at A_{600}=0·56. Parts of the cells were ruptured by French press and the extract was analysed for ^{14}C-ACP and ^{14}C-CoA (ref. 15). ^{14}C-ACP accounted for 97 per cent of the incorporated radioactivity. The remaining cells were subjected to osmotic shock treatment[17]. Stage 1 fluid—20 per cent sucrose supernatant; stage 2 fluid—supernatant after shock treatment in 5×10^{-4} M $MgCl_2$ (contains proteins released from periplasmic space). Sonic extracts of intact and osmotically shocked cells were made by treatment of cell suspensions for 90 s with a Branson sonifier, model LS 75. 5′-Nucleotidase was assayed with 5′-adenosine monophosphate according to Neu and Heppel[18].

released into the osmotic shock fluid. Thus ACP is localized either within the cytoplasmic membrane or in the cytoplasm and not—like some transport factors and enzymes such as 5′-nucleotidase and alkaline phosphatase[17]—in the periplasmic space between the cytoplasmic membrane and cell wall.

Preparation of Tritiated Cells

To localize tritiated ACP by electron microscopy and autoradiography, a number of control experiments were necessary to define certain parts of the cell. The preparation of cells labelled with various ^{3}H-labelled metabolites for autoradiography is described in Table 2. Cells were grown on [*methyl*-^{3}H]-thymidine to label the nuclear area, on ^{3}H-tryptophan or ^{3}H-glutamic acid to label proteins in general, and on different concentrations of β-^{3}H-alanine to label ACP and CoA. When the β-alanine auxotroph, M99-2, was grown on an excess of β-^{3}H-alanine (2·0 μM), it contained 8 disintegrations/day/cell with 89 per cent of the radioactivity in CoA and 11 per cent in ACP. When grown on limiting β-alanine concentrations the auxotroph contained 1·5 disintegrations/day/cell (32 per cent in CoA and 68 per cent in ACP) when harvested in log phase and 1·0 disintegration/day/cell (with 89 per cent as ^{3}H-ACP) when harvested in early stationary phase. The cells had to be harvested in early stationary phase because of increased reversion during the growth in β-alanine limiting conditions.

Electron Microscopy and Autoradiography

Electron microscopy with autoradiography of cells in which DNA was labelled with [*methyl*-^{3}H]-thymidine and proteins were labelled with L-^{3}H-tryptophan or DL-^{3}H-glutamic acid was done to establish that this method would adequately demonstrate the nuclear and cytoplasmic areas of the cell. The distribution of grains in the cells in Fig. 1 indicates a concentration of grains over nuclear areas in the thymidine labelled cells (*a*). A relative paucity of grains over nuclear material and increased numbers over the cytoplasm characterize preparations in which the label was in protein (*b*). The grain distribution in the β-alanine cells varied according to the β-alanine concentration and duration of growth. Those cells grown on excess β-alanine (*c*), in which 89 per cent of the label was in CoA and 11 per cent in ACP, had a grain distribution similar to cells in which proteins in general were labelled (*b*). In the cells grown on limiting β-alanine and harvested in early stationary phase (*d*), in which 89 per cent of the label was in ACP, many grains are centred over cell surfaces and a greater proportion are outside the cell than in the other preparations.

Histograms[20] were constructed to demonstrate the cellular distribution and median of grains in the different radioactive cells (Fig. 2) and these support the apparent surface localization of ACP. Thus the nuclear distribution of thymidine (*a*) is obvious. Both tryptophan (*b*) and glutamic acid (*c*) heavily labelled the cytoplasm and these patterns resemble the grain distribution seen with cells

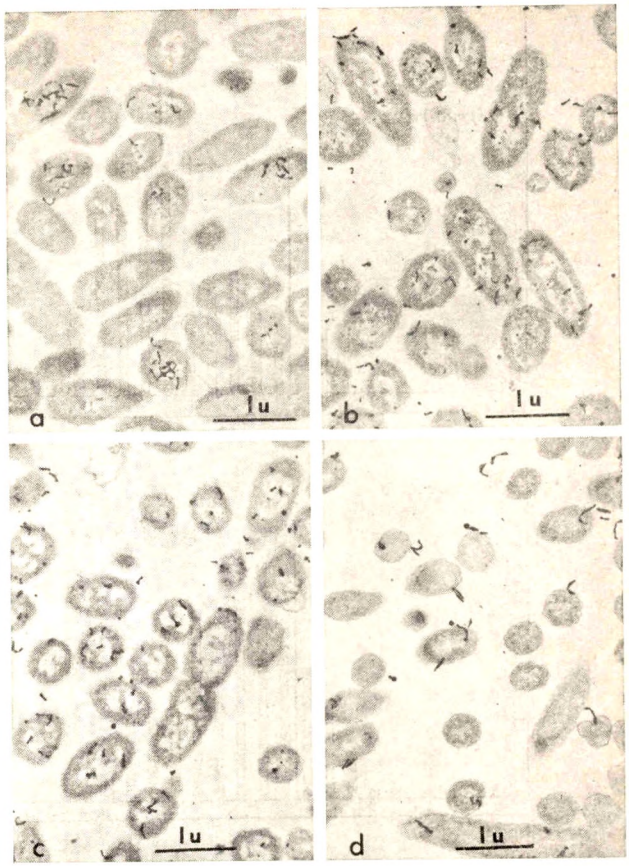

Fig. 1. Electron microscope autoradiography of tritiated cells. Washed cells prepared as described in Table 2 were resuspended in 1 ml. medium E, fixed in 1 per cent OsO_4 and processed for electron microscopy and autoradiography by a method to be published elsewhere (J. R. W. and H. van den B.). Loss of ^{3}H was monitored during fixation, staining and dehydration of the β-^{3}H-alanine cells. Cells grown in 2·0 μM β-^{3}H-alanine retained 53 per cent and cells grown in 0·05 μM β-^{3}H-alanine retained 80 per cent of ^{3}H after these procedures. Exposure time was 6 months. *a*, [*methyl*-^{3}H-thymidine; *b*, L-^{3}H-tryptophan; *c*, β-^{3}H-alanine (11 per cent of ^{3}H in ACP); *d*, β-^{3}H-alanine (89 per cent of ^{3}H in ACP).

grown on excess β-alanine (*d*). In the cells grown on limiting β-alanine the median of the grain distribution shifts towards the cell surface in conditions where the label is concentrated in ACP (*e* and *f*). The means and medians of these different preparations are listed in

Table 2. PREPARATION OF LABELLED CELLS

E. coli cultures	^{3}H-Metabolite	Conc. (μM)	Spec. act. (Ci/mmole)	A_{600} at harvest	Radioactivity (disintegrations/day/cell)
Hfr 139	[*methyl*-^{3}H]-thymidine	30·0	6·7	1·40	5·0
Hfr 139, Trp 3	L-^{3}H-tryptophan	40·0	2·5	0·2	41·0
Hfr 139	DL-^{3}H-glutamic acid	2·0	26·9	0·62	20·0
M99-2†	β-^{3}H-alanine	2·0	5·2	1·48	8·0 (89% as CoA)
		0·05	5·2	0·16	1·5 (32% as CoA)
		0·05	5·2	0·48	1·0 (11% as CoA)

All cells were grown in medium E with 0·4 per cent glycerol as carbon source. *E. coli* Hfr[139] was supplemented with 2·0 μM pantothenate and 1·7 μM thiamine. ^{3}H-Thymidine cells: Hfr 139 was grown in medium supplemented with [*methyl*-^{3}H]-thymidine, harvested and washed three times with medium E containing unlabelled thymidine. ^{3}H-Tryptophan cells: Hfr 139, Trp 3, a tryptophan auxotroph derived from Hfr 139 and donated by Dr D. F. Silbert, was grown in medium supplemented with L-^{3}H-tryptophan and washed as above with medium containing unlabelled tryptophan. ^{3}H-Glutamic cells: Hfr 139 was grown in medium supplemented with DL-^{3}H-glutamic acid. β-^{3}H-alanine cells: M99-2, a β-alanine auxotroph (donated by Dr W. Maas), was grown with either 2·0 or 0·05 μM β-^{3}H-alanine The cells grown on limiting β-alanine concentrations (0·05 μM) were harvested either in the logarithmic phase at A_{600}=0·16 or in early stationary phase at A_{600}=0·48 and washed as above. ^{3}H-CoA and ^{3}H-ACP were determined by DEAE-cellulose chromatography. β-^{3}H-alanine (specific activity 5·2 Ci/mmole) was obtained by reductive dehalogenation of α-bromo-β-aminopropionic acid with carrier-free tritium gas in dimethylformamide in the presence of 5 per cent palladium on alumina and an equimolar amount of triethylamine (carried out by New England Nuclear Corp., Boston). The α-bromo-β-aminopropionic acid was synthesized according to Schöberl and Braun[19].

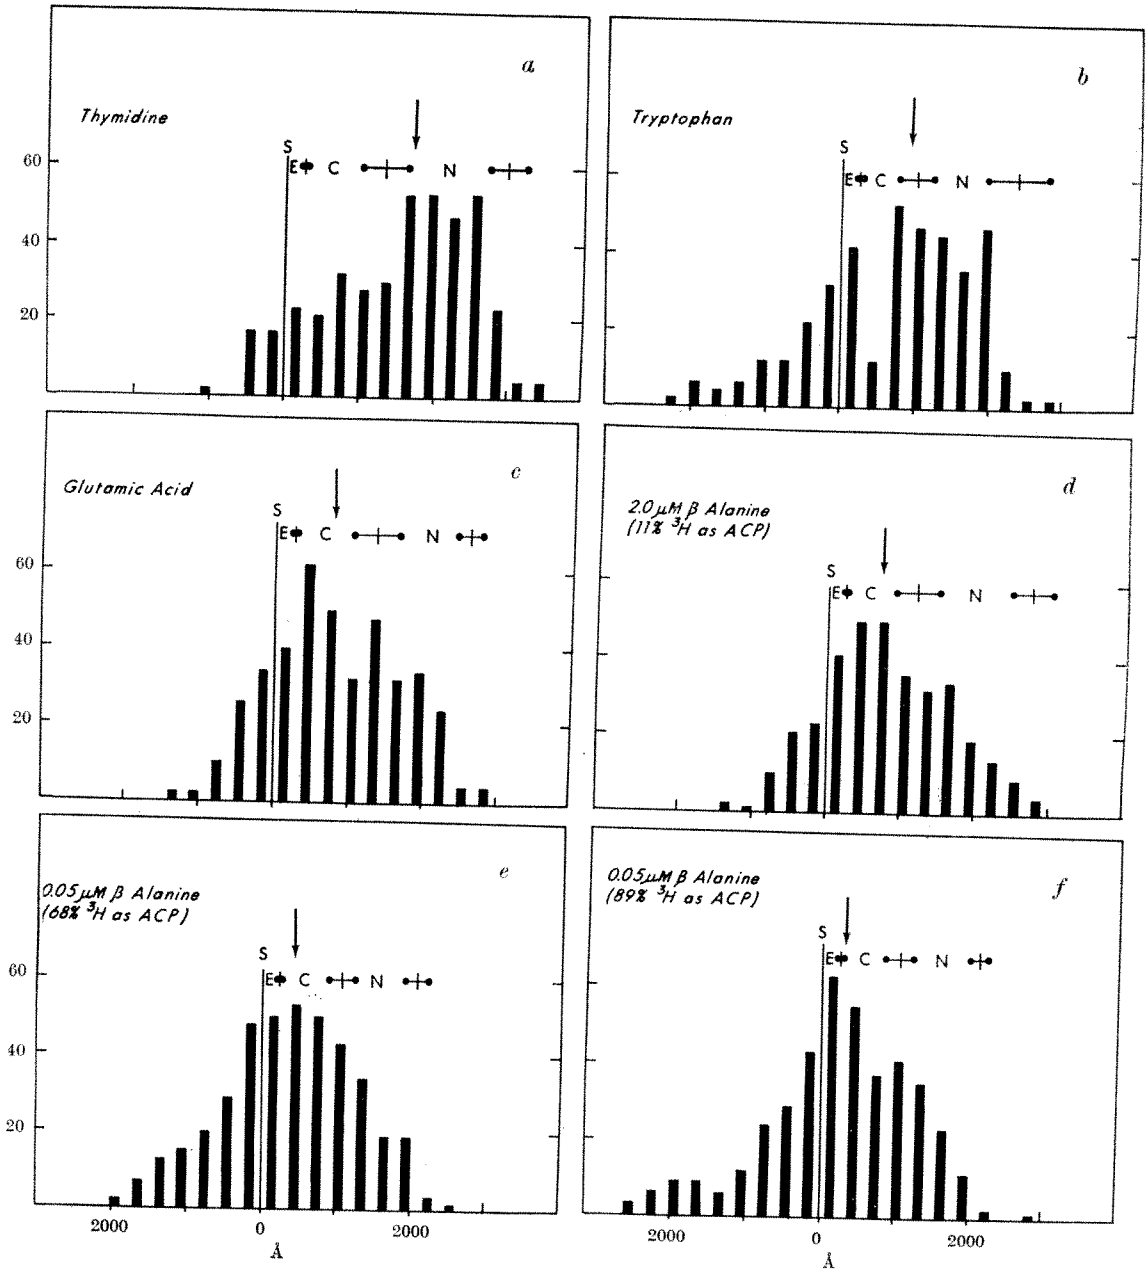

Fig. 2. Histograms of grain distributions in tritiated cells. The shortest distance from the midpoint of each grain to the cell surface (S) was measured with a dial caliper. Grains longer than 2500 Å, regardless of their location, were not included. From the tabulated measurements histograms[20] were constructed. The width and distance from the cell surface of the cell envelope (E), cytoplasm (C), and nuclear area (N) were obtained from measurements on fifty different cells in each group and are indicated ±s.d. The arrow indicates the median of the grain distribution in each group. *a*, [*methyl*-³H]thymidine; *b*, L-³H-tryptophan; *c*, DL-³H-glutamic acid; *d*, β-³H-alanine (11 per cent ³H as ACP); *e*, β-³H-alanine (68 per cent ³H as ACP); *f*, β-³H-alanine (89 per cent ³H as ACP).

Table 3. A χ^2 test (Table 4) comparing grain distributions indicates that each group differs significantly from the others except for the tryptophan, glutamic acid and excess β-alanine groups (2, 3 and 4 respectively), which do not differ from each other but do differ significantly from the remaining groups.

The results of these experiments indicate that ACP is located in the plasma membrane or very near the cytoplasmic side of the membrane. That ACP is not present in the cell wall is evident from the fact that bacterial L forms, which lack cell wall, are fully capable of synthesizing both fatty acids and complex lipids for membrane synthesis. The retention of at least 90 per cent of ^{14}C-labelled ACP inside osmotically shocked cells which had lost 81 per cent of the 5′-nucleotidase activity indicates that little if any ACP is present in the periplasmic space. The localization of ACP by electron microscopy autoradiography is based on visual inspection of the autoradiograms, the mean and median values for grain distribution in the various groups, and the χ^2 test of homogeneity of grain distributions. The χ^2 test results indicate the presence of four different patterns of grain distributions in the six experimental groups. This information, along with what we know about the cellular distributions of the radioactive constituents in three of the six groups, permits us to infer the source geometries responsible for the distribution of grains in the remaining three groups. The mean and median of the grain distribution for cells labelled with thymidine are, as expected, nearer the centre of the cells than the mean and median of the grain distributions for cells labelled with tryptophan or glutamic acid. These differences correspond to the distribution of nuclear material and cytoplasm. The mean and median grain distribution of β-alanine cells containing 89 per

Table 3. MEAN AND MEDIAN OF GRAIN DISTRIBUTIONS

Label	Mean ± s.e. (Å)	Median (Å)

2, 5	27·75	17	< 0·05
2, 6	49·27	16	< 0·001
4, 5	57·19	19	< 0·001
5, 6	42·49	17	< 0·001

1* = [*methyl*-^{3}H]-thymidine; 2 = L-^{3}H-tryptophan; 3 = DL-^{3}H-glutamic acid; 4 = β-^{3}H-alanine (11 per cent ^{3}H in ACP); 5 = β-^{3}H-alanine (68 per cent ^{3}H in ACP); 6 = β-^{3}H-alanine (89 per cent in ACP).

cent of the label in ACP are quite close to the cell surface, in fact just beneath the cell envelope in a position corresponding to the plasma membrane. Because the distribution of grains in each β-alanine group is different ($P < 0.001$) and the mean and median shift toward the cell surface as the ratio of ACP to CoA increases, and because we have independent evidence that ACP is not present in the cell wall or the periplasmic space, it seems reasonable to infer that ACP is associated with the plasma membrane. This association is such, however, that rupture of the membrane releases the ACP into solution.

The localization of ACP on or near the inside surface of the plasma membrane would be consistent with its role in the synthesis of fatty acids and phospholipids which are present almost exclusively in the cytoplasmic membrane of *E. coli*. The fact that ACP is not randomly distributed in the cell suggests a degree of organization for a central component of the fatty acid synthetase which has not been appreciated before. This finding suggests that the *E. coli* fatty acid synthetase may be organized *in vivo*, perhaps in a typical multienzyme complex which includes the ACP.

We thank Dr S. Choi for the statistical analyses, Mr Walter L. Nulty, jun., for performing some of the experiments, and Mrs Jackie Bayer for technical assistance. This work was supported by grants-in-aid from the US Public Health Service and the US National Science Foundation.

Field and Laboratory Observations of the Crown-of-Thorns Starfish, *Acanthaster planci*

Although there have been many reports of the large scale destruction of Pacific coral reefs by the crown-of-thorns starfish, *Acanthaster planci*, little is known about the starfish's ecology and behaviour. We publish here reports of its population density in the Pacific Ocean, and studies of its locomotory and feeding behaviour in the laboratory.

Densities of *Acanthaster planci* in the Pacific Ocean

THERE have been widely publicized reports of damage to coral reefs by *Acanthaster planci* (Linnaeus), the crown-of-thorns starfish[1–4]. Between December 1968 and April 1970 I studied, by diving, the occurrence and abundance of *Acanthaster planci* on eighty-three widely distributed coral reefs in the Pacific (Table 1). Many dives were made on reefs of Australia's Great Barrier Reef complex, including some reefs previously surveyed[3].

Acanthaster was recorded as common if more than five specimens were seen in a 20 min dive, and as scarce if there were between one and five specimens. None was found on 81 per cent of the reefs visited, which included twenty-one reefs on the northern section of the Great Barrier Reef (between Thursday Island and Lizard Island). On 14 per cent of the reefs the starfish was recorded as "scarce". I found denser populations on John Brewer and Lodestone Reefs off Townsville and two patch reefs in Fiji, but none of these populations attained the level which Pearson described[5] as an "infestation" (that is to say, more than forty starfish counted during 20 min of searching).

Accounts of "plague" densities have suggested that they are a new phenomenon following human interference with

the environment[3,4,6,7], but Mortensen[8], who studied *Acanthaster planci* in the Java Sea in 1929, wrote in 1931: "This species was found rather commonly on the coral reefs at the little island of Haarlem off Batavia, near Onrust . . .". It seems quite probable that Mortensen's record of "common" might have been applied to the modest densities which constitute plagues, according to the criteria established by Endean[2] and Pearson[5]. It has been widely held that Green Island experienced the first known plague on the Great Barrier Reef in 1960, but an experienced professional diver from Townsville, D. Tarca (personal communication and *Sunday Mail*, September 7, 1969), recalled that there were large numbers on the south-east side of Lodestone Reef in 1954. I have spoken to fishermen in the Solomon Islands who recall large concentrations of them many years ago. It was said of Maringe lagoon, Santa Ysabel, that night-time fishing on the reef was especially hazardous about forty years ago, because of the numbers of *Acanthaster* then. The recent outbreak of reports about *Acanthaster* may perhaps be explained by great public attention and increases in the numbers of divers rather than of starfish.

The suggestion that plague populations result from removal by human shell collectors of the natural predator, *Charonia tritonis* (Linnaeus)[3], seems unlikely to be supported by further research. Although this large gastropod occasionally preys on *Acanthaster*[3,4,6] it usually prefers *Linkia laevigata* (Linnaeus), a starfish which is normally much more abundant than *Acanthaster*. Given an unlimited supply, one *Charonia* attacked only one *Acanthaster* in six days, and several of the victims escaped with the loss of a few arms[4].

Another form of interference suggested is that mechanical damage, by blasting or dredging, leaves large areas of dead coral on which *Acanthaster* larvae can settle, without being engulfed by the plankton-feeding coral polyps, establishing "seed" populations that may develop by further breeding into plagues[4]. It seems well established that metamorphosis of echinoderm larvae can be delayed until they discover an area suitable for settlement[9] and the older photonegative larvae[10] may be expected to visit the bottom repeatedly, while being carried by water currents for several days. It is less clear, however, that the searching larvae are vulnerable to predation by coral. If they are photonegative, it is probable that most of their searching is carried out during daylight, when the coral polyps are not feeding. The shaded crevices of coral reefs offer many suitable surfaces for settlement, such as dead coral, shell fragments and algal-encrusted stones, which are free from filter feeders and would provide for the attachment of brachiolaria larvae and the protection of young metamorphosed starfish. Mechanical destruction of coral would seem to be unnecessary for the survival and metamorphosis of *Acanthaster*, and might be unfavourable through reducing the available food. It does not necessarily follow, moreover, that a localized "seed" population of adults would result in heavy settlement of larvae, for the larvae have a planktotrophic life of considerable duration, during which they must be widely dispersed.

Mortensen[8] reared the larvae of *A. planci* for sixteen days, by which time they had reached the brachiolaria stage, indicating that the pelagic life lasts at least two or three weeks. The great variations in abundance of *A. planci*, including occasional plagues, may therefore result from the vicissitudes of life in the plankton. Such variations are to be expected and have often been recorded in invertebrates having a long planktotrophic stage[10]. We are probably observing natural fluctuations in the population of an animal which appears to be one of the main predators of coral. There is no real evidence to support the view that human interference is affecting the phenomenon to any extent. The greatest toll on *Acanthaster* is likely to be from pelagic predators. Endean[2] mentions that reef fishes have been observed to consume the eggs. During the breeding season of *A. planci* in Queensland waters (December 20 to January 20 (ref. 2)) there are abundant ctenophores, medusae and other plankton predators in the area of the Great Barrier Reef. This is the season for mackerel fishing and for peak abundance of other plankton feeding fish.

I thank the Rotary International Foundation for a travelling fellowship, Professor C. Burdon-Jones for extending to me the facilities of the School of Biological Sciences at the James Cook University of North Queensland, where I was based for one year as a postgraduate research student, and Professor E. W. Knight-Jones for helpful discussions of this problem.

Locomotory Response of *Acanthaster planci* to Various Species of Coral

THE crown-of-thorns starfish, *Acanthaster planci*, which consumes coral tissues[1,2], is destroying coral communities in widespread localities in the Pacific[3–5].

During a recent survey in Micronesia we noted that some corals survive better than others in the face of starfish attack. Some aspects of the physiological basis of selective predation were subsequently investigated. We here describe the locomotory response of *Acanthaster planci* to certain species of coral.

Four starfish were used in experiments carried out in a large shallow aquarium. Trials were mostly conducted in the late evening and early morning when the animals were most active. A starfish was turned on to its aboral surface and a stiff wire screen suspended horizontally above it. Such a starfish invariably pulled itself on to the underside of the screen and walked across it. In this position, numerous tube feet projected through the screen, allowing pieces of coral to be held where the tube feet would encounter them. Pieces of coral were also placed on top of the screen in the path of a walking starfish. The responses of the tube feet to various species of coral are summarized in Table 1.

Although there were wide differences in response to different coral species, the reactions to any given coral were consistent, and usually of one type (I–IV), with all the tube feet responding in the same manner. Certain corals elicited more than one kind of response in different tube feet at the same time. This may have been caused by local variations in the surface of the coral. The starfish reacted more strongly to the calicinal side of *Pavona frondifera* than to the acalicinal (living) side. Except for *Porites* (*Synaraea*) *iwayamaensis*, the tube feet formed strong attachments to the washed skeletons of all corals tested. It is therefore probable that the withdrawal reaction is a response to living coral tissue.

To test the effect of tentacular nematocysts on the reaction of the tube feet, the octocorallian *Heliopora coerulea* and the scleractinian *P.* (*S.*) *iwayamaensis* were induced to expand by placing then in cold sea water and

then returning them to normal temperatures. When tube feet touched these corals, there was a much more rapid withdrawal than occurred with the same colonies in the contracted state. From this we conclude that nematocysts are an important factor in the withdrawal of tube feet.

Corals, such as *P.* (*S.*) *iwayamaensis*, which produced a weak reaction in an unfed *Acanthaster planci*, provoked an immediate response after the starfish had fed for several hours. Thus satiety in the starfish may potentiate the withdrawal reflex.

Similar withdrawal responses were seen when corals were placed in the path of a starfish moving over the bottom of the aquarium. The tips of the arms on the advancing half of the animal were curled up, their terminal tube feet extended and performing exploratory motions. When an obstacle was encountered, the arm or arms involved reared back, and the larger, more central podia brought to bear on it. In this way, the starfish climbed over the obstruction. If the obstacle were a living coral, this reaction was modified, the tube feet touching the coral being withdrawn and the ambulacral grooves often closed. The arms involved curled back as the animal advanced. If about to feed, the starfish will mount the coral with minimal use of the tube feet, gaining purchase with its heavy spines. Mounting was due chiefly to muscular action of the arms. Starfish not about to feed may simply climb over the coral, if it is small. If, however, the terminal tube feet continue to encounter living coral as the arms rear up, then the coral is skirted with the arms held back (Fig. 1).

The responses of the extruded stomach to mechanical and other stimuli were examined by pulling two starfish from the corals on which they were feeding. The gastric folds were then prodded with pieces of *Pocillopora* and *Acropora*. Localized contractions of the muscles in the gastric folds were seen. Similar contractions were produced by prodding with a blunt rod. But gentle stimulation with a sharp needle caused larger responses. Thus we conclude that the stomach is less sensitive to the nematocysts than are the tube feet.

Field observations suggest that some coral species are more likely to survive than others in the face of moderate to heavy *Acanthaster* predation. For example, the hydrozoan *Millepora* and the octocorallian *Heliopora*, and, among scleractinians, large heads of *Porites*, particularly *P. lutea* and *P.* (*S.*) *iwayamaensis*, predominate on reefs devastated by *Acanthaster*. There is also evidence that large heads of *P. eydouxi* (personal communication from T. F. Goreau) and some *Galaxea* are less likely to be eaten than other such corals.

Table 1. REACTIONS OF THE TUBE FEET OF *Acanthaster planci* TO CONTACT WITH VARIOUS SPECIES OF CORAL

Coral[7]	Touch		Walking	
	Living coral	Washed coral skeleton	Living coral	Washed coral skeleton
Pocillopora eydouxi	I (7)	V (1)	I (4)	V (1)
Pocillopora damicornis	I (1)	—	I (1)	—
Acropora formosa	I–II (7)	V (1)	I–II (4)	V (1)
Acropora hyacinthus	II (1)	V (1)	II (1)	V (1)
Porites (*Synaraea*) *iwayamaensis*	III–IV (6)	IV (3)	III–IV (4)	IV (3)
Porites lutea	III (5)	V (1)	III (3)	V (1)
Porites andrewsi	I (3)	V (1)	I (3)	V (1)
Pavona frondifera (oral surface)	I–II (4)	—	—	—
*Millepora platyphylla**	I–IV (1)	V (1)	I–IV (1)	V (1)
*Millepora tenera**	IV (2)	V (1)	IV (3)	V (1)
Heliopora coerulea†	I–IV (2)	V (1)	I–IV (2)	V (1)

The grades of reaction are: I, instant retraction when the tube foot contacted the coral surface; II, exploration of the coral surface followed by rapid retraction; III, exploration, placement of adhesive disk, followed by rapid retraction; IV, exploration, placement of disk with weak adhesion to the coral, such that the tube feet were not broken when the substrate was pulled away; V, exploration, placement of disk with strong adhesion to the coral such that the tube feet were stretched and often broken when the substrate was pulled away. Reactions are of tube feet encountering coral held above the wire screen (touch), and corals placed on the screen in the path of a moving starfish (walking). The numbers in parentheses represent the number of days on which a given species of coral was tested. On each occasion a freshly collected specimen of coral was used.

* Hydrozoa, Milleporina.
† Anthozoa, Octocorallia.

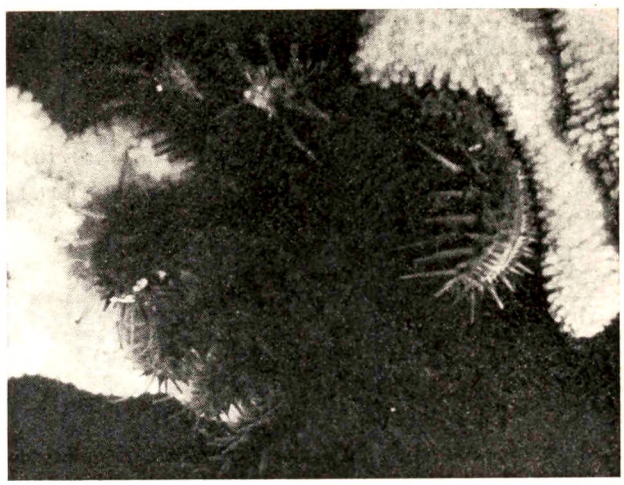

Fig. 1. Photograph showing *Acanthaster planci* walking between two pieces of *Pocillopora damicornis*. The living coral on the left has stimulated an avoidance reaction in one arm which is held back from the coral with the ambulacrum closed. The starfish is using its tube feet to climb over the washed coral skeleton on the right of the photograph.

Acanthaster planci feeds by everting its stomach through the mouth, and spreading the gastric folds over the coral surface by means of the tube feet[6]. The nematocysts seem ineffective against the stomach, but very effective against the tube feet. The peculiar humped position often observed in *Acanthaster* feeding on corals may arise from the necessity to keep tube feet away from the coral tissue while the stomach is being extended. Spreading by means of the tube feet suggests that it may be difficult for the starfish to insert its stomach into crevices. Corals growing in crevices, such as *Galaxea*, are to a certain extent protected. Furthermore, in the clefts often present in massive corals, areas of tissue often survive attack. This was particularly evident in *Platygyra lamellina*.

When climbing a coral, the starfish uses its arms and spines as much as possible. The branching staghorn coral, *A. formosa*, in spite of its strong defence mechanism, is more easily mounted than the smooth massive growths of *P. lutea*, which has weaker defences. The size of the polyps, and their arrangement in the skeleton, may be important, both in the localization of nematocysts and in the accessibility of tissue for digestion. For example, in the hydrozoan corals, most of the tissue is within the skeleton, and the nematocysts are concentrated in dactylozooids which present a formidable defence when they emerge. In addition, some corals, such as *P.* (*S.*) *iwayamaensis*, seem to be more palatable than others[6,7].

None of the resistant corals is immune from attack, but experiments described here and in the following letter[6] indicate that physiological factors, such as hunger and the time of day, affect the ability of the starfish to overcome the defences of the coral.

We acknowledge the advice and help of the late Professor T. F. Goreau in the preparation of the manuscript. The work was partially supported by the US Department of the Interior and the Office of Naval Research.

Triggering of the Stomach Eversion Reflex of *Acanthaster planci* by Coral Extracts

RECENT observations of *Acanthaster planci* populations in Micronesia suggest that the animal may eat certain corals in preference to others. The starfish feeds by everting its stomach and applying it to the coral surface. Neither the stimuli evoking stomach eversion nor the mechanism by which the stomach is applied to the coral surface has been described (see Figs. 1 and 2 for explanations of the structure of *Acanthaster*).

The behaviour of *Acanthaster* in aquaria was studied: within a few hours this starfish, like a number of other asteroids[1,2], moved on to the glass side of the aquarium. It is thus possible to observe the activities associated with feeding, without disturbing the animal.

"Extracts" of coral tissue were prepared by scraping the coral surface, by crushing and grinding pieces of skeleton, or by washing off the tissue with a jet of seawater. Although each type of extract produced much the same reaction in the starfish, the latter method was used because it produced the least crude preparation. Standard "extracts" were prepared by repeatedly squirting the same 5 ml. of seawater at ten different spots on the surface of the coral. The extracts were rather viscid because of the production of mucus by the corals. Under the microscope, such extracts were seen to include zooxanthellae, cell debris, including discharged and undischarged nematocysts, and skeletal fragments. Extracts were presented to the starfish along an inter-radius, through a blunted 6 inch hypodermic needle, insinuated gently between the animal and the aquarium wall. The tip of the needle was slightly bent so that the extract could be directed into the oral region.

The injection of coral extracts into the mouth of the starfish resulted in highly reproducible responses that are distinct from the minor responses produced by similar injections of seawater (see Table 1 and Figs. 3 and 4).

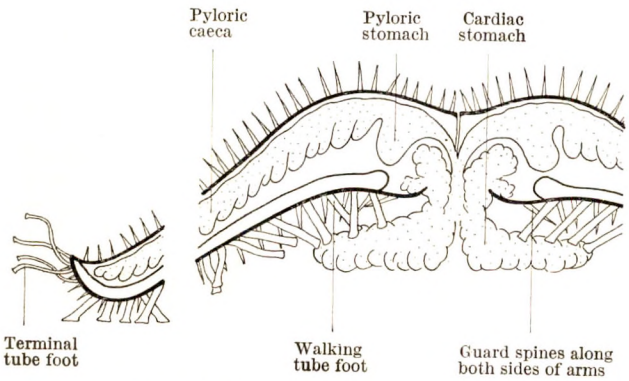

Fig. 1. A much simplified diagram of a section through the central disk and one arm of an *Acanthaster planci* everting its stomach. The mouth is distended and its guard spines held back. The aboral side of the disk is depressed and the whole disk is raised above the substrate as the cardiac stomach is everted through the mouth and then spread out by the tube feet.

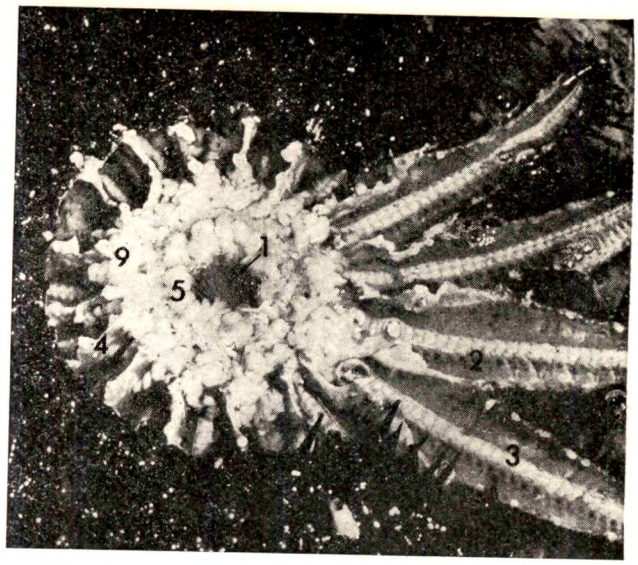

Fig. 2. Aboral dissection of *Acanthaster planci*. The roof of the central disk, and of four arms, has been removed to expose the folds of the cardiac stomach (5) and the pyloric stomach (4) surrounding it. The pyloric stomach gives off a pouch or caeca into each arm. These caecae have been removed from the dissected arms to show their skeletal elements, the ambulacral ossicles (3) and the balloon-like ampullae (2) that provide hydrostatic pressure for the tube feet. Some of the spines that guard the mouth can be seen through the mouth, at the centre of the disk (1). When the cardiac stomach is everted through the mouth, these spines are moved out of the way.

Extracts from *Acropora formosa* cause intense activity of the circum-oral tube feet within 1 min of introduction. During the next 2 to 4 min this activity spreads outwards along the ambulacral grooves. A widening of the oral opening occurs 5 to 7 min after injection and, at the same time, the horizontal spines bordering its margin are turned outwards, enlarging the opening further. The gastric folds can now be seen. Activity of the tube feet surrounding the mouth continues, and some of the more central ones are extended across the mouth region. Extrusion of the gastric folds is accompanied by flattening, then depression, of the aboral side of the central disk. This "lowers" the stomach to the central tube feet, which

Table 1. RESPONSE OF *Acanthaster planci* TO VARIOUS CORAL EXTRACTS

Donor species	Type of extract	Number showing response: Withdrawal —	Withdrawal +	Withdrawal ++	Stomach eversion —	Stomach eversion +	Stomach eversion ++	Stomach eversion +++
Acropora formosa	1 and 2	3	1	0	0	0	4*	0
	3	11	1	0	1	2	9*	0
Pocillopora eydouxi	3	1	3	0	0	0	2	2
	4	5	0	0	0	1	3	1
	5	0	1	2†	0	1	0	1
Porites spp.	3	0	3	5‡	6	1	1	0
Sea water	—	2	2	0	4	0	0	0

Responses were elicited by placing 3 ml. of the various extracts into the oral opening of *Acanthaster* specimens of diameter 10 to 12 inch tip to tip.

Types of extracts used: (1) scrapings of coral surface resuspended in seawater and allowed to settle for 5 min; (2) whole branch of coral (2 inches long) ground up with 10 ml. seawater and allowed to settle; (3) 5 ml. of seawater sluiced repeatedly over the coral surface as described in the text; (4) supernatant from centrifuged type 3 extract; (5) precipitate from preparation of type 4 extract, resuspended in 5 ml. of seawater. Responses were graded, to 3+ on an empirical scale.

* One animal in this series proceeded through the usual sequence of tube foot activation, to expansion of oral opening, but then moved away, still in a feeding configuration, and was found shortly afterwards feeding on a piece of coral left in the aquarium.

† One animal after a violent withdrawal reaction moved away, as though escaping from an irritating stimulus.

‡ Two experiments with type 4 *Pocillopora* extract failed to elicit withdrawal responses, but produced only ++ and +++ stomach eversions. One experiment with heat-treated type 5 extract failed to elicit either withdrawal or eversion response.

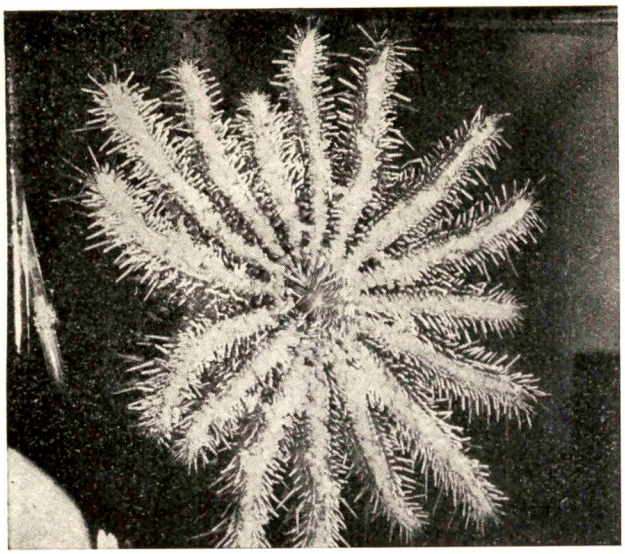

Fig. 3. A 10 inch specimen of *Acanthaster planci* in resting position on wall of aquarium. Note disposition of tube feet and position of circumoral spines covering closed oral opening.

then retract. The adhesive disks of the podia form attachments which pull on the gastric folds, spreading them out. Subsequent activity of the podia pulls and pushes the gastric folds into position until, after about 10 to 15 min, the everted part of the stomach covers an area slightly larger than the central disk. The folds seem to be extruded by hydrostatic pressure in the coelom, but observations of *Acanthaster* feeding on corals indicate that the tube feet are chiefly responsible for moulding the stomach to the contour of the substrate. The intensity of the response decreases after about 20 min, so that most animals return to the resting condition within 30 min after injection of the extract.

Extracts of *Pocillopora eydouxi* cause a similar response, but with two differences. First, there is an initial retraction of the tube feet that come into contact with the injection mass. This quickly gives way to the activity described above. Second, extracts of *Pocillopora* produce responses persisting considerably longer than those seen with *Acropora*.

Extracts from two species of *Porites* (*P.* (*Synaraea*) *iwayamaensis* and *P. lutea*) evoke a pattern of response in which tube foot withdrawal predominates. Three to five minutes after injection of such extracts, all portions of the ambulacral grooves near the mouth are closed up, and the animals remain suspended only by their "finger-tips". It usually takes 10 to 15 min for the animal to return to its original state. In two out of eight instances this initial aversive response was followed by gradual opening of the mouth and extrusion of the stomach, which in one case reached maximal extension after about 30 min.

When extracts of *Pocillopora eydouxi* are centrifuged for 20 min at 2,000*g*, the resultant supernatant is water-clear, and retains its ability to cause stomach extrusion. The response, however, appears less intense. The initial withdrawal reaction is abolished. Boiling the supernatant for 20 min does not further decrease the extrusion responses. When the sediment from the centrifugation is resuspended in seawater and given to the starfish, an initial withdrawal response is obtained, usually followed by stomach extrusion. Heat treatment of the centrifugate abolished the withdrawal reaction, but did not prevent stomach eversion.

Extracts produced by grinding up portions of the gastric folds of *Acanthaster planci* have no effect when presented to intact starfish in the aquaria, but similar extracts prepared from the pyloric caeca of the same specimen caused a strong and enduring gastric eversion response. This suggested either the storage of active components from past meals in the caecal pouches, or, possibly, the presence of chemical control substances elaborated by the animal.

There are indications that the responsiveness of *Acanthaster* to chemical evocation of stomach eversion is not constant, but varies with the physiological state of the animal. As with other asteroids, the time of day[3,4], and nutritional status[5], are two factors which give rise to such changes. Thus, during daylight hours, animals usually seem less reactive than at night, and the peak of activity seems to be between midnight and dawn. Animals not deliberately stimulated by administration of coral extract invariably are found on the aquarium walls in the resting state during the day. On the other hand, between midnight and 0200 h on four successive nights, 64 per cent of all observations of the same animals showed specimens with partly opened mouth and visible gastric folds. In a few instances, the stomach was partially everted at this time. Nutritional status likewise seems to affect responsiveness. Thus it was observed that, one day after being fed with live coral, all specimens tested responded feebly to preparations that had previously elicited marked stomach eversion. Similarly, the intensity of tube foot withdrawal increases in these circumstances[6].

Although evocation of feeding behaviour by chemical means in coelenterates has previously been described, the only comparable observations in echinoderms relate to stimulation of locomotion by extracts from prey organisms[7,8] and to the evocation of opening of the mouth by acetylcholine[9].

Two of us (R. W. B. and M. R. J.) have been able to stimulate stomach eversion in *Asterias forbesi* and in *Astropecten vulgaris* with extracts of the bivalve molluscs *Venus mercenaria* and *Crassostrea virginica*. In these cases, as well as in the case of *Acanthaster*, the active elements producing stomach eversion seem to be water soluble, heat stable chemicals of low molecular weight. The initial withdrawal response was seen only in *Acanthaster*-treated extracts of certain coral species. The active elements seem to be insoluble and heat labile. It seems likely that nematocysts are responsible, particularly as there is other evidence to indicate that nematocysts cause tube food withdrawal[6].

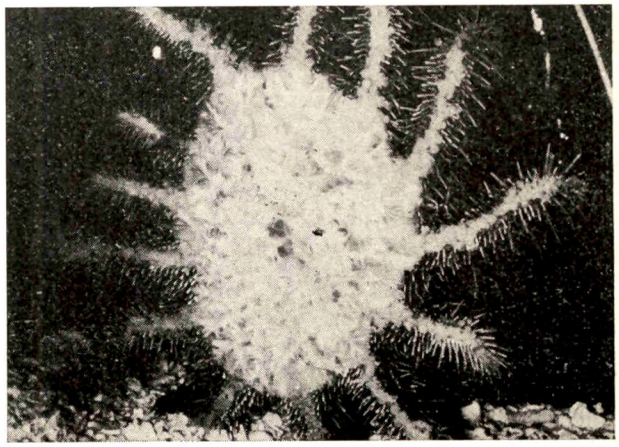

Fig. 4. Maximal stomach eversion in the specimen shown in Fig. 3 15 min after administration of 3 ml. of type 3 *Pocillopora eydouxi* extract. Note position of tube feet visible beyond edge of expanded stomach. The yellow suction disks of many other tube feet applied to the folds can be made out through the membranes. Note also the highly developed network of haemal canals within the gastric folds, corresponding perhaps to similar but smaller structures in lining of the cardiac stomach in other asteroids[10].

It is possible that there is a further factor operating so that *Acanthaster* finds some extracts more acceptable than others. *Porites* (*S.*) *iwayamaensis* has weak nematocyst defences, unlike most other corals which the starfish tends to leave alone. Thus it is significant that extracts of *P.* (*synarea*) *iwayamaensis* always evoke a withdrawal reflex[6], but seldom stomach eversion.

We acknowledge the advice and help of the late Professor T. F. Goreau in the preparation of the manuscript. The work was partially supported by the US Department of the Interior and Office of Naval Research.

Preliminary observations have been carried out to look for radio signals associated with gravitational waves. Although inconclusive, the observations from five receivers in the British Isles suggest the value of pressing on with further experiments.

Towards the end of last year, the evidence for the detection of pulses of gravitational waves[1] had reached a significance sufficient to arouse interest in many areas of astronomy and physics. It occurred to one of us (J. V. J.) that if Weber's flux were $\sim 10^4$ erg cm^{-2} s^{-1} (ref. 1) at the Earth, an exceedingly small fraction ($\sim 10^{-19}$) of this energy, which might be radiated into ~ 1 MHz bandwidth of the radio spectrum, would be detectable with the very simplest of radio antennae (a single dipole for example) and a receiver of even modest performance. This suggestion, made casually at a meeting in Cambridge, was immediately taken up by the Mullard Radio Astronomy Observatory. It was realized that the detection of isolated radio pulses, of say a few per day, in the presence of man-made interference, lightning or other geophysical phenomena, required simultaneous observations at widely spaced sites. It was further realized that observations at two or more frequencies could in principle provide valuable evidence as to whether any events observed were galactic in origin, for the interstellar plasma would cause dispersion. Any such events need not, of course, necessarily be associated with gravitational pulses but could originate, for example, in supernovae explosions[2] or in the rather energetic events which Scargle and Harlan[3] suggest are responsible both for the wisp activity and the pulsar spin-up in the Crab nebula. It may be of relevance that coincident radio pulses have already been observed, on a baseline ~ 150 km and during hours of darkness, in the course of early work[4] on scintillation phenomena; as far as we know, these events have not been explained and further events of this type might easily have been overlooked in the course of subsequent radio astronomical investigations.

We are here reporting some preliminary observations which have been carried out simultaneously with receivers sited at five locations distributed over England, Scotland and Ireland, covering a range of baselines between 110 and 500 km. These sites are shown in Fig. 1. At 151 MHz all five sites were equipped with almost identical systems. Each station had two half-wave dipole antennae mounted on the ground, 5λ apart, approximately $(\lambda/4)$ above a metal ground plane on an EW-baseline; they operated as phase-switched interferometers[5]. Bandwidths varied

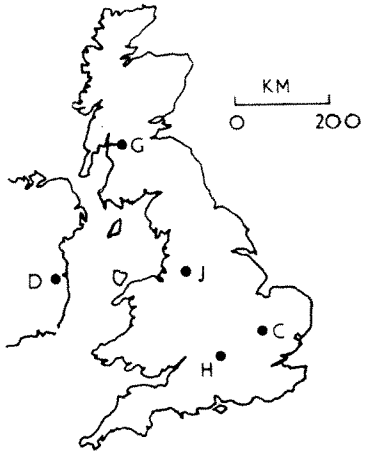

Fig. 1. Location of the observing stations. C, Cambridge (151, 81 MHz); D, Dublin (151, 70 MHz); G, Glasgow (151, 81, 47 MHz); H, Harwell (151 MHz); J, Jodrell Bank (151, 45 MHz).

among the stations, between 200 kHz and 1·5 MHz, and integrating time constants of between 0·3 and 1·0 s were used. The central lobes of these five interferometers were aligned to account for the differences in geographical longitude. Recordings were made on chart paper at speeds ranging between 6 inch and 24 inch per hour, and time marks enabled an accuracy ranging from ±24 s to ±6 s to be attained for the times of the recorded events. Similar interferometers at lower frequencies also operated at certain stations as noted in Fig. 1. Most of the stations were operating by January 1, 1970, and the observations have been analysed until the end of May.

Many two-fold and multiple coincidences were obtained from the outset, but it soon became apparent that most of these were occurring during daylight hours and were attributable largely to Type III solar bursts. We therefore use in the analysis only events which occurred between sunset and sunrise.

At all stations, occasional pulses of radio emission were observed at a rate of a few per night and with durations ranging up to several minutes. To avoid making any prior assumptions about the likely intrinsic duration of any interesting radio "event" or its dispersion through the receiver bandwidth, all such bursts of radio emission were classified as "events". The only acceptance criterion applied was that each burst should exceed three times the normal "peak-to-peak" noise level in the records. This corresponded to a minimum detectable flux density $\sim 10^{-18}$ ergs cm^{-2} s^{-1} Hz^{-1} per cent.

The times of the events recorded at the five individual stations at 151 MHz have been compared for evidence of the simultaneous observations of the same event at two or more stations. Coincidence resolving times of 1 min and 20 s have been used, these values taking account of the accuracy of timing and also the possibility of slight differences of arrival times at the five stations. These could arise from interstellar dispersion and the fact that the central frequencies of the receivers were not all precisely the same, on account of local interference problems. A dispersion measure $DM = \int n_e \, dl$ of 400 cm^{-3} pc, for example, produces a frequency sweep rate of 1 MHz s^{-1} at 151 MHz; this dispersion measure is about the highest

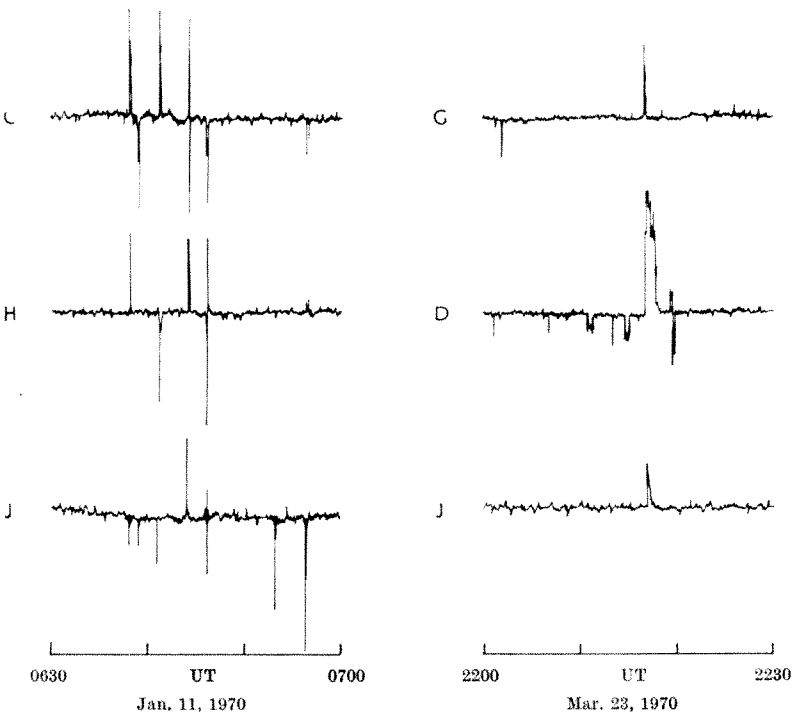

Fig. 2. Tracings of interferometer records for the three stations involved in two of the "triple-coincidence" events.

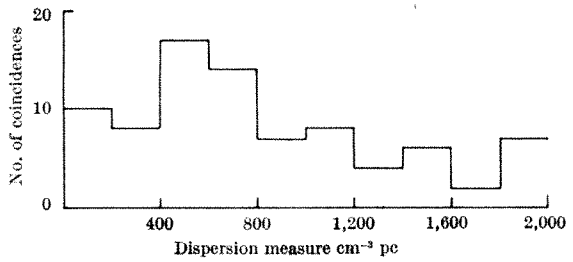

Fig. 3. Histogram of delayed coincidences as a function of dispersion measure.

so far observed for any pulsar[6]. The numbers of two-fold coincidences expected to occur by chance were estimated by a similar intercomparison of the times of events at pairs of stations, when the times of events at one station were delayed by 3 min. In this way, allowance could be made for the very variable single-station counting rates and occasional operating failures at individual stations.

During five months of operation, some seventy-two "prompt" two-fold coincidences were observed within a 1 min resolving time, compared with forty-seven "delayed" coincidences. When the coincidence resolving time was reduced to 20 s, these numbers fell to thirty-five "prompt" and twenty-two "delayed" coincidences. The numbers of "prompt" two-fold coincidences are thus barely distinguishable from those expected by chance.

Five "prompt" coincidences occurred between three stations, however; these twice involved sequences of more than two pulses. Examples are shown in Fig. 2. Inspection of these three-fold events suggests that they are not attributable to a distant source, for (i) the precise pulse shapes differ at the individual stations and (ii) the polarity changes in the pulse sequence are inconsistent with the motion of a celestial source through the interferometer lobes. It is also significant that no four or five-fold coincidences have ever been observed. The 151 MHz data alone have therefore not so far yielded any evidence for radio pulses of extraterrestrial origin.

Recordings at the other frequencies have been scrutinized for evidence of delayed pulses. The technique used has been to assume a particular value of DM, compute the radio pulse delays expected at different frequencies and then, starting with event times recorded at the highest observing frequencies, look for corresponding events at the appropriate delay at lower frequencies. A computer program performs this analysis for successive increments of 25 in values of DM up to 2,000 electrons cm^{-3} pc. In this way, a plot of "delayed coincidences" versus DM is obtained and any contribution of genuine radio pulses from a source at a particular value of DM appears as a peak on this distribution. The results of this analysis are shown in Fig. 3. There is seen to be an excess in the region $DM \sim 600$ cm^{-3} pc. Although this has a statistical significance of about 1 per cent if it is assumed that the data of Fig. 3 follow a Poisson distribution, we feel that further observations are required before the excess can be regarded as convincing. Such a value for the dispersion measure would not be wildly unreasonable, however, for a source at the galactic centre[7] on the basis of an assumed mean interstellar electron density of 0·06 cm^{-3} (ref. 8) and a distance of 10 kpc. Higher values of DM, on the other hand, might be difficult to observe with the present equipment

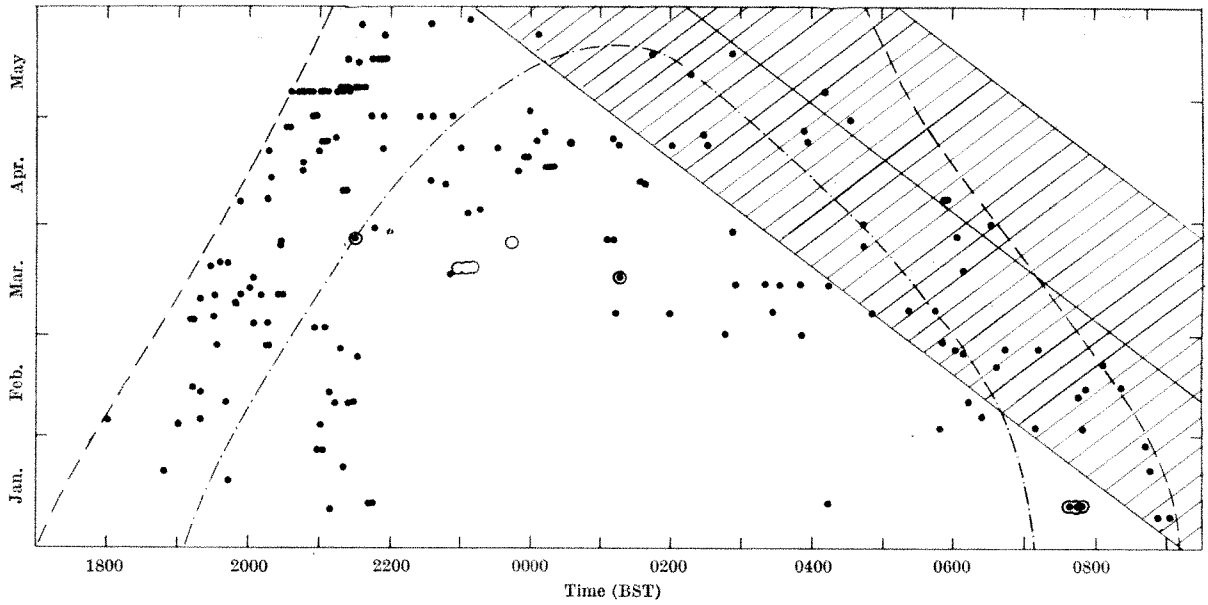

Fig. 4. The distribution of 151 MHz event arrival times during the hours of darkness for one station. ●, Events; ○, triple coincidences; - - -, time of sunrise and sunset; · · · · ·, start or end of astronomical twilight; ———, transit time for galactic centre. The shaded area indicates when the galactic centre was above the horizon.

because of increase of the pulse length at the lower frequencies.

Weber's latest investigations[7] indicate that his gravitational events probably originate in the direction of the galactic centre which, because of its low maximum elevation ($< 10°$) at our latitudes, was not favourably placed for our simple dipole antennae. For this reason, four of the existing stations, and a fifth on Malta, have now been equipped with suitably orientated directional antennae specifically designed for galactic centre observations. This new program commenced in May but no results are yet available. We understand that Drs Partridge and Ruffini of Princeton are carrying out similar galactic centre observations at microwave frequencies.

Although unlikely to be astronomical, the origin of the coincident events and of most of the individual events is of interest. In general, the rate of events was found to be greatest for a few hours after sunset or a few hours before sunrise (Fig. 4). While some events undoubtedly originate in local interference, particularly in the evening, this is unlikely to be the explanation of the high pre-dawn rate. The cause of these increased rates is not at present understood, although ionospheric scattering of solar bursts, or reflexion of terrestrial signals by meteor trails, are possibilities. The occurrence of coincident events does not correlate in any obvious way with electrical storms, unusual geomagnetic activity, meteor showers or transits by man-made satellites. Further observations designed to clarify the nature of this phenomenon are in progress.

We thank Sir Martin Ryle for his helpful suggestions and enthusiastic encouragement. Work carried out in University College, Dublin, was partially supported by a US Air Force grant.

Contribution to the Co-rotating Magnetic Field Model of the Pulsar

by

V. G. ENDEAN
J. E. ALLEN

Department of Engineering Science, Oxford

A new general solution of the electromagnetic field equations convenient for rotating field problems is used to analyse the case of low plasma number density. Two localized pulse emitting regions rotating with the star at approximately twice the velocity of light radius are predicted.

RECENT observations[1,2] of the polarization of the radio pulses from pulsars lend qualified support to the idea of a co-rotating magnetic field as proposed by Gold[3] and discussed by several authors[4–8]. Gold[4] has shown that radio frequency radiation from the Crab pulsar is much too small to explain its observed rate of slowing down and has suggested that loss of relativistic gas from the star's magnetosphere constitutes the principal cause of drag torque. Pacini[5] pointed out earlier that radiation of the rotating dipole into a vacuum produces the right order of magnitude for drag torque. He dismissed then the possibility that even approximate vacuum conditions could prevail, although he and Rees[8] have now qualified this assertion. Ostriker and Gunn[6] have shown that the measured rate of slowing down of the Crab pulsar, its present age and the estimated energy supply to the surrounding nebula are all in very good agreement with the attribution of the pulsar energy loss to dipole radiation

into an approximate vacuum. We analyse the case where the plasma number density is low, by which we mean $\lesssim 10^{19}$ m^{-3} in the case of the Crab pulsar. This leads to straightforward electrodynamics. It provides simple explanations of the transmission of energy from the pulsar to the surrounding nebula, and of many features of the structure of both optical and radio pulses. In particular, it predicts that there should be two localized emitting regions, a feature that has not so far been explained. They are located approximately two velocities of light radii away from the star and on opposite sides of it. We start by giving our own solution of the field problem which presents the results in a form more amenable to the subsequent analysis.

In the stationary coordinate system orientated on the rotation axis of the star, Maxwell's equations apply with no complications of a general relativistic nature. Provided that approximate vacuum conditions apply, and we justify this retrospectively, spatial homogeneity may be assumed and the field problem then reduces to solving the complex vector Helmholtz equation

$$\nabla^2 \boldsymbol{A} + k^2 \boldsymbol{A} = 0 \tag{1}$$

where $e^{i\omega t}$ time variation has been assumed, $\boldsymbol{A}$ is a solenoidal vector which may be either the electric or the magnetic field and k is the complex wave number for the medium. We solve the equation in spherical polar coordinates as follows. (i) Write it out in cylindrical polar coordinates (ρ,φ,z). (ii) Remove the simultaneity by introducing

$$A_1 = (A_\varrho + iA_\varphi); \quad A_2 = (A_\varrho - iA_\varphi) \tag{2}$$

(iii) Transform to spherical polar coordinates (r,θ,φ) retaining the field quantities A_1, A_2, A_z. (iv) Separate variables. This yields the general solution

$$\begin{matrix} A_1 \\ A_2 \\ A_z \end{matrix} = \sum_{m,n} \begin{matrix} 1 \\ 2 \\ z \end{matrix} C^{z}_{mn} j_n(kr)\, P_n^{\begin{matrix} (m+1) \\ (m-1) \\ m \end{matrix}} (\cos\theta) e^{i(m\varphi + \omega t)} \tag{3}$$

where the Cs are constants, the js spherical Bessel functions, and the Ps associated Legendre functions. This solution is particularly suitable for simple rotating fields $(m = 1)$. The solenoidal condition has to be applied, but as the curl of any solution is also a solution, this poses no great difficulty.

For the case of the magnetic dipole orientated at right-angles to and rotating about the polar axis, we reject the spherical Hankel function corresponding to the advanced solution which is non-physical and retain the retarded solution, so that the full field becomes

$$\begin{aligned} E_\theta &= \frac{M\omega}{4\pi r^2}\,(kr - i)e^{i(\varphi + \omega t - kr)} \\ E_r &= 0,\ E_\varphi = i\cos\theta\, E_\theta \\ H_\varphi &= \frac{M}{4\pi(\mu_0 r^3}\,((kr)^2 - ikr - 1)\, e^{i(\varphi + \omega t - kr)} \\ H_r &= \frac{2\sin\theta}{\omega\mu_0 r} E_\theta,\ H_\theta = -i\cos\theta\, H_\varphi \end{aligned} \tag{4}$$

where M is the dipole moment and the real part of the solution is understood. The drag torque on the dipole may be obtained by computing the Maxwell stresses over a sphere centred on the origin, E_r is zero, so only the tension associated with the H-field contributes and the torque T is given by

$$T = \underset{r\to 0}{\text{Limit}} \int_0^{2\pi}\int_0^{\pi} \mu_0 H_r H_\varphi r^3\, d\varphi \sin^2\theta\, d\theta \tag{5}$$

Assuming k is real, most of the terms vanish identically or over the φ integration and the result is

$$T = \frac{M^2}{6\pi\mu_0} k^3 \tag{6}$$

The same result can be obtained by computing the radiated power and dividing by the frequency, but this method emphasizes that there is a real drag torque on the dipole. The radiation component of (4) agrees with Deutsch's result[9]. The intermediate field produces little complication. If there is a time independent axi-symmetric component of the field, it has no radiation associated with it and no electric field in the rest coordinate system. Its magnetic field can be linearly superposed on equation (4). It can be seen by inspection that the field lines are static in the rotating coordinate system. The rotating magnetic field lines in the plane $\theta = \pi/2$ are shown in Fig. 1. In the case of the Crab pulsar, M is estimated as 10^{21} Wb.m., ω $(= kc)$ is 60 π s^{-1}, and using equation (6), $T \sim 10^{29}$ Nm and the radiated power $\sim 2 \times 10^{31}$ W. These figures show good agreement with the experimental evidence[6]. If it could be assumed that the moment of inertia of the star and its dipole moment remained constant in time, then equation (6) would predict that the rate of slowing down was proportional to the cube of the frequency. The star is expected to change shape, however, and variations from this law are therefore expected. It can also be concluded from considerations of Maxwell stress that if the magnetic dipole is not perpendicular to the rotation axis, the torque vector remains at right-angles to the dipole and co-planar with the dipole and the rotation axis. This may tend to align the dipole with the rotation axis, depending on the mechanical properties of the star, and such alignment would decrease the slowing down rate[10,11].

It is now necessary to explain why the plasma should be very nearly transparent. For any solenoidal field in which the φ dependence is $e^{i\varphi}$ it may easily be shown that

$$\nabla \times (r \sin\theta\, \hat{\varphi} \times \boldsymbol{A}) = -i\boldsymbol{A} \tag{7}$$

The plasma will be in equilibrium, neglecting gravitational and inertial effects, provided its motion is such that

$$\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B} = 0 \tag{8}$$

Inside the velocity of light cylinder, synchronous rotation of the plasma is one possibility, and using equation (7)

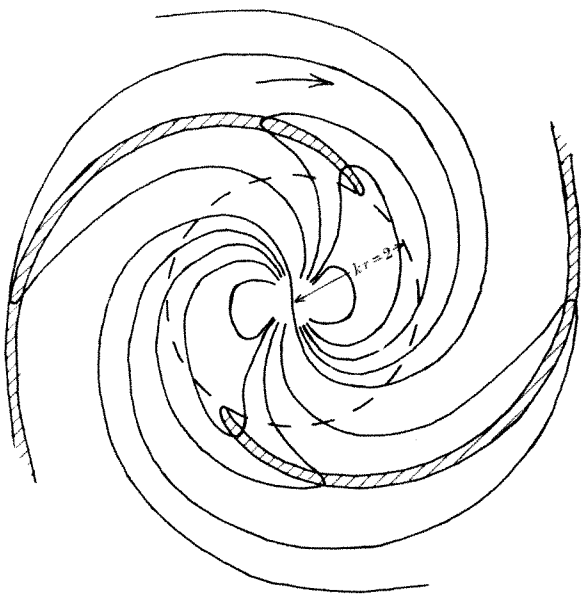

Fig. 1. Rotating magnetic field lines in the plane $\theta = \pi/2$. The plasma disk rotates at half synchronous speed and becomes relativistic near the radius $kr = 2$. It is only when the shaded zones pass through the plasma outside this radius, however, that it is forced to become highly relativistic. It is proposed that the leading edges of the zones are the pulse emitting regions.

it may easily be shown that this does ensure

$$\nabla \times (\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B})=0 \qquad (9)$$

To satisfy equation (8) completely, however, a space charge density σ is required such that

$$\sigma = -\varepsilon_0 \nabla \cdot (\boldsymbol{v}\times\boldsymbol{B}) = 2\omega\,\varepsilon_0 B_z \qquad (10)$$

where terms of order $(v/c)^2$ have been neglected. Equilibrium is thus possible provided there are enough charged particles to satisfy equation (10). The number density required near the surface of the star is $\sim 10^{19}$ m^{-3}. A charge redistribution similar to equation (10) is also required by an axi-symmetric component of magnetic field[12]. There is little doubt that such a co-rotating equilibrium region will exist. Assuming that the number density is $\lesssim 10^{19}$ m^{-3}, however, its boundary will be close to the nominal surface of the star, simply because of a shortage of charged particles. We demonstrate below that for this case, the number density in the remainder of the magnetosphere will then be very low, except near an equilibrium surface, because all charged particles, except those near the equilibrium surface, will be attracted to the co-rotating region. This being the case, the free space field solution (4) will be approximately valid outside the co-rotating region, with the minor qualification that the charges required by equation (10) mean that the pure magnetic dipole source is supplemented by an electric quadrupole source with a negligible effect on the field beyond the immediate vicinity of the co-rotating region.

In order that equation (8) should be satisfied, a necessary condition is

$$\boldsymbol{E}\cdot\boldsymbol{B}=0 \qquad (11)$$

This quantity is Lorentz invariant, and it is sufficient, therefore, to calculate it in the rest coordinate system. Outside the co-rotating region, the solution (4) applies and

$$\boldsymbol{E}\cdot\boldsymbol{B} = -\frac{M^2\omega\cos\theta}{(4\pi)^2 r^5} \qquad (12)$$

which is an elegant result independent of φ and t. In the plane $\theta=\pi/2$, equation (11) is satisfied. For $\theta<\pi/2$, $\boldsymbol{E}_{\parallel}$ is always opposite in direction to $\boldsymbol{B}$. For $\theta>\pi/2$, $\boldsymbol{E}_{\parallel}$ is always in the same direction as $\boldsymbol{B}$. But all magnetic field lines are closed loops passing through the co-rotating region and none cross the plane $\theta=\pi/2$. Thus charged particles not in the plane $\theta=\pi/2$ cannot be in equilibrium. Most particles will be accelerated rapidly along their field lines until they reach the co-rotating region, although some may be deposited in the plane $\theta=\pi/2$ or escape from the magnetosphere altogether. If an axi-symmetric magnetic field is present the surface satisfying equation (11) becomes fixed in the rotating coordinate system, inclined at an angle to the $\theta=\pi/2$ plane, and no longer a plane for large kr. Nevertheless it still exists and the argument remains substantially unchanged.

Continuing the analysis for the case of no axi-symmetric magnetic field, application of equation (8) to particles in the plane $\theta=\pi/2$ yields

$$E_\theta + \mu_0 (v_\varphi H_r - v_r H_\varphi) = 0 \qquad (13)$$

and this is satisfied by $v_r=0$, $v_\varphi=-r\omega/2$, that is, by rotation of the particles at half the synchronous speed. Clearly, not only is equilibrium possible in this plane, but also relativistic speeds are not required until kr reaches ~ 2, when equation (13) is no longer valid.

Outside the circle defined by $kr=2$, it is appropriate to examine the formula for $\boldsymbol{v}$

$$\boldsymbol{v} = \frac{\boldsymbol{E}\times\boldsymbol{B}}{B^2} + \frac{(\boldsymbol{v}\cdot\boldsymbol{B})\,\boldsymbol{B}}{B^2} \qquad (14)$$

obtained by taking the cross product of equation (8) with $\boldsymbol{B}$. The second term is simply the component of velocity along the instantaneous direction of $\boldsymbol{B}$ which is left unspecified by both equations (8) and (14). This formula breaks down when other forces, gravitational, inertial or reaction due to relativistic particle radiation become important. For a relativistic particle following approximately the circle $kr=2$, the synchrotron radiation reaction becomes important first, at a value of γ given by

$$\frac{e^2 r^2}{6\pi\varepsilon_0 c^4}\left(\frac{\omega}{2}\right)^4 \gamma^4 \sim er\left(\frac{\omega}{2}\right) B \qquad (15)$$

where e is the electron charge and $\gamma=(1-v^2/c^2)^{-\frac{1}{2}}$. Substituting approximate values yields $\gamma\sim 10^7$. A value of this order is required before equations (8) and (14) become invalid. (The centrifugal forces are negligible until $\gamma\sim 10^9$.) The component of velocity along $\boldsymbol{B}$ can be reduced without violating equations (8) and (14). Clearly this will happen first and will involve comparatively modest values of γ. Assuming this component of velocity is zero, equation (14) yields

$$v = \frac{r\omega}{2}\left[1+\left(\frac{H_\varphi}{H_r}\right)^2\right]^{-\frac{1}{2}} \qquad (16)$$

When equation (16) yields $v>c$, $(E>cB)$, the equation is clearly no longer valid, and the particles must become highly relativistic. Note that $E\sim 10^9$ V m^{-1} at $kr=2$. The boundary curves $E=cB$ are fixed in the rotating coordinate system and obey the equation

$$\tan(\varphi+\omega t-kr) = [kr-\{(kr)^2-4\}^{\frac{1}{2}}]^{-1} - kr \qquad (17)$$

The zones are shown in Fig. 1. Because they rotate at synchronous speed, while particles leaving the circle $kr=2$ are rotating at about half synchronous speed, many of the particles will be caught by the leading edges of the zones and concentrations of highly relativistic particles must be expected there.

Identification of the leading edges of the zones as the pulse emission regions would explain the optical observations of the Crab pulsar[13,14] on the basis of the proposed simple geometric model[14]. It also fulfils the basic requirements to explain the radio pulses. A build-up of number density sufficient to make correlated radio emission probable might be expected. The field lines in the emitting region are normal to the direction of propagation. Thus the synchrotron emission will propagate as the extraordinary mode across the field lines and produce predominantly linearly polarized radiation. The circularly polarized Whistler mode, which propagates along field lines, will find conditions unsuitable, which means that the strong pulses occurring approximately every 10^4 ordinary pulses[2] must have a different explanation.

For $kr\gg 2$, all particles encountered by the field will be accelerated to highly relativistic speeds and take energy from the field through mechanisms such as those discussed by Ostriker and Gunn[6]. The effect on the field will be to give k a small imaginary part resulting in a spatial exponential decay in the solution (4). Thus the electromagnetic momentum will not be radiated away to infinity but will be absorbed by the surrounding nebula.

Pulsar Distributions without Magnetic Decay

SEVERAL authors have recently argued for the necessity of decay of the surface magnetic field of neutron stars with a characteristic time of a few million years in order to explain the details of the observed pulsar sample. Gunn and Ostriker[1] have summarized these arguments, pointing to the three empirical pieces of evidence which imply such decay: (1) the scarcity of long period pulsars, (2) the apparent decrease in surface magnetic field with age, and (3) the decrease in pulsed radio luminosity with age.

Setti and Woltjer[2] have indicated that magnetic decay is not necessary for the explanation of the relative scarcity of long period pulsars, but have not tried to explain the other two observations. In this report we point out that the assumption of a period-dependent pulsed radio luminosity can, in fact, explain the age dependence of both the surface field and pulsed radio luminosity, although an additional assumption must be made to reconcile the model with the two observed young pulsars, NP 0531 and PSR 0833.

Gunn and Ostriker[1] have found good agreement with the observed pulsar sample by assuming that the radio luminosity is period-independent; in other words, that it is proportional to the square of the surface field only, and that this field decays with a characteristic time of a few million years. If, instead, it is assumed that the radio luminosity is a fixed fraction of the total electromagnetic energy loss rate of the rotating neutron star, such radio luminosity becomes explicitly period-dependent. In all electromagnetic models[3–5], the electromagnetic luminosity is proportional to the square of the surface field and inversely proportional to the fourth power of the rotation period. Setti and Woltjer[2] have shown that the scarcity of long period pulsars is an immediate consequence of this assumption (in fact, a rather wide range of inverse period indices will yield consistency with the observed period distribution at large periods without the additional assumption of a decaying field).

The present model can account for the other two characteristics of the pulsar sample as well. For pulsars the periods of which are much larger than their initial values, the radio luminosity is proportional to the inverse square of the product of the surface field and the age. That the radio luminosity should decrease as a function of age is an obvious consequence of this relation. A further consequence of this assumption is a selection effect for lower field pulsars as a function of age, owing to the inverse square dependence of the radio luminosity on the field. Thus, if the detection threshold is age-independent, the high-field pulsars will become unobservable at a younger age than otherwise identical low-field objects.

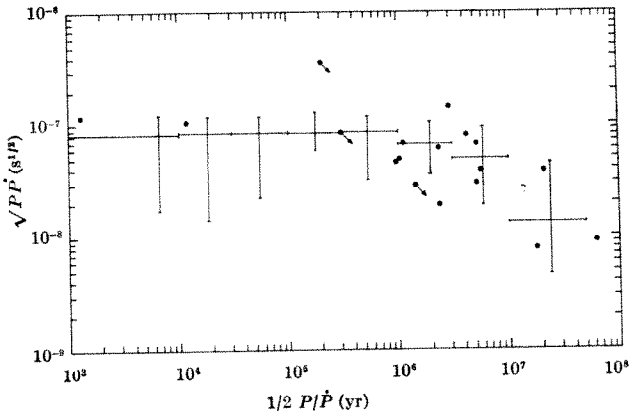

Fig. 1. Surface magnetic fields of pulsars as a function of age. The dots represent pulsars with measured P and $\dot{P}$ (ref. 6). The error bars represent the median and 1σ levels for the surface field in each age group. These quantities were computed for pulsars with random position, age and surface field in 100 trial galaxies of radius 12 kpc and thickness 200 pc. The probability distributions in position, age and surface field were uniform, with an arbitrary pulsar birth rate, and a maximum field value corresponding to $P\dot{P}=2\times10^{-14}$ s.

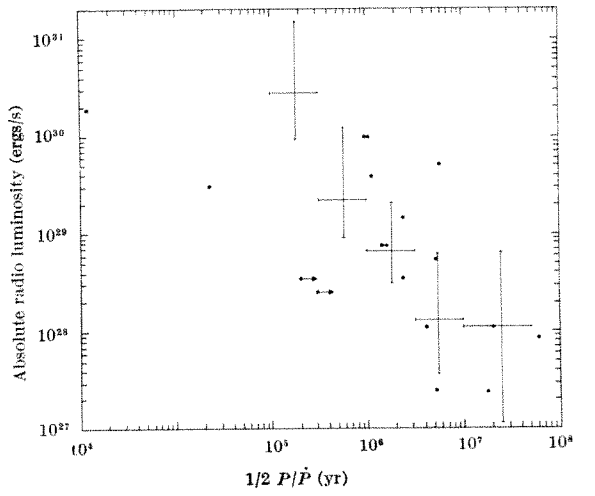

Fig. 2. Absolute pulsed radio luminosities as a function of age. The dots represent pulsars with measured P and $\dot{P}$ and the error bars represent the median and 1σ levels for the radio luminosities in each age group, based on calculations as described in the text and in the caption to Fig. 1.

In Figs. 1 and 2 we have compared quantitatively the observed pulsar sample with the consequences of this assumption. The error bars in each age group represent the calculated standard 1σ deviations from the median in 100 trial galaxies of pulsars generated at random in space, time and surface field. The pulsar birth rate and the probability of the pulsar "beam" intersecting the Earth are assumed arbitrarily to be one pulsar birth per 100

years in the galaxy, and a probability of 1/4. The observation threshold is then adjusted such that the period distribution above the maximum at $\sim 0{\cdot}6$ s is matched. The results are found to be insensitive to the birth rate and observing probability in the sense that they may both be varied substantially and the threshold adjusted such that the period distribution above $\sim 0{\cdot}6$ s is reproduced.

The calculated and observed magnetic fields agree at all ages, as they must if this model is tenable. At ages less than $\sim 10^6$ yr, however, the model predicts many more pulsars (and with higher luminosity) than the two, NP 0531 and PSR 0833, which are actually observed; this is the same problem which faced Setti and Woltjer[2] for periods below $\sim 0{\cdot}6$ s. Among the variety of possible additional assumptions which could account for both the small number of observed young pulsars and their low radio luminosity, one is particularly interesting. If, for young pulsars, the pulsar beam is extremely narrow (so that the probability for observation of the beam is much smaller than the $\sim 1/4$ assumed earlier), then we would expect to see no pulsars younger than $\sim 10^6$ yr on the beam. If also there is a roughly isotropic pulsed component four or five orders of magnitude less intense than the component on the beam, this would explain why NP 0531 and PSR 0833 (both young close pulsars) are observed at a lower intensity than expected for the pulsar beam, and why more distant pulsars which are younger (for example, the pulsars which might be associated with Cas A and SN 1572) are below the threshold of observability.

Volcano on Jan Mayen Alive Again

On September 19–20 the Beerenberg volcano on Jan Mayen Island in the Norwegian Sea (71° N, 8°–9° W) became reactivated after being dormant for several hundred years, perhaps thousands of years. Reports by whalers at sea of activity on the southern slope of the volcano in 1732 and 1818 have been subject to doubt. But steam and carbon dioxide occur in fractures, and earthquakes are common.

The present eruption was preceded for 1 or 2 days by earthquakes with epicentres which were, however, some distance to the north-east. On the morning of September 20, smoke and steam rose to 30,000 feet on the north-east flank of the volcano, apparently coming from a 5–6 km long fracture (Fig. 1) with five main parasitic crater centres. Geologists from the Norsk Polarinstitutt were rushed to the island and are observing the activity from land, sea and air. After 2 days, explosive activity decreased, but a great amount of basaltic lava continues to emerge, and cascade down the slope to build up a new coastal platform at least 500 m wide and 3·5 km long. Because most of the volcano is covered by glaciers, a great deal of meltwater has caused floods (Jökulhlaup) that have formed deltas in other places. The lava has formed a dense basaltic rock with conspicuous olivine phenocrysts up to cm size. Phenocrysts of plagioclase (An 60) occur, but these are smaller.

The geology of Jan Mayen has been studied extensively in recent years, in particular by British geologists[1]. The formation of the island was started by extensive submarine basaltic flows. Rocks of phyric basaltic, trachy-basaltic and even trachytic composition then built up the island as lava and pyroclastics emerged from vents and fractures, generally following two principal directions, an older N 50° E and a younger N 40° E. The present fracture seems to coincide with the latter, and falls in line with the earlier development of the Beerenberg volcano as described by Fitch, Roberts and Hawkins[2,3].

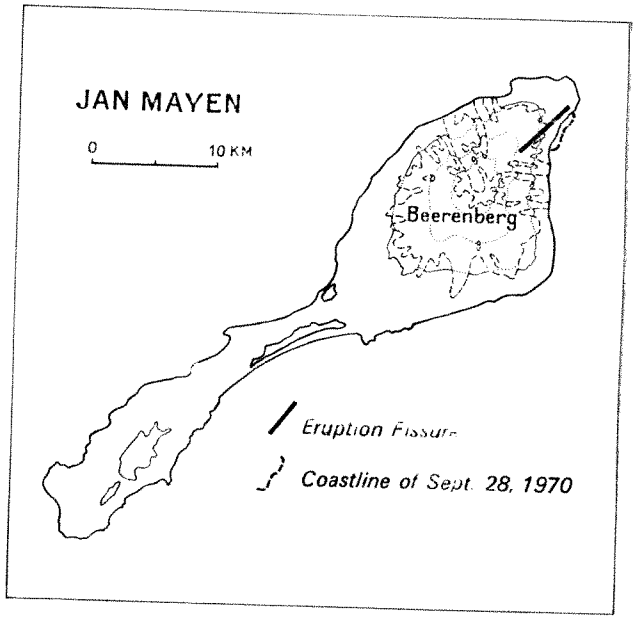

Fig. 1. The volcano on Jan Mayen Island.

The structural setting of Jan Mayen is intricate. According to Johnson[4], it is located on the intersection of an important NW–SE striking fracture zone and an N–S trending easterly marginal ridge of the Icelandic Plateau that occupies the major part of the Mid-Atlantic ridge in the region. Johnson interprets the morphological and earthquake data in favour of a displacement of the crest of the Mid-Atlantic ridge 200 km laterally eastwards along the Jan Mayen fracture zone. It should be noted, however, that the island of Jan Mayen itself is trending SW–NE, parallel to the direction of the crest both to the south of Iceland and to the north of the fracture zone (the Mohn ridge), and occupying a central position within the ridge.

The renewal of the volcanic activity of Jan Mayen calls for a close study of the island itself, as well as of the structural relationship of the Mid-Atlantic ridge in the Norwegian Sea.

Temporal Patterning of Post-Pleistocene Glaciation

MOST post-Pleistocene glaciation has apparently been confined to four phases at intervals of around 2,600 years[1]. The exact timing of these phases will be examined in relation to recent carbon-14 age corrections and additional glacial chronologies.

The earliest glacial phase, the Cochrane–Cockburn, occurred in North America and has been dated by ^{14}C methods at around 8,000–9,000 years BP, probably nearer 8,000 years BP (ref. 2). The correlation of the Cochrane–Cockburn glacial phase with Swiss[3], Austrian[4] and Swedish[5] glaciation is still uncertain. The second phase, the Atlantic/sub-Boreal transition, is now well documented from North America[6–9] and from Europe[5,6,10] as occurring around 4,500–5,000 ^{14}C years BP and culminating between 4,600–4,800 years BP. The third phase, the sub-Atlantic minimum, culminated around 2,600–2,800 ^{14}C years BP in North America[1,7] and in Europe[1,4,7,11,12] and probably in Australia[13]. The last phase, the "Little Ice Age", had a world-wide culmination around AD 1,550–1,900 (ref. 1) which was synchronous for North America, Arctic–Eurasia and the Southern Hemisphere.

The mid-points of the culmination of these four glacial phases were 8,000 (tentatively), 4,700 and 2,700 ^{14}C years BP and 225 years BP. Studies of conversion of ^{14}C to true time[14,15] indicate that from 0–2,500 BP, ^{14}C and true time were the same; 2,500–5,500 ^{14}C years BP there was an underestimate of true time; and around 8,000 BP, ^{14}C and true time were, again, about the same. Correction factors of 1·03 for 2,700 BP, of 1·14 for 4,700 BP and of 1·03 for 8,000 BP were estimated (from ref. 15) to give corrected dates of 8,250, 5,350 and 2,780 BP. These dates, together with the recent date of 225 BP, give intervals of 2,900, 2,570 and 2,555, of which the first is not very reliable. Neglecting the first interval, the last three glacial phases are separated by around 2,600 years. An arithmetic progression starting with 22 years (the complete sunspot cycle) and a first term of four results in a sequence of 88, 440 and 2,640 years. The estimate of an 11 year half cycle is based on the mean length of 11·04 years for 214 BC–AD 1382 and 1830–1957 (ref. 16) and neglecting the interval 1382–1830 as a sunspot dearth period.

The apparent cyclic recurrence of the four glacial phases and, with the possible exception of the first phase, their synchronism in Europe, North America and elsewhere, suggest they have a similar cause. The most likely explanation of the recent glacial phase was lower temperature and a shorter ablation season[17,18]. If all four phases were caused by a periodic decline in temperature, then the decline would have been modified by the chief trend in temperature during the Holocene, because there is a decreased severity of glaciation from the first to second phase and an increased severity to the third and fourth phase. This pattern may reflect a periodic temperature decline which was of decreasing expression as a result of the predominant rising temperature of the early to mid-Holocene, and of increasing expression as a result of the subsequent temperature decline following the Thermal Maximum. The periodic appearance of glacial phases throughout the Holocene and their occurrence near the Thermal Maximum suggest that the mechanism underlying these phases is independent of that determining the predominant Holocene temperature trend.

There seem to be two major Holocene temperature patterns: (1) the predominant trend of increase in temperature followed by a slight decrease, exemplified by retreat of Pleistocene ice and the subsequent renewal of alpine glaciation and by the rapid rise and later fall in ocean level; and (2) a secondary trend of recurrent cold phases with greatly increased glaciation at higher altitudes and latitudes. As noted earlier, these two patterns are probably causally independent, but are additive in their expression. The first pattern has often been interpreted as a result of changes in the Earth's orbit relative to the Sun[19]. The second pattern may be related to cyclic intervals of decreased solar activity[1]. The most recent glacial phase has been correlated with an extended period of decreased solar activity[1]. Because the preceding two, and probably three, phases had a similar regular occurrence[1] and a similar short duration of from four to six centuries[1,2,6,7,10,20], they may also be related to recurrent periods of reduced solar activity. A glacial phase before the Cochrane–Cockburn, the Windermere, which occurred at 10,150–10,810 ^{14}C years BP, also had a relatively short duration of around four to six centuries[17].

If the two temperature patterns noted here continue, the following changes may be expected: (1) a period of slow cooling to around AD 2450, followed by an interval of more cooling lasting some 3,000 years, according to the first pattern[19]; and (2) a period of cooling and glaciation around AD 4300 according to the second pattern. A conservative estimate of cooling for the first pattern was made at 3·1° and 2·7° C for latitudes 25° and 65° N (ref. 21). For England, cooling as a result of the second pattern showed a decline of nearly 2·0° C from AD 1000–1300 to the "Little Ice Age"[22,23]. If cooling of around 3·0° C as a result of the first pattern is insufficient to trigger a glacial era, then it is conceivable that the temperature decline of nearly 2·0° C estimated for mid-latitudes for the second pattern could contribute the cooling necessary for continental glaciation. A possible new glacial era may begin, therefore, somewhere around AD 4300, the next predicted 2,600 year temperature decline, or sooner, if the rapid cooling predicted from the first pattern to occur after AD 2450 is sufficient.

Deformation of Particles during Briquetting

THE briquetting of small particles usually consists of the application of pressure in controlled conditions so that the individual particles hold together to form a

coherent compact. Many mechanisms have been suggested to explain why the particles cohere to form a compact, but none have been based on satisfactory observation of the behaviour of the individual particles under stress. Our present studies have involved such detailed observation and we describe here the essential difference in behaviour of particles of a number of different materials.

Some materials which are generally regarded as brittle are considered to behave plastically when the particles are small and subjected to high degrees of stress (microsquashing). Considerable study has been made of the behaviour of coal particles in this connexion[1–4]. The critical size for microsquashing rather than for brittle fracture to occur is uncertain but may well vary over a considerable range depending on the material of the particle and the nature of the stress system applied to it. Newman[5] considered that there was evidence of plastic flow in coal particles of the order of 1 mm linear dimension. Microsquashing has been considered[6] to be important in the achievement of sufficient area of contact between coal particles in a compact for the whole to remain coherent after release of the briquetting pressure.

One of the difficulties inherent in an experimental study of the compaction process is the observation in sufficient detail of the behaviour of individual particles. Most observations have been made using optical instruments characterized by limited resolution and depth of field. During the present study a scanning electron microscope has been used to observe both particles and sections of briquettes. This microscope has a resolution of approximately 500 Å and a depth of field very many times greater than the size of the particles being observed.

Three materials were chosen for study, namely sodium chloride, a medium volatile coal (NCB classification 502, 85 per cent carbon) and sucrose. It was expected that the coal would behave in a manner intermediate between that of the sodium chloride, which was expected to be plastic[7,8], and that of the sucrose, which was expected to be brittle[9]. A sample of each material in the size range 251–295 μm was prepared; such particles are approximately in the middle of the range over which it has been suggested in the past that microsquashing might occur. The briquettes were formed in a cylindrical floating die under a pressure of $1{\cdot}55 \times 10^3$ kg cm^{-2} applied at a rate of 13·8 kg cm^{-2} s^{-1} at room temperature.

Briquettes formed from each of the three materials were broken and a portion cleaved from the centre was fixed to the mounting stub of the scanning electron microscope. Because the powders were badly conducting materials each specimen was covered with a very thin layer of silver to prevent the charging up of the surface. This has no effect on the observation of detail, for the layer thickness is much less than the resolution of the instrument. At the same time samples of the unbriquetted powder were examined in similar fashion.

The photographs in Fig. 1 were taken at low magnification in order to give a better general impression of the change taking place in individual particles during compaction. The specimens were, however, observed at a magnification of the order of 40,000, at which fine detail down to the limit of resolution is clearly visible. Even under high magnification the uncompacted particles showed no evidence of cracking; the briquette sections showed no more detail than is given at the lower magnification. The difference in behaviour of the three materials is shown in Fig. 1.

Figs. 1*a* and *b* are of sodium chloride particles before and after compaction respectively; *c* and *d* are a comparable pair for the coal used; *e* and *f* are for the sucrose. In the case of the sodium chloride there is no evidence for any fragmentation of the individual particles, the compact suggesting a mass of deformed cubes. This supports the view that the densification of sodium chloride is by plastic deformation[10,11]. In the case of the sucrose there is extensive fragmentation of the particles, each seemingly losing its original identity. The behaviour of the coal is intermediate between that of the sodium chloride and the sucrose. Some fragmentation does occur, but it is nowhere as extensive as with the sucrose and large portions of the original particles can be seen. It seems unlikely that plastic flow on the scale suggested by Newman[5] is taking place in this particular case. It may well be that the underlying mechanism is coal fragmentation combined with plastic deformation of the small fragments or of regions of the large particles.

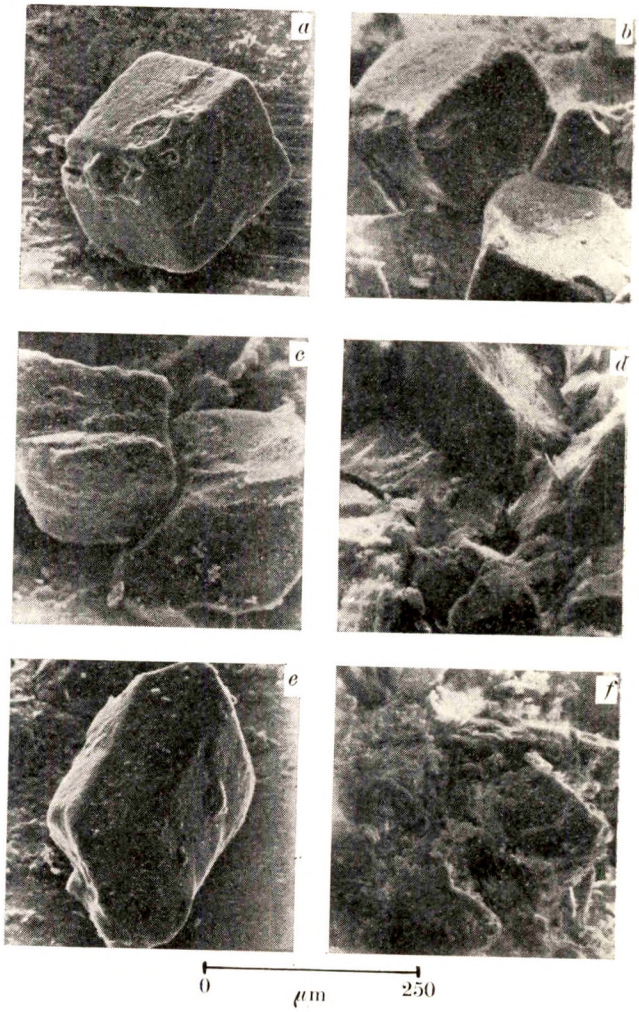

Fig. 1. *a* and *b* are sodium chloride particles before and after compaction; *c* and *d* are a comparable pair for the coal used; *e* and *f* are for sucrose.

The above observations are supported by measurements of specific surface of the particles before and after compaction. There is very little change in the case of sodium chloride and a ten-fold increase with sucrose.

The observations described in this note indicate the nature of the changes likely to be taking place in particles of the materials used. Previous workers[10,11] have deduced that plastic flow together with some fragmentation must be taking place in sodium chloride compacts, but there has never been any direct evidence. The present work provides strong support for a mechanism involving plastic flow. The behaviour of this material contrasts strongly with that of sucrose, and coal particles behave

in a fashion intermediate between these two extreme cases.

We thank the Science Research Council for financial support and the Department of Metallurgy for help in making available the electron microscope.

Crystal Structure of 18αH-Oleanane

DISTILLATES boiling in the range 340°–550° C contain molecular types belonging to the triterpane family, C_nH_{2n-8} (ref. 1). So far the structures of three compounds, corresponding to chromatography peaks labelled E, F and H (ref. 1, Fig. 5), have been solved by X-ray crystallography using trial and error methods. Triterpane E has been shown to be a spiro-triterpane[2,3], while triterpane H has been shown to be a member of the hopane family.

Triterpane F crystallized, surprisingly, in both triclinic and orthorhombic forms and the triclinic form was readily shown to be the parent hydrocarbon 18αH-oleanane. The orthorhombic form of F, however, contained two molecules in the asymmetric unit and posed the formidable task of finding sixty independent carbon atoms. Even so the structure has been successfully determined by the use of direct methods with no preliminary assumptions made about the molecular architecture.

Orthorhombic F has a unit cell $a = 20{\cdot}44$ Å, $b = 20{\cdot}90$ Å, $c = 12{\cdot}20$ Å; space group $P2_12_12_1$; $Z = 8$. 2,610 significant structure amplitudes were collected on a PAILRED diffractometer by courtesy of Dr G. J. Bullen (University of Essex), brought to a common scale and used to calculate a set of normalized structure factors. As an indication of the severity of the problem, the magnitude of the triple product $E_HE_KE_{(H-K)}$ had to exceed 28·7 for centrosymmetric reflexions for a 97 per cent probability of phase correctness and to be greater than 22·3 for non-centrosymmetric reflexions for a variance of 0·5 square radians[4].

With four reflexions to select the origin and enantiomorph and four symbolically phased reflexions (two real and two complex), a total of only eighteen reflexions could be obtained by the Σ_2 formula which satisfied the above criteria. Nevertheless, two definite phase relationships were obtained involving the two real and one complex symbolic phases and a third, less certain relating the two complex phases. In view of the very limited amount of data, this third relationship was ignored and sixty-four starting phase combinations developed for the eighteen initial reflexions. The tangent formula[5] was used to calculate phases for about 190 reflexions with $E \geq 1{\cdot}6$ for each starting set followed by the calculation of an E map. It became clear that the residuals calculated in the tangent formula were consistently lower for one combination of the symbolically phased real reflexions and that the third relationship was essentially true. The starting set which gave the lowest residual of all yielded the correct structure and the resulting E map contained no less than fifty-two clearly resolved atoms, that is twenty-six atoms in each molecule; indeed, in retrospect the remaining eight atoms were also present in the map but with much weaker peaks. An Fo map phased directly on these fifty-two atoms showed clearly the remaining atoms and the first structure factor calculation for all sixty atoms resulted in an R index of 28 per cent; two further cycles of least-squares refinement have reduced it to 18·2 per cent, and further refinement is in hand.

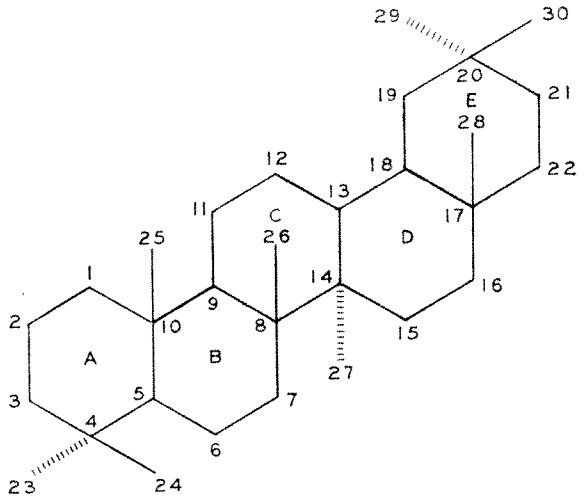

Fig. 1. 18αH-Oleanane.

The power of the symbolic addition procedure and tangent formula has been amply demonstrated by the relative ease with which the correct solution was revealed. Although sixty-four starting phase combinations were to be investigated sequentially, the correct solution was obtained before all cases were calculated and it is noteworthy that, had the third phase relation been used, the number of alternative starting sets would have been drastically reduced.

It is therefore remarkable that not only was the structure obtained by starting with a small number of phases and relatively weak phase relationships but also for the clarity with which the E map revealed nearly 90 per cent of the structure with only about 190 reflexions having $E \geq 1{\cdot}6$. This is in contrast with the suggestion[6] that about nine to ten reflexions per atom are required for good resolution. In addition no recycling procedure as advocated by Karle[7] proved necessary. The diffraction data for this structure may, of course, possess special features but this was not in any way apparent from the intensity statistics. We therefore attribute the success of solving this structure to a cautious approach by accepting only those phases which have a high probability of correctness and to very strict rejection criteria in the tangent formula. While this led to a small number of reflexions available for the calculation of the E map, the map for the correct solution was exceptionally clear and had relatively few noise peaks. Most of these peaks were weak and the few strong ones in obviously non-bonded

positions. An analysis of the phase angles of 135 complex reflexions gave an average error of 28°. It should be mentioned that two likely solutions were obtained in the process. Both contained about forty atoms corresponding to complete rings B, C, D and incomplete A and E rings of both molecules. One structure could be discarded on packing consideration and the other would not refine. It did, however, bear close resemblance to the true structure and corresponded to a starting set wherein one of the symbolically phased reflexions had changed by π.

This is, we believe, the first time that the parent hydrocarbon 18αH-oleanane (Fig. 1) has been positively identified, although derivatives are known and triterpane E has been reported[2,3] as a spiro modification of it. In the structure both molecules lie approximately parallel to the $1\bar{1}0$ plane on the same level as each other with the mean plane of their rings at about 45° to the *ab* plane. There is a displacement between them of approximately $\frac{1}{4}(a-b)$. A full description of this structure will be published elsewhere.

Ionization in Carbon Monoxide Flames

It is now generally believed that ionization in hydrocarbon flames results chiefly from a chemi-ionization process involving the reaction

$$CH + O \rightarrow CHO^+ + e^- \quad (1)$$

There is evidence that the same process occurs in hydrocarbon/oxygen flames[1,2], and in hydrogen[3] and carbon monoxide[4] flames to which small amounts of hydrocarbons have been added.

The presence of ions in flames in which the fuel and additive includes carbon but not hydrogen, for example, carbon monoxide plus carbon tetrachloride, would require an ion formation process other than (1) above. In fact it has been reported that carbon tetrachloride gives a slightly greater response than methane in the carbon monoxide flame[5]. Hydrogen and water are also said to give a sensitive response in this flame[6]. More recently, however, it has been shown that the ion current in a carbon monoxide flame containing small quantities of added ethylene is proportional to the square of the ethylene concentration and this result has been interpreted as consistent with reaction (1) on the assumption that both reactants for the ionization step are provided by the hydrocarbon[7].

In view of these apparently conflicting results we have carried out a series of experiments on the carbon monoxide flame, initially using 99·5 per cent pure carbon monoxide (J. T. Baker Chemical Co., Phillipsburg, New Jersey, USA) burning at a 0·10 inch inner diameter platinum jet at a flow rate of 35 ml./min. Additives could be continuously introduced into the flame at a controlled rate either by a direct pressure control system (for hydrogen) or by passing a portion of the total carbon monoxide flow through a saturator (for water, carbon tetrachloride and liquid hydrocarbons). Ion currents were measured with a Keithley model 300 operational amplifier (Keithley Instruments Inc., Cleveland, Ohio) with the platinum jet 300 V positive with respect to ground. A full description of the flame assembly, amplifier and saturator used in these studies will be published elsewhere[8]. With this arrangement we could obtain no significant signal for either hydrogen, water or carbon tetrachloride (May and Baker, research grade) when added to the carbon monoxide flame, and at a carbon tetrachloride concentration of approximately 1·4 volumes per cent the flame was extinguished.

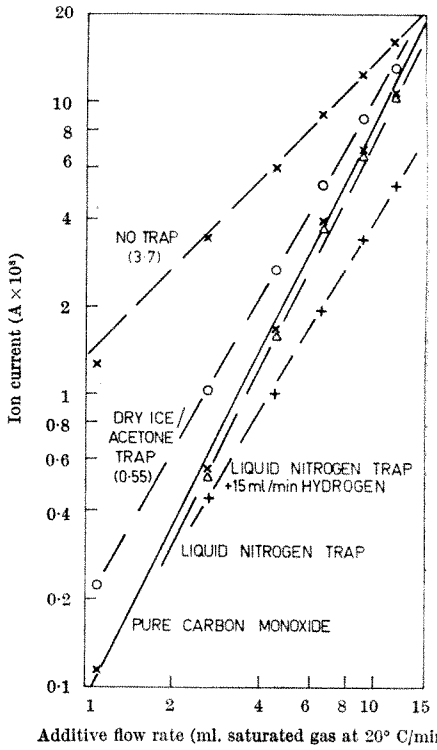

Fig. 1. Response of the carbon monoxide diffusion flame to ethanol for pure carbon monoxide (solid curve) and impure carbon monoxide (broken curves), plotted on log–log scales. Figures in brackets indicate corrections made for the residual background current due to the methyl formate impurity.

The results for carbon tetrachloride and hydrogen have been repeated using a second sample of 99·5 per cent pure carbon monoxide (Matheson Company Inc., East Rutherford, New Jersey, USA) at flow rates from 35 to 90 ml./min. Again no response could be obtained for carbon tetrachloride (irrespective of the addition or not of up to 15 ml./min of internal oxygen), or for hydrogen at low rates of addition. At a hydrogen flow rate of 20 ml./min and carbon monoxide of 50 ml./min a small signal ($1{\cdot}7 \times 10^{-9}$ A) was obtained, and at still higher hydrogen flow rates the signal increased rapidly with hydrogen addition. The appearance of the flame indicated that solid carbon formation was occurring[9] and this may well account for the marked increase in ionization observed in these conditions.

In the case of ethanol (Fig. 1) our results with pure carbon monoxide are similar to those previously reported for ethylene[7]. Benzene, toluene and *n*-heptane, however, all gave a substantially first order response at ion currents greater than 1×10^{-8} A (Fig. 2), although the toluene

results in particular suggest a square law dependence at lower concentrations. This change in kinetic dependence may arise from cracking reactions which give relatively high yields of some hydrogen-containing species which are precursors to reaction (1) above, or are directly involved in this reaction. This is possible because the ion formation process is a minor one, only about 1 ion being produced per 10^6 molecules of additive. The addition of up to 30 volumes per cent of hydrogen, however, to a carbon monoxide/ethanol flame resulted in only a marginal change towards first order dependence and a net reduction in the ion current (Fig. 1).

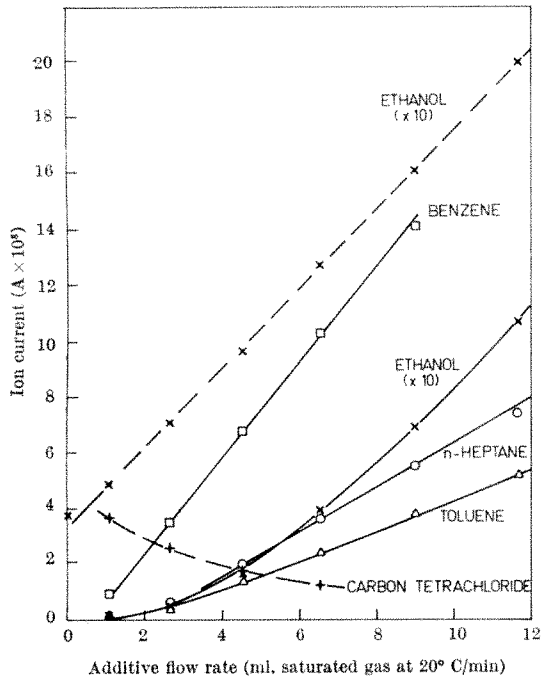

Fig. 2. Response of the carbon monoxide diffusion flame to various additives for pure carbon monoxide (solid curves) and impure carbon monoxide (broken curves).

In later experiments using a third sample of carbon monoxide (Matheson Company Inc., East Rutherford, New Jersey, USA) it was observed that the response was almost linear with ethanol concentration, but a large background signal was obtained in the absence of any organic additive. The introduction of carbon tetrachloride in this case reduced the level of the background signal as shown in Fig. 2 (broken curves). Trapping out the impurity giving rise to this signal, by using either a liquid air or dry ice/acetone bath, reduced the signal to zero irrespective of the addition of either carbon tetrachloride, hydrogen or water to the flame. Removal of the impurity in this way also resulted in the ethanol response reverting to a square law dependence as previously found with pure carbon monoxide (Fig. 1). Mass spectrometric analysis suggested that the major impurity in the carbon monoxide was methyl formate. This has been confirmed from the infrared spectrum of a sample of the trapped impurity, and its concentration has been determined by gas chromatographic analysis as 1·6 volumes per cent.

The above results show that neither hydrogen, water nor carbon tetrachloride produce significant ionization in the carbon monoxide flame, and this is consistent with ions being produced by reaction (1) above. The response due to hydrogen-containing organic compounds, however, appears to be complicated by kinetic factors arising from the effect of the cracking processes occurring in the flame.

I thank Miss C. Drummond who carried out most of the experimental work reported here, Dr I. R. Wilson for valuable discussions on the kinetic aspects of these results, and the Shell Group of Companies in Australia for the award of a research fellowship.

Aquoluminescence from Gamma-irradiated Alkali Halides

We report here the observation of a faint bluish green glow with a peak around 5000 Å when gamma-irradiated NaCl, NaBr, KCl or KBr is dissolved in distilled water. To observe the glow the room must be dark and the eye must be acclimatized to the darkness for a few minutes. A high speed (400 ASA) photographic film is blackened by direct exposure to the glow in about 10 min (Fig. 1).

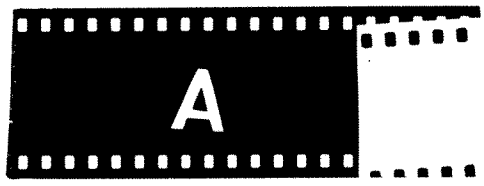

Fig. 1. Blackening of photographic paper by aquoluminescence.

We propose to call this emission aquoluminescence. The glow can be received on a photomultiplier and the output displayed on an oscilloscope. Fig. 2 for NaCl shows a typical trace. The maximum intensity develops in about 0·1 s while the decay time extends to about 2–3 s.

The following mechanism is proposed.

$$e^-_{\text{trapped in lattice}} + \text{water} \rightarrow e^-_{aq} \qquad (1)$$

$$e^-_{aq} + Cl\cdot \rightarrow Cl^-_q + h\nu \qquad (2)$$

The emission of a photon in a reaction of the above type does not appear to have been reported hitherto.

From a study of the reduction in intensity of aquoluminescence due to pre-thermal annealing of the irradiated salt, we have obtained data for (*a*) the energy barrier for the trapped electron (1·1 eV for NaCl), (*b*) the first order rate constant for thermal annealing ($3{\cdot}5 \times 10^{-2}$ s^{-1} at 423 K) and (*c*) the maximum number of defects produ-

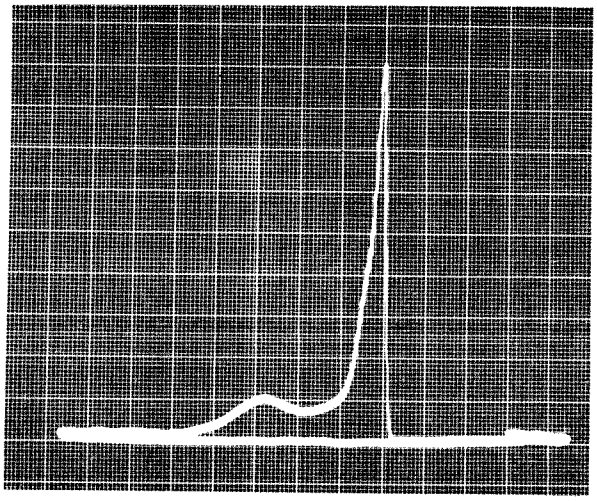

Fig. 2. Oscilloscope pattern of aquoluminescence from γ-irradiated NaCl.

cible by gamma irradiation (2×10^{19}/mole in NaCl). These results agree with values reported earlier[1-3]. The phenomenon thus seems to provide a relatively simple method for studying irradiation effects in crystals.

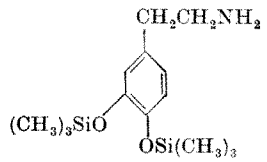
BIOLOGICAL SCIENCES



Possible Dopamine Derivatives capable of Crossing the Blood–Brain Barrier in relation to Parkinsonism

The exact neurophysiological role of dopamine is still unclear, but it has been implicated in the functioning of the extrapyramidal motor system (EPS)[1,2]. Experiments on animals and humans, however, indicate that the smooth functioning of the EPS depends on a fine balance between several biogenic amines[3-5]. Nevertheless, deficiencies of brain dopamine resulting from degeneration of the substantia nigra seem to be associated with the extrapyramidal symptoms of Parkinson's disease[1-6]. In accordance with these observations, attempts have been made to raise brain dopamine levels in patients suffering from Parkinsonism. Dopamine itself cannot be used, for it is incapable of crossing the blood–brain barrier, and therefore dopamine precursors, in particular L-3,4-dihydroxyphenylalanine (L-dopa), have been used[7-10]. Although such treatment apparently relieves the symptoms of hypokinesia, rigidity and posture, tremor is little affected and the necessity for large daily dosage and the side-effects of nausea and hypotension remain as serious drawbacks to the therapeutic use of L-dopa. Stock[11] has recently suggested that 2-amino-4-hydroxy-6,7-dimethyltetrahydropteridine may be a potential anti-parkinsonism agent since this tyrosine hydroxylase co-factor may be deficient in patients suffering from Parkinsonism[12].

Implicit both in Stock's suggestion and in the use of L-dopa is the assumption that dopamine precursors capable of crossing the blood–brain barrier will be enzymatically transformed *in vivo* into dopamine, thereby increasing brain dopamine levels. I propose that such levels could more easily be increased by administration of labile, lipophilic derivatives of dopamine. The modification of pharmacological activity by the synthesis of labile derivatives which undergo either enzymatic or non-enzymatic hydrolysis *in vivo* to regenerate the parent drug is well known, and the principle has been successfully applied to noradrenaline[13]. The 3,4,β-triacetate and 3,4,β-*tris*-(trimethylsilyl) derivatives of noradrenaline cause the sustained release of the parent catecholamine in mouse brains[14]. It therefore seems likely that similar derivatives of dopamine, for example I[15] and II[16], may penetrate into

I

II

the central nervous system and be converted to dopamine in the vicinity of the basal ganglia, for both *in vitro* and *in vivo* experiments[1,2] indicate that dopamine is preferentially taken up by these parts of the brain.

Sunlight-induced Pyrimidine Dimers in Human Cells *in Vitro*

Pyrimidine dimers have been implicated in much ultraviolet light induced damage in bacteria[1], and it has been shown that they can be induced in mammalian cells with short wavelength ultraviolet light[2-7]. In placental mammals, pyrimidine dimers are not repaired by direct monomerization by photoreactivating light[2,8,9], although a dark repair mechanism, somewhat similar to that found in bacterial cells, has been demonstrated[10].

It has recently been reported[11–13] that cells of people with the hereditary disease, xeroderma pigmentosum, have a low capacity for DNA repair replication[14,15] and do not excise the ultraviolet-induced pyrimidine dimers[16,17]. These patients are very sensitive to ultraviolet light and exhibit a high incidence of skin cancer[18–20]. This report demonstrates that normal exposures to natural sunlight, which is known to induce skin cancers but contains no detectable wavelengths shorter than 290 nm at sea level, can induce significant formation of pyrimidine dimers.

Human amnion (AV_3) cells were plated (8×10^5 cells/plate) into 60 mm Petri dishes containing ^{3}H-thymidine (1 μCi/ml.; 2·0 Ci/mmole specific activity) in Eagle's minimal essential medium (MEM) (10 per cent calf serum) and incubated for 24 h. Twenve hours before exposure to sunlight, the labelled medium was discarded and enough non-labelled cells in non-labelled medium were added to the labelled monolayer of cells to form a second layer of cells on a series of plates. This was done to mimic the dead, horny layer of cells found on the epidermis of human skin. The cells were then carefully washed and 2 ml. of Hanks buffered saline was placed on each plate, which was exposed for various times to the sunlight. Plates were placed in a special constant temperature bath at 4° C. for the duration of the exposure. Subsequent pyrimidine dimer analysis was done according to methods previously described[2,21].

Table 1. EFFECT OF SUNLIGHT ON THE INDUCTION OF THE THYMINE-CONTAINING DIMERS IN HUMAN CELLS GROWN *in vitro*

Treatment	$\frac{\wedge}{XT/T}$ (c.p.m.)	Per cent of thymine as dimer
Experiment 1, July 26, 1968*		
Two cell layers		
Sunlight 2 h	89/121,700	0·07
Sunlight 3 h	123/98,200	0·12
Sunlight 5 h	318/137,000	0·23
Sunlight through 1 cm plate glass	0/216,500	0·00
Dark control	0/167,800	0·00
Experiment 2, August 11, 1968†		
One cell layer		
Sunlight 2 h	822/582,700	0·11
Sunlight 3 h	1,053/607,000	0·17
Sunlight 5 h	1,040/283,500	0·36
Two cell layers		
Sunlight 2 h	441/583,700	0·07
Sunlight 3 h	1,029/682,100	0·15
Sunlight 5 h	1,225/463,500	0·26

* Average dosimetry readings of sunlight, taken at five different times from 1030–1530, were $6{\cdot}5 \times 10^5$ erg/cm^2/s under 1 cm of plate glass and $7{\cdot}8 \times 10^5$ erg/cm^2/s without glass.

† Average dosimetry readings of sunlight, taken at five different times from 1030, were $6{\cdot}8 \times 10^5$ erg/cm^2 s under 1 cm of plate glass and $8{\cdot}4 \times 10^5$ erg/cm^2/s without glass.

Table 2. ABSENCE OF EFFECT OF SUNLIGHT ON THE MONOMERIZATION OF ULTRAVIOLET LIGHT-INDUCED PYRIMIDIME DIMERS

Treatment*	$\frac{\wedge}{XT/T}$ (c.p.m.)	Per cent of thymine as dimer
Ultraviolet alone†	1,376/920,000	0·14
Ultraviolet + 2 h sunlight‡ (cells in MEM)	737/536,400	0·13
Ultraviolet + 4 h sunlight (cells in MEM)	898/629,300	0·14
Ultraviolet + 4 h dark incubation (cells in MEM)	978/858,837	0·11
Ultraviolet + 2 h sunlight (cells in Hank's)	1,180/800,300	0·14
Ultraviolet + 4 h sunlight (cells in Hank's)	588/370,300	0·15

* Average dose rate of sunlight on August 4, 1969, taken from five readings between 1030 and 1530 was $5{\cdot}7 \times 10^5$ erg/cm^2/s (determined through 1 cm of plate glass with a YSI model 65 radiometer).

† Cells were irradiated with 300 erg/mm^2 of ultraviolet light at 2537 Å. Dose rate was 20 erg/mm^2 s.

‡ Cells were exposed to sunlight through 1 cm of plate glass.

To test for the possible monomerization of pyrimidine dimers by sunlight, ^{3}H-thymidine labelled cells (1 μCi/ml.; 2·0 Ci/mmole specific activity; 24 h incubation) were irradiated with 2537 Å ultraviolet light in the laboratory (300 ergs/mm^2 at 20 ergs/mm^2/s). After irradiation, 2 ml. of Eagle's MEM was added to each plate and the plates, in a water bath at 21° C. were then exposed to various doses of sunlight under plate glass (1 cm thick) and later analysed for pyrimidine dimers.

Assuming that the sunlight-induced photoproducts, which had the same chromatographic R_f values as thymine containing pyrimidine dimers, are in fact thymine-containing dimers, it follows that these can be induced by sunlight (Table 1). The quantity of pyrimidine dimers formed during 5 h of exposure at those dates and places is equivalent to approximately 600 ergs/mm^2 of 2650 Å ultraviolet light[2]. The human amnion (AV_3) cells do not photoreactivate ultraviolet induced damage by monomerization of pyrimidine dimers by sunlight (Table 2).

These empirical findings support the findings and hypothesis of Harm[22] that sunlight-induced lesions in DNA are the same as those made by 254 nm irradiation. The results of this study are of some empirical interest, for it has been suggested that ultraviolet-induced cancer might be explained by the somatic mutation theory[23,24]. If, in fact, mutations can cause cancer in humans, and if mutations are the result of defective repair of ultraviolet-induced pyrimidine dimers, as in bacteria[25], then these findings demonstrate that there is a molecular basis for such an hypothesis.

Decreased Host Cell Reactivation of Irradiated SV40 Virus in Xeroderma Pigmentosum

Bacteria possess enzyme systems for repairing in the dark the damage caused by ultraviolet irradiation[1] in which damaged regions of DNA are excised and replaced[3]. Damage to an infecting phage can also be repaired. This capacity, known as host cell reactivation (HCR), is manifested by the lowered survival of ultraviolet irradiated phages in radiation-sensitive mutant host bacteria[3,4]. Mammalian cells also possess repair systems. In xeroderma pigmentosum, a genetic disease associated with unusually high sensitivity to sunlight and a greatly increased susceptibility to carcinomas and melanomas of the skin, the capacity of fibroblast cells for repair is

much lower than that of normal fibroblasts[5]. Recent evidence suggests that xeroderma pigmentosum cells are defective in the first reaction of the DNA repair mechanism[2,6]. Previous investigations have raised the possibility of a host cell reactivation system in mammalian cells[7–13]. We have shown directly that normal human cells have HCR capacity by comparing the ultraviolet sensitivities of two viral functions of the DNA tumour virus SV40—transformation and T-antigen induction—in normal and xeroderma pigmentosum cells.

Human cell cultures were derived from punch biopsies of normal (non-tumorous) skin from a 5 year old male (XP-1) and a 7 year old female (XP-2) with xeroderma pigmentosum and from a clinically normal 12 year old male (M. G.). Cells were grown in Dulbecco's modification of Eagle's medium supplemented with 10 per cent unheated calf serum, and they were used within the first twenty generations in culture.

The SV40 virus induces permanent alterations in the morphology and growth properties of several mammalian species in tissue culture including human cells[14]. Transformants can be recognized by their ability to form dense, piled-up colonies against the background of normal contact-inhibited cells. This lack of normal growth restraint induced by the virus provides the basis for the quantitative assay of transformation[15] (see legend to Fig. 1). Two to three weeks after infection with SV40, densely growing colonies of epithelioid cells could be recognized as early transformed colonies. After about 24 days, the cultures were fixed for 30 min with 10 per cent formalin and stained for 60 min with Harris haematoxylin. Transformed colonies were scored under a low power dissecting microscope. The transformation frequency was expressed as the total number of transformed colonies obtained per total number of cells inoculated (corrected for plating efficiency). The transformation frequency with the control SV40 was approximately 0·25 per cent for each cell strain. Thus, if the ultraviolet repair enzyme or enzymes deficient in xeroderma pigmentosum cells were necessary for the process of transformation, their presence at markedly lower levels still permitted a normal transformation frequency in the xeroderma pigmentosum cells.

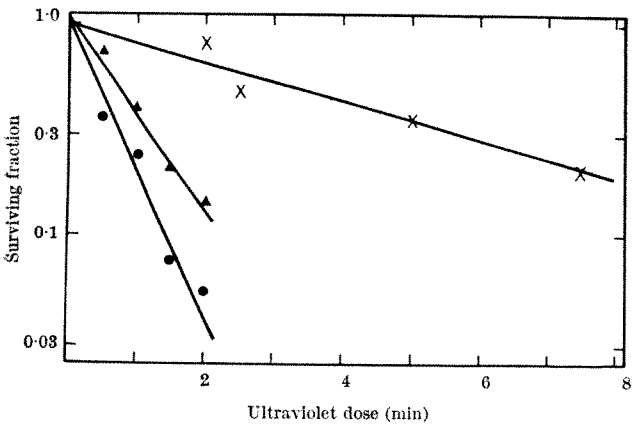

Fig. 1. Ultraviolet survival curves of SV40 transformation in normal and xeroderma pigmentosum cells. The virus used was a plaque purified pool of the small plaque (SV-S) variant of SV40 (ref. 6) which titred 5×10^8 plaque forming units (p.f.u.) per ml. in African green monkey kidney cells. The results are the average of two experiments. Transformation frequency with unirradiated virus for M. G. (×), 0·025 per cent; XP-1 (●), 0·03 per cent; XP-2 (▲), 0·023 per cent. Thin layered samples of SV40 were exposed to ultraviolet light for different times at room temperature in conditions of constant agitation of the fluid. The energy at the surface of the sample was 40 erg/mm²/s at a wavelength of 2537 Å measured with an ultraviolet dosimeter (Ultraviolet Products). Each aliquot was then reconstituted to its original volume with sterile distilled water. In the transformation assay, Petri dishes containing around 5×10^5 normal or xeroderma pigmentosum cells were exposed to normal SV40 (200 p.f.u./cell) or to equal amounts of ultraviolet-irradiated virus. The cells were then subcultured to several new Petri dishes, each at 10^4 or 5×10^4 cells per dish. The plating efficiencies for the cell strains were 60–85 per cent and were not decreased by exposure to SV40. Because SV40 can grow to a limited extent in human cells, all SV40 infected cultures were continually maintained in the presence of 0·5 per cent calf SV40 antiserum (Baltimore Biologic Laboratories). This concentration was capable of neutralizing between 10^5 and 10^6 p.f.u./h at 37° C.

The ultraviolet survival curves for transformation are shown in Fig. 1. These have been normalized to the transformation frequency of unirradiated virus. The data are adequately described by single hit, exponentially decreasing functions. The slope of the ultraviolet survival curve for the normal cell strain was very similar to that obtained for other normal human cells tested in identical conditions[16]. The ultraviolet survival curve of transformation in both types of xeroderma pigmentosum cells was considerably steeper than that of the normal cell strain, M. G. The slope for the most ultraviolet sensitive cell strain (XP-1) was about eight times greater than the slope for the normal fibroblasts.

SV40 T antigen is known to appear in acutely infected cells and to persist in transformed cells. It can be localized in the cell nucleus by an indirect fluorescent antibody test[17]. With infection by normal SV40 the number of human cells synthesizing T antigen during the acute infection is maximal at 72 h (ref. 18). The fraction of normal and xeroderma pigmentosum cells containing the antigen at this time was scored. The ultraviolet survival curves are compared in Fig. 2. As with transformation, the ultraviolet sensitivity of T antigen induction was greater in the two radiation-sensitive human cells. The slopes for XP-1 and XP-2 were calculated to be 9·0 and 5·0 times greater than normal, respectively.

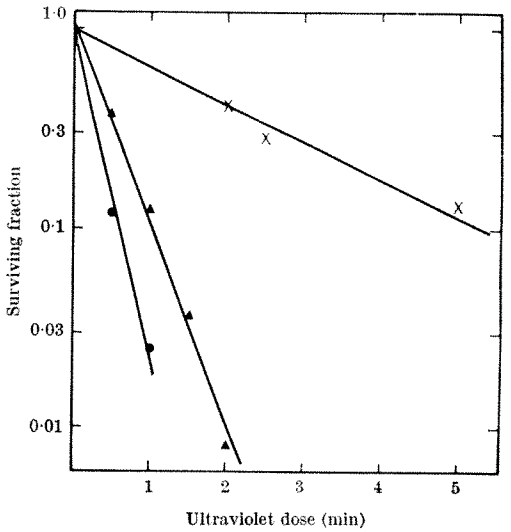

Fig. 2. Ultraviolet survival curves of SV40 T antigen in normal and xeroderma pigmentosum cells. T antigen was measured 72 h after infection. The results are the average of two experiments. The T antigen level with unirradiated virus in M. G. (×), 5·1 per cent; XP-1 (●), 6·2 per cent; XP-2 (▲), 6·9 per cent. At appropriate times, cells grown on coverslips in the presence of SV40 antiserum were fixed in acetone at −20° C for 10 min, and then incubated for 30 min with hamster SV40 T antiserum, washed carefully, and then incubated for the same time with fluorescein-conjugated goat anti-hamster globulin. Each coverslip was scored by two observers. At least 200 positive cells or 20,000 total cells were examined for each point.

Our findings are consistent with the hypothesis that xeroderma pigmentosum cells have little or no ability to reactivate ultraviolet-damaged SV40. The kinetics of T antigen induction in normal human and mouse cells are delayed by ultraviolet-irradiated virus[16], and we therefore studied the kinetics of T antigen formation with ultraviolet-damaged SV40 in the xeroderma pigmentosum cells. Fig. 3 shows the percentages of T antigen positive cells at different times after infection of normal and xeroderma pigmentosum cell strains by the control SV40 and by the ultraviolet-irradiated SV40. The T antigen levels for control virus

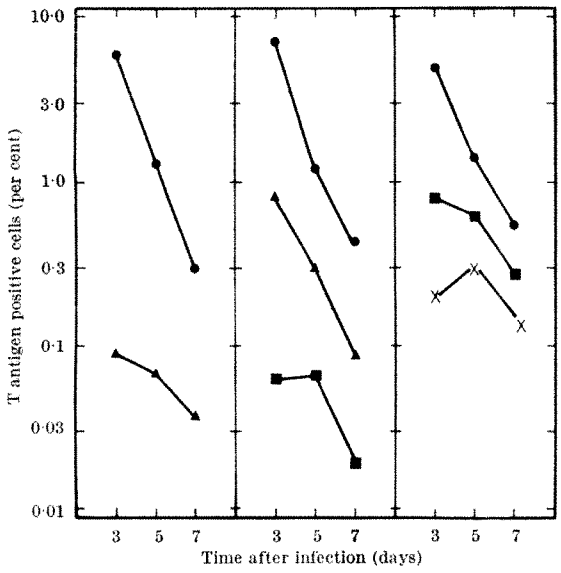

Fig. 3. T antigen levels measured at different times after infection by control and ultraviolet-irradiated SV40. Ultraviolet doses: ●, 0 min; ▲, 1 min; ■, 2 min; ×, 5 min. Left, XP-1; middle, XP-2; right, M.G.

were 5–7 per cent in each cell strain after 3 days and thereafter declined at similar rates. There was a definite delay in the induction of T antigen in the normal cells by the ultraviolet-irradiated virus. With the xeroderma pigmentosum cells, also the timing of the induction of T antigen by ultraviolet-irradiated SV40 was altered. The time course of T antigen appearance was similar in xeroderma pigmentosum and normal cells, although the absolute T antigen levels were much higher in the latter. This suggests that although the probability of host cell reactivation of damaged virus in the xeroderma pigmentosum cells was much lower than in normal cells, if reactivation did occur it did so with a time course similar to that seen in the normal cells.

Skin fibroblast cells from patients with certain genetic diseases associated with a high risk of tumour formation have a markedly increased susceptibility to transformation *in vitro* by SV40[15,18]. Our tests on xeroderma pigmentosum cells have not revealed an abnormally high transformation frequency with unirradiated virus, although both xeroderma pigmentosum patients had skin tumours, and one (XP-1) died of leukaemia (personal communication from R. M. McAllister). Thus the SV40 screening test may not detect the increased tumour susceptibility of xeroderma pigmentosum patients.

We have compared the survival of two functions of the tumour virus SV40 in normal and xeroderma pigmentosum cells at identical virus multiplicities. The results clearly showed a markedly lower survival of both transformation and T antigen functions in the xeroderma pigmentosum cells. By analogy with studies in bacteria (see review by Rupert and Harm[19]), this host cell effect on ultraviolet-damaged virus is most consistent with the hypothesis that ultraviolet-damaged SV40 is repaired by enzymes in the normal human cell that are missing or at much lower levels in xeroderma pigmentosum cells. The results also indicate that enzymes present in normal human cells can reactivate an ultraviolet-irradiated DNA tumour virus. The data obtained with strains XP-1 and M. G. indicate that the normal cell can have 8–9 times more HCR capacity than the repair-deficient cell. This is similar in magnitude to the difference between the abilities of normal and radiation-sensitive bacteria to reactivate ultraviolet-irradiated T1 bacteriophage[3].

Strain XP-1 produced steeper survival curves than XP-2 for both T antigen and transformation functions. That consistent differences were found in the ability of the two xeroderma pigmentosum strains to "reactivate" damaged SV40 implies that these cells have relative and not absolute defects in their DNA repair capacity. Similarly, relative differences in repair replication have been found for several xeroderma pigmentosum cell strains[5]. The repair replication ability of strain XP-1 was tested by Dr J. Cleaver and found to be about 5 per cent of the normal using his assay methods (personal communication). Our results showing about 12 per cent of the normal HCR in XP-1 indicate that there may be a close correlation between the capacities for repair replication and HCR in human cells.

New Form of Molecular Defect in Xeroderma Pigmentosum

XERODERMA pigmentosum is a rare hereditary disease of the human skin. After slight exposure to sunlight the skin develops widespread poikiloderma with spotted dyschromia, telangiectasia and atrophy of the epidermis including multiple hyperplasia and the following malignancies of epidermal and dermal origin: basal cell and squamous cell carcinoma, melanoma, fibroma, sarcoma, histiocytoma, neurofibroma and angioma[1,2]. The molecular basis of light sensitivity and accelerated light induced carcinogenesis of xeroderma pigmentosum may involve a decreased tolerance of individual cells to light[3]. The initial direct damage is not increased, but the ability of cells to tolerate light induced DNA damage is decreased: investigation of cultured fibroblasts of xeroderma pigmentosum patients showed that these cells are unable to repair ultraviolet-induced single-strand DNA lesions[3]. The molecular defect lies in the initial stage of the repair process, probably at the endonuclease level[4,5].

Skin grafts, 0·2–0·3 mm thick, were cut from unaffected skin with a dermatome and divided into small pieces (2 × 2 mm). These pieces were irradiated with an unfiltered

xenon lamp[6] at various energies (total output: $2{\cdot}1 \times 10^6$ erg cm^{-2} s^{-1}, measured by a compensated thermopile 'CAI'; Kipp & Zonen). Immediately after irradiation, the specimens were incubated in tissue culture medium 199 (Difco) for 4 h at 37° C with 1 μCi/ml. [*methyl*-^{3}H]-thymidine. They were then fixed in formalin, sectioned, stained with acid haemalaun and autoradiographed using Kodak 'AR 10' stripping film and an exposure time of 7 days.

Three sporadic cases of xeroderma pigmentosum, of the autosomal recessive type, showed the same degree of heavy labelling in the basal cells as in the control group consisting of six normal persons, 20–30 years old. There seems to be no difference between patients with xeroderma pigmentosum and normal persons as far as the DNA replication in the S-phase of cell cycle is concerned. The repair activity of the lightly labelled xeroderma pigmentosum epidermal cells (basal cells, keratinocytes and granular cells) and fibrocytes of the upper dermis is reduced to about 10–20 per cent of the values of the control group (Table 1). These findings agree with those of Cleaver[4] and Setlow[5].

Repair activity as expressed by the number of lightly labelled epidermal cells out of 200 cells investigated. Mitotic activity is expressed by the number of heavily labelled (S-phase) cells out of 1,000 basal cells investigated.

We have found two female cases with normal brown pigmentation in which light produces an alteration of the skin resembling xeroderma pigmentosum. These actinic skin changes occurred between 35 and 40 years of age, but now, some years after the onset, extensive senile elastosis with poikiloderma, multiple keratosis and malignancies including melanotic freckles have developed. From the clinical point of view this condition has to be classified somewhere between extensive solar keratoses and a mild form of xeroderma pigmentosum. We therefore call it pigmented xerodermoid. Nevertheless, epidermal cells exhibit normal repair activity (Table 1). In spite of good pigmentary protection and the extensive lesions in skin exposed to the Sun, with multiple keratomata and malignancies, the early manifestation leads us to separate this phenomenon from what is usually known as actinic or solar damage. Further investigations at the cellular level show a normal percentage of heavily labelled basal cells in the unirradiated specimens of pigmented xerodermoid. Although in normal skin the reduction in premitotic synthesis of DNA is reduced in proportion to the irradiation energy, in our two cases of pigmented xerodermoid we find a strong and almost total depression of DNA synthesis after application of a relatively low dosage of ultraviolet light. Repair replication as detected by the incorporation of labelled thymidine is therefore not disturbed.

We conclude that the first steps in the repair process involving the enzymes endonuclease, exonuclease and DNA polymerase are functionally normal. But we suggest, in consequence, that the increased sensitivity to light involving semiconservative DNA replication in epidermal basal cells may explain the extensive damage in areas of skin exposed to light. The specific defect in these two cases must reside in the final steps of the repair process such as the action of the ligase or could involve a DNA polymerase system of semiconservative replication that is not necessary for the repair process. A third explanation could be that another, separate process correcting ultraviolet induced DNA damage is involved. This might be the recombinational form of repair which interferes with post-irradiation semiconservative replication rather than repair and may be depressed by caffeine[4,7].

Toxicity of Poly I·Poly C for Rabbit Eyes

A SYNTHETIC polyriboinosinic acid·polyribocytidylic acid complex (poly I·poly C) is known to be a potent inducer of interferon[1] and to mediate resistance to various viral and nonviral infections *in vivo* and *in vitro*. Recently poly I·poly C was reported to be effective in herpetic keratitis in rabbits without producing any evidence of local or systemic toxicity[2]. While studying the effects of intravenous poly I·poly C on herpetic kerato-uveitis in rabbits, however, we noticed ocular changes in many animals and here describe the ocular toxicity in rabbits which received only intravenous poly I·poly C.

Thirty-eight New Zealand white rabbits (2–4 kg) were divided into four groups—A, B, C and D. Poly I·poly C was obtained from three commercial firms (Biopolymers, Inc., Dover, Lot M–6; Miles Laboratories, Elkart, Control No. 11-4-321; P-L Biochemicals, Inc., Milwaukee, Lot 2026) and was reconstituted from its lyophilized or solution form as directed. On days 0, 2 and 4, 1 ml. of solution containing 1 mg of poly I·poly C was injected into the ear veins of the rabbits in groups A, B and C, each group receiving the same batch of poly I·poly C from a single source. The control group D received 1 ml. of phosphate-buffered saline (*p*H 7·2) (PBS) by the same route. The eyes of each rabbit were examined with the slit-lamp and ophthalmoscope. The examiners did not know which animals had received poly I·poly C or saline. The level of circulating interferon induced by intravenous injection of 1·0 mg poly I·poly C was approximately eight times greater than that produced by 0·1 mg (ref. 3). A similar dose (1·0 mg) was used by Park *et al.* in the successful treatment of herpetic ocular infections in rabbits with systemic poly I·poly C (ref. 4).

Among animals receiving poly I·poly C, one of ten animals in group A and two of ten animals in group B died within the first two weeks. In group C two of twelve animals died within 12 h after the first injection, three others died within the first week, one died the second week, and one became ill the first week and remained ill throughout the seven weeks of the experiment. All of the other animals in the three groups remained well, and

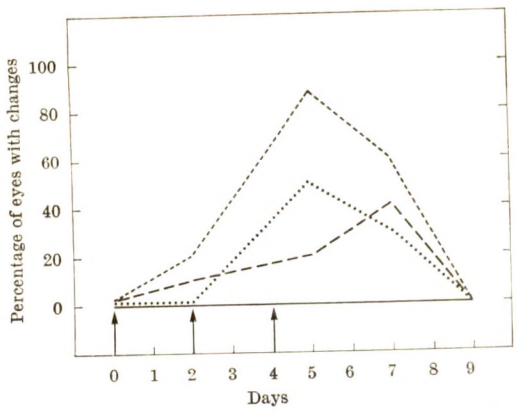

Fig. 1. Frequency of aqueous flare in the anterior chambers of rabbits inoculated intravenously (at arrows). Groups A (. . .). B (- - -) and C (— — —) received poly I·poly C from various sources; group D (———) received PBS.

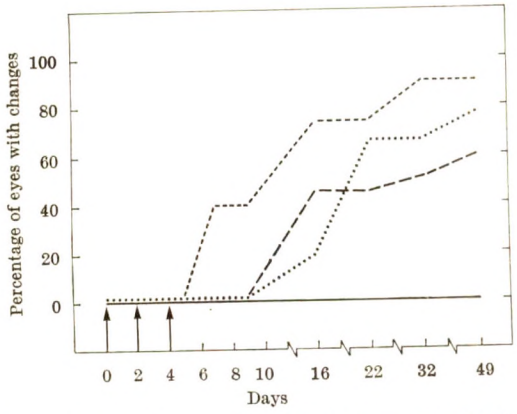

Fig. 2. Occurrence of lens opacities following intravenous injection (at arrows) with poly I·poly C. Cataracts were not observed in the control group (D). For explanations, see Fig. 1.

none of the six animals in control group D died or appeared ill at any time.

In surviving animals treated with poly I·poly C hyperaemia of the iris, aqueous flare (a manifestation of protein in the aqueous humour), and aqueous cells (thought to be white blood cells by virtue of their size and colour) were all noted in each of the three poly I·poly C-injected groups. The frequency with which aqueous flare developed (Fig. 1) paralleled the development of other inflammatory signs. These changes appeared soon after the first injection of poly I·poly C and reached their maximum between the fifth and seventh days. Inflammatory signs were not observed after the ninth day. No signs of inflammation were noted in control group D. In a previous investigation[5], the vascularity of the optic disk was increased by poly I·poly C, but in this study no such effect was noted, perhaps because the drug was given on alternate days instead of daily.

Opacification of the lens began as an increase in sheen posteriorly. This progressed to a posterior subcapsular plaque with posterior cortical changes (Fig. 2). In our initial experiment[5], clear lens fibres were seen behind the opaque lens fibres when the animals were followed for at least 20 weeks (Figs. 3 and 4), suggesting that the toxicity was for developing lens cells only.

Opacities in the anterior vitreous were noted as early as five days after injection of poly I·poly C (Fig. 5). In most instances they appeared to be crystalline in form and may well have been aggregates of poly I·poly C or its derivatives; cellular elements could not be ruled out, however. The opacities persisted for over a month. No changes in the vitreous were noted in control group D.

We considered the possibility that the observed ocular changes induced by poly I·poly C in these experiments were due to endotoxin contamination, but the ocular effects of typhoid endotoxin (100 μg), though similar in a similar model, were much less marked than those induced by the poly I·poly C. Although there were some differences in the degree of ocular toxicities of the three lots of poly I·poly C tested (Figs. 1 and 2), the numbers of animals tested with each lot were not great enough to make any valid comparisons. The 50 per cent mortality in group C, however, was clearly much greater than in groups A and B.

Various side effects of poly I·poly C have recently been reported. An increased mortality rate has been noted in mice; pyrexia and embryotoxic effects have been encountered in rabbits; and toxic effects on thymus and spleen have been noted in mice and rats[6–8]. Clearly, it is important thoroughly to evaluate the toxicity of poly I·poly C before any clinical trials in man.

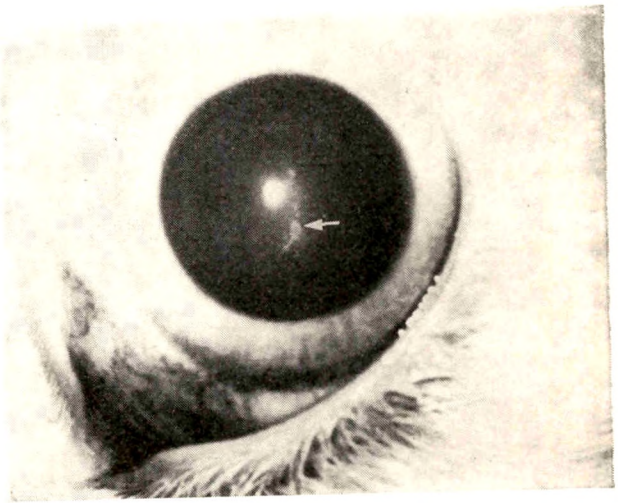

Fig. 3. Lens opacity (arrow) in a rabbit 208 days after intravenous administration of poly I·poly C. On slit lamp examination this was in the posterior cortex and there was a relatively clear zone between the lesion and the posterior lens capsule. The white circular spot is a reflexion of the photographic flash.

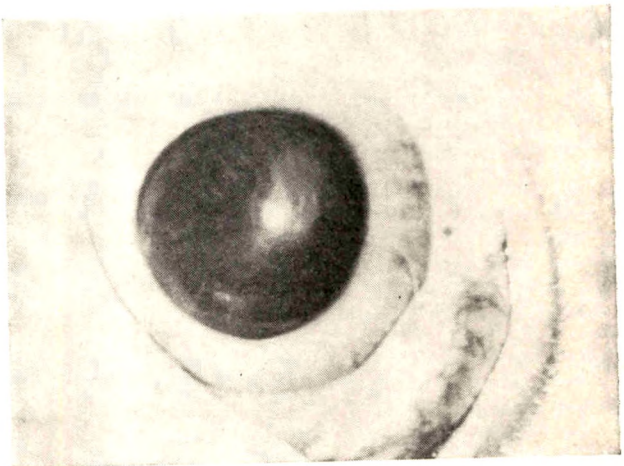

Fig. 4. Photograph of a lens opacity in a rabbit 208 days after the first injection of poly I·poly C. This opacity involved both the anterior and posterior cortex, sparing the inner portion of the lens. Both the central and peripheral lens cortex were involved.

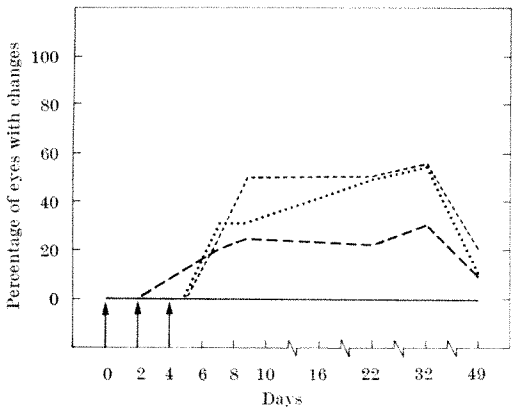

Fig. 5. Frequency of opacities in the vitreous following intravenous poly I·poly C injection. These opacities were discrete needle-like white crystals which were semitransparent, and were unlike the diffuse or focal vitreous opacities seen in infections of the posterior eye. For explanations, see Fig. 1.

Cell Surface Charge Increase by both Tumour Inhibitory and Tumour Growth Promoting Polyanions

Many tumour growth inhibiting substances have been studied in various tumour systems: aliphatic diamines, hydroxy-amines, aromatic bases with two terminal groups[1], the synthetic polypeptides of lysine such as positively charged poly-DL-lysine[2], polyornithine[3], histones[4], lysine-rich histone fractions[5], DEAE-dextran[6,7], polyethylenimine[8,9], polyvinylamine bisulphate and polypropylenimine[9]. The synthetic double-stranded ribonucleic acid—a complex of polyinosinic acid and polycytidylic acid—(poly I·poly C), which is highly negatively charged, has also been demonstrated to inhibit the growth of several transplantable malignant murine tumours of known or unknown viral aetiology[10–17]. Some reports describe the protective action of poly I·poly C on non-viral diseases as well[10,18]. Certain polysaccharides isolated from lichens significantly inhibited the growth of implanted sarcoma-180 in mice and caused complete tumour regression in many cases[19], whereas acid mucopolysaccharides promoted tumour growth[20–29].

An increase in concentration of acid mucopolysaccharide (AMP) has been observed in human patients with proliferating malignant tumours[20,21]; and subjects with disseminated malignant diseases, particularly those with leukaemia, have increased urinary excretion rates of AMP, the major component of which is similar in composition to chondroitin sulphate (CS)[22]. Ozzello *et al.*[23] demonstrated the promoting activity of AMP *in vitro* on the growth of human mammary carcinoma cells, and Takeuchi[24–29] reported that the acid mucopolysaccharide chondroitin sulphate had some promoting effect on the tumour growth. Acid mucopolysaccharides contain hexosamine and hexuronic acid as the structural components[30] but the growth promoting activity of 2 per cent D-glucosamine hydrochloride, 0·2 per cent D-glucuronic acid, and 0·2 per cent N-acetyl-D-glucosamine was not so marked as that of chondroitin sulphate[28]. Takeuchi also observed[29] that the cationic proteins, egg albumen, calf serum and muramidase (lysozyme, EC 3.2.1.17) tended to counteract the promoting activity of chondroitin sulphate on tumour growth. Following current trends (see ref. 44) he suggested that the marked inhibitory effects of these basic proteins on the chondroitin sulphate activity resulted from a decrease in its negative charge.

The α-carboxyl groups (pK approximately 2·8) of neuraminidase-susceptible N-acetylneuraminic acid (NANA) on the tumour cell surface account for the bulk of the charge[31–34] (about 43 per cent of the electron charges[35]). Positively charged amino groups[35], sulphydryl groups[36] and ribonuclease susceptible phosphate groups[37] are also present in the cell periphery and the cells at physiological pH exhibit a net negative charge equivalent to approximately 10^7 electron charges per cell (see ref. 35 for review). The invasiveness and decreased adhesiveness of tumour cells (and other properties), at least in some systems, were attributed to the high electron charge density (anodic electrophoretic mobility, zeta potential) of tumour cells[38–44].

It was recently reported that positively charged polyornithine of high molecular weight inhibited the transplantability of mouse leukaemia, the inhibitory effect being reversed by the highly negatively charged mucopolysaccharide heparin[3]. My electrokinetic studies demonstrated that only the lysine polypeptides of high molecular weight and high charge density, which were reported to inhibit tumour transplantation/development, changed the tumour cell surface negative charge to zero or high positive values, presumably because of adsorption of the polycations on the cell surface; heparin inhibited or reversed this effect[44].

The recent spate of evidence on the highly negatively charged polymer poly I·poly C possessing tumour-inhibiting properties[10–18] and my observations that poly I·poly C increased the net negative charge of the Ehrlich ascites tumour cells[45,46], and the human platelet[45,46] seemed significant, but contradictory to the surface charge hypothesis—"associating high surface charge density with the invasive properties and the unsocial behaviour of tumour cells". These test systems offered an ideal situation to investigate the effect on the surface charge of cells treated with the negatively charged acid mucopolysaccharide (approaching raised levels in human patients) which promoted tumour growth and compare with effects produced by tumour-inhibiting polyanions.

Solutions of polyinosinic acid (1 mg/ml.) and polycytidylic acid (1 mg/ml.) were prepared in phosphate buffered saline (0·01 M phosphate buffer in 0·15 M NaCl containing 5×10^{-3} M Mg^{2+} as $MgCl_2$). Equimolar amounts of poly I and poly C were mixed at 37° C to prepare poly I·poly C. A decrease of about 40 per cent in the absorbance at 245 nm was observed as would be expected from the average absorbances of the unannealed

materials. The molecular weight of the poly I·poly C was believed to be several millions: too large to enter into a 2 per cent polyacrylamide gel in electrophoresis experiments (personal communication from Dr H. Levy of the US National Institutes of Health).

The sample from Bethesda was stored in a freezer and used to prepare test solutions in standard saline (2 mg/ml.). Chondroitin sulphate was supplied by Sigma (London). Electrokinetic studies were carried out as described[35,44].

Earlier, it had seemed plausible that the negative charge on the tumour cell membrane played a part in its invasive properties by way of electrostatic interactions between the positively charged tumour-inhibiting substances and the negative charges on the tumour cell surface. Blocking these sites and imparting the tumour cells, a high positive charge by treating with the polycations could, conceivably, suppress their invasiveness and the other allied properties[44]. The data in Table 1 demonstrate that the negative charge of the tumour cell membrane increased on treatment with both the polyanions poly I·poly C (tumour inhibitory) and chondroitin sulphate (tumour growth promoting).

Table 1. POLYANIONS POLY I·POLY C (TUMOUR INHIBITING) AND CHONDROITIN SULPHATE (TUMOUR GROWTH PROMOTING) INCREASE THE NET NEGATIVE SURFACE CHARGE OF CELLS

Cell type	Treatment	Electrophoretic mobility (μm/s/V/cm (with s.d.)	Change (per cent)
Ehrlich ascites tumour (of mice)*	Control	−1·05 ± 0·06 (105)	
	Poly I·poly C	−4·48 ± 0·09 (200)	×4 the original charge
	Chondroitin sulphate	−1·31 ± 0·06 (150)	+24 per cent
Human blood platelets†	Control	−0·88 ± 0·05	
	Poly I·poly C	−1·18 ± 0·08 (ref. 46)	+34 per cent

* Cambridge Radiotherapeutics strain of tumour[35,36,44].
† Normal healthy individuals.

Numbers in parentheses represent the numbers of cells examined. Evaluation of the electrokinetic parameters: zeta potentials, surface charge densities and the numbers of electron charges per cell, standard deviations, and so on, by the digital computer have been discussed recently[44]. The P values for all these experiments evaluated for the "unpaired" t tests: $P < 0.001$. Only values of electrophoretic mobility are included in this table. The medium was 0·145 M NaCl (pH 7·2 ± 0·2); mobilities were determined at 25° C.

It therefore seems an oversimplification to attribute both invasive properties and tumour growth promoting activities to the high electron charge density of the tumour cell membrane.

Great caution in the interpretation of the electrokinetic data on cells (chemically treated or otherwise) must be emphasized: the concept of charge alone will not explain all the phenomena observed.

I thank Professor J. S. Mitchell and Dr N. Taptiklis for discussion, Mr E. King for supplying the inoculated mice, Miss Janice Wright for technical assistance, and the Cancer Research Campaign for financial support.

Susceptibility of *E. coli* K-12 to Actinomycin D after Infection with Phage M13

Escherichia coli cells are normally impermeable to the antibiotic actinomycin D[1] which inhibits DNA-dependent RNA synthesis[2] and the consequent inducible enzyme synthesis. Leive has shown that after treatment with EDTA, *E. coli* cells are more susceptible to actinomycin D[3] and that a lipopolysaccharide is released from the cell wall[4]. We have confirmed the observation[5] that *E. coli* cells also release a lipopolysaccharide into the medium after infection with the small filamentous phage M13 (unpublished results). Here we show that M13 infected cells are permeable to actinomycin D. It should be noted that M13 infected cells continue to grow and multiply while releasing progeny phage particles[6,7].

E. coli HfrC was grown in modified M9 medium[6] to log phase and then infected with M13 phage at a multiplicity of 10–20. The infected as well as control healthy cells were treated with 20 μg/ml. actinomycin D in the growth medium. Fig. 1 shows that the cells continued

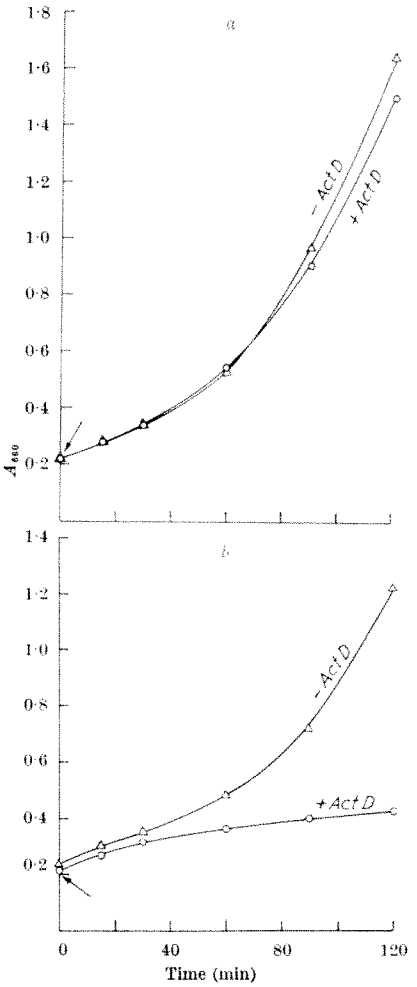

Fig. 1. Kinetics of growth of healthy and M13-infected *E. coli* HfrC in the presence of actinomycin D (20 μg/ml.), which was added simultaneously with the phage in the case of infected culture. The absorbance at 660 nm was measured at different times. (*a*) Normal cells, (*b*) infected cells with and without actinomycin D.

to grow for about 30–40 min when the antibiotic was added simultaneously with the phage. Then the growth of the infected cells almost levelled off while the growth rate of the healthy cells was not affected by the presence of the antibiotic. The addition of the antibiotic at different times after infection indicated that the infected cells become permeable to the antibiotic at about 30–40 min after infection. It has also been found that infected cells rapidly lose the ability to form colonies after treatment with the antibiotic even if it is removed before plating on nutrient agar. Control experiments indicated that the viability of healthy cells is not affected by the presence of the drug.

Fig. 2 is a photomicrograph of the M13-infected cells with and without treatment with actinomycin D. The healthy and infected cells were almost of comparable size, about 2·4 μm long, whereas the antibiotic treated infected cells became three to four times as long, suggesting lack of cell-septum formation. Actinomycin D has a similar effect on *B. subtilis* cells, which are normally permeable to the antibiotic[1]. With *E. coli*, there is no evidence of cellular lysis and the viability studies indicate that the elongated cells cannot form colonies. If we assume that actinomycin D specifically inhibits RNA synthesis without affecting DNA synthesis, then presumably the elongated cells are multinucleate and cell division is prevented. Various antibacterial agents of completely different modes of action are known to produce filamentation in *E. coli*[8–10]. The mechanism is not completely understood.

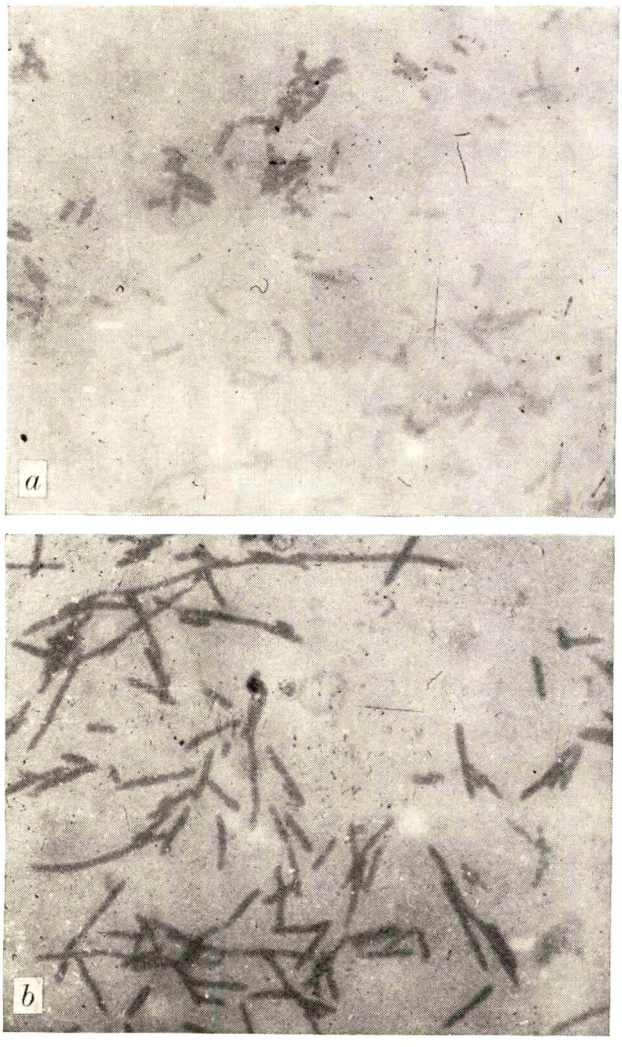

Fig. 2. Photomicrograph of *E. coli* cells stained with crystal violet. *a*, Infected cells; *b*, infected cells treated with actinomycin D for 2 h. The drug was added along with the phage (×*c.* 1,400).

The relationship between lipopolysaccharide release and actinomycin D susceptibility may be fortuitous. The site of the permeability barrier to actinomycin D in *E. coli* is presumably the cell wall, for the *E. coli* spheroplasts are permeable to the former[11]. We have recently found, however, that infection with M13 does not produce all the effects of EDTA treatment in *E. coli*. For example, periplasmic enzymes and acid-soluble ultraviolet absorbing materials are not released (unpublished results).

We thank Dr P. Hofschneider for the *E. coli* HfrC and M13 phage strains, Dr W. Gall of Merck, Sharp and Dohme for the gift of actinomycin D and Dr S. Chaudhuri for photography. The research was supported by a grant from CSIR, India.

Collagenolytic Activity of Sarcoma Tissues in Culture

The possibility that the invasiveness of malignant tissues may result from collagenolytic action of tumour cells was early considered[1–3]. This idea, however, was not supported by subsequent efforts to isolate a specific enzyme from neoplastic tissues or by attempts to obtain lysis of collagen enclosed in perfusion chambers embedded in tumour bearing animals[4].

With the demonstration that certain non-tumour epithelial tissues could produce an enzyme specific for the hydrolysis of reconstituted collagen in physiological conditions[5], interest in the collagenolytic capacity of tumour cells was renewed. First observations indicated that only epithelial cells were able to produce the lytic enzyme[6,7]. More recently, reports of degradation of collagen by non-epithelial tissues have appeared[8–10], but because most of these tissues were either abnormal or infiltrated with inflammatory cells, a question regarding the collagenolytic capacity of normal connective tissue cells still exists. There has been no convincing evidence of collagen lysis by normal tissues of mesodermal origin such as fascia, dermis, muscle or nerve. The role of infiltrating lymphoid or granular cells has not yet been thoroughly investigated.

Riley and Peacock[11] reported collagen lysis in cultures of a series of neoplastic and normal human tissues. They concluded that collagen breakdown was primarily associated with epithelial and not with deep connective tissue elements. The tumours of connective tissue origin which they tested did not produce lysis of collagen.

We report here the results of culturing fragments of human tumours on a collagen substratum in an effort to determine whether neoplastic tissues of mesenchymal

origin differ in collagenolytic activity from those of epithelial origin.

Collagen was dissolved by weak acid from rat tail tendons and reconstituted as a film on glass coverslips according to the method of Bornstein[12]. Small samples of tumour proper having the gross appearance of viable tissue were dissected from human tumour biopsies. These were cut into 1 mm cubes for culture. Each small fragment was then placed in the centre of a collagen film and covered with a sheet of sterile 'Cellophane' dialysis membrane moistened in Hanks solution. This was assembled into a multipurpose culture chamber[13] which was then filled with Eagle's basal medium containing 10 per cent bovine embryo serum and incubated for periods of from 1 to 8 days. To see how much digestion had taken place, we fixed the collagen film in Bouin's fluid and coloured it with van Gieson's stain. Areas around active fragments where collagen had been hydrolysed remained unstained (see Fig. 1).

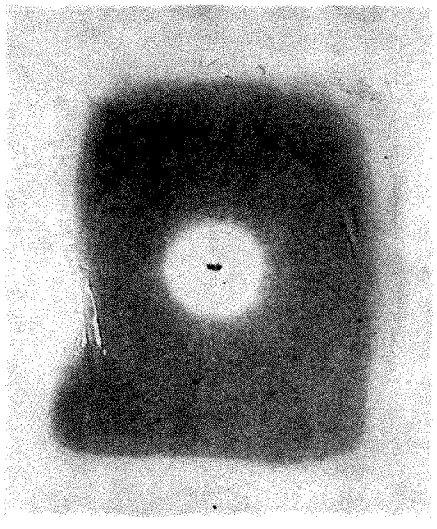

Fig. 1. Appearance of a collagen film stained after culturing for 3 days with a rhabdomyosarcoma fragment. The tumour fragment is in the centre of a clear area where the collagen has been removed by enzyme digestion.

Table 1 summarizes more than 300 cultures from 36 specimens removed from patients at the University of Texas M. D. Anderson Hospital and Tumor Institute at Houston. Most of the samples of carcinoma (21 out of 30) exhibited lysis of the collagen film. These findings support those of Riley and Peacock[11]. On the other hand, four of the six sarcomas tested also produced collagen breakdown (Fig. 1). The collagenolytic capacity of these neoplastic forms of striated muscle and fibrous connective tissue is in distinct contrast to normal tissues of the same types which have, in repeated tests, consistently failed to digest collagen.

Although there were tissues in both categories of tumour which did not digest collagen, this fact cannot be considered evidence that the tumour cells were incapable of elaborating collagenolytic enzyme. Numerous experiments have shown that the liberation of collagenase can occur only from synthesizing cells[5,6]. The lack of collagen lysis in some of the negative cultures may be because the tissues isolated from the tumour for culture did not survive. In such cultures, there was histological evidence of necrosis of the tumour cells. In cultures which did digest collagen, living cells were seen either in phase contrast examination of the cultures themselves or in histological sections of the cultured fragments. In the circumstances of these tests, therefore, the number of negative cases in the two categories of tumour is not of prime importance. What is of particular significance is the fact that some of the tumours of non-epithelial origin were capable of producing an enzyme that hydrolysed collagen, just as do some normal and malignant epithelial tissues.

If normal mesodermal tissues are unable to lyse collagen, it seems that the neoplastic transformation of mesenchymal tissues induces synthesis of a collagenolytic enzyme.

Lymphocyte-mediated Transport of Aggregated Human γ-Globulin into Germinal Centre Areas of Normal Mouse Spleen

GERMINAL centres develop early in the immune response, and although knowledge of these structures is far from complete, they are known to be intimately associated with the capacity to produce specific antibodies after antigenic stimulation[1]. The localization of antigen in these centres coincides with the appearance of specific serum antibody[2], which is found in a close relationship to reticular cells in these areas[3]. It produces a characteristic dendritic intercellular pattern of immunofluorescent staining or autoradiography when isotopically labelled. This localization of antigen in germinal centres did not occur in rabbits

rendered tolerant to haemocyanin or human serum albumin[4], but injected immune complexes produced an identical pattern of localization of antigen in germinal centres in normal rat lymph nodes[5].

More recent studies[6] have established that alteration of heterologous IgG either by heat aggregation or by complexing as antibody with specific antigen is necessary for its localization in the germinal centres of auricular lymph nodes of normal guinea-pigs after injection into the ear. Such localization was not seen in animals given native, monomeric heterologous IgG. Nevertheless it does not depend on the antigenicity of the injected aggregate, for it was also seen in animals rendered specifically tolerant.

Thus germinal centre localization of antigen is mediated by specific antibody molecules through the configurational changes that they undergo on complexing with antigen, but the localization mechanism itself is obscure. With regard to localization, aggregated human IgG behaves identically to the antibody component of immune complexes[6]. It therefore provides a convenient substitute for complexes in further studies of the localization mechanism.

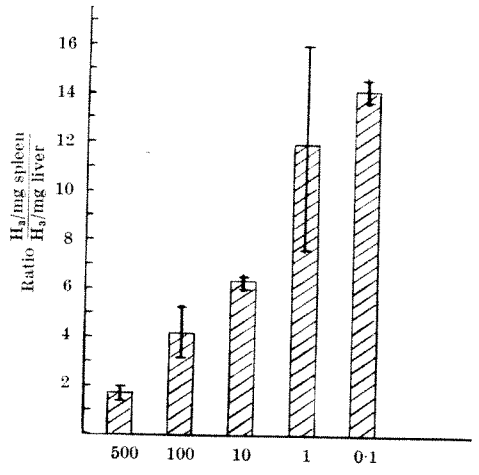

Fig. 1. Uptake at 24 h of human IgG aggregate by spleen and liver tissues in Balb/c strain adult mice. Vertical lines show range (500, 100, 0·1 μg, two mice; 10 μg, four mice; 1 μg, eight mice).

Preliminary experiments showed that heat aggregated[6] human IgG becomes localized in germinal centres in the white pulp of the mouse spleen within hours of intravenous injection. Normal mice were then studied using heat aggregated human IgG labelled with ^{125}I. A monospecific rabbit anti-human IgG fluorescein conjugate was used to produce immunofluorescence. Intravenous injection of less than 10 μg aggregated human IgG produced a dendritic pattern of germinal centre staining in the spleen. There was no evidence of phagocytosis of this material by macrophages in the red pulp of this organ or by the Kupffer cells of the liver. With larger amounts of aggregate, extensive phagocytosis of IgG by macrophages in the liver and spleen was seen. This phagocytosed material was rapidly catabolized, as shown by loss of isotopic label and loss of fluorescence from the spleen and liver, both more or less completed by 24 h after injection. At this time there was always bright germinal centre staining of IgG.

In the guinea-pig experiments[6], this germinal centre localization persisted for at least 4 weeks. It therefore seemed that germinal centre localization of human IgG is one means of preserving molecules of this protein intact in the body. This preservation of aggregated IgG by the mouse spleen (Fig. 1) is shown by the increasing ratio of spleen/liver uptake 24 h after intravenous injection of decreasing doses of protein. Maximal incorporation of

Table 1. SPLENIC UPTAKE AND GERMINAL CENTRE LOCALIZATION OF CEL BOUND AGGREGATED HUMAN IgG ON TRANSFER TO SYNGENEIC Balb/c MIC

No. of recipients	Cell source	No. of cells transferred	Protein bound to cells (μg)	Splenic uptake at 24 h (μg)	Germinal centre staining
1	Blood leucocytes	$2{\cdot}6\times10^6$	5·7	0·016	Negative
2		20×10^6	7·29	0·023	Negative
2		40×10^6	6·21	0·028	+
2	Spleen	100×10^6	8·0	0·096	++

aggregated IgG into the germinal centre of mice spleens occurred 24 h after intravenous injection, when most of the phagocytosed material had been catabolized. Immunofluorescence a few hours after injection of aggregated IgG showed a diffuse pattern of localization in the white pulp marginal zones and after 24 h the typical dendritic pattern of distribution had developed. Mouse complement was not detected by staining in these areas in sections treated with rabbit anti-mouse complement conjugate. Because lymphocytes are the cells which characteristically migrate from the blood to the splenic white pulp[7], cells of this type might be involved in the mechanism whereby aggregated IgG reached germinal centres. Two types of experiment were done.

In the first, peripheral blood leucocytes or spleen cell suspensions from normal C57Bl or Balb/c mice were incubated *in vitro* with ^{125}I-labelled aggregated human IgG in medium 199 containing normal mouse serum at 4° C. Uptake was measured by scintillation counting. In these conditions 10–20 per cent of the radioactivity was retained after exhaustive washing of the cells. Immunofluorescence revealed that at least 40 per cent of the cells had taken up the IgG on their surface membranes in a characteristic staining pattern. These had the morphological features of lymphocytes and not macrophages. The cell membrane staining was punctate and distributed uniformly around cells like a necklace. Occasional cells showed polar staining with concentration of IgG at one or two areas on the surface of the membrane. Table 1 shows that the intravenous injection of 40×10^6 peripheral white cells or 100×10^6 splenic cells, pre-incubated in this way with aggregated IgG, caused germinal centre localization of IgG in the spleens of normal syngeneic recipients. It should be noted that less than 1 per cent of the injected IgG was localized in the spleens in this way, the rest being catabolized. Thus many of the cells carrying human IgG were either removed by the phagocytic cells of the recipients or lost their labelled IgG to them. The amount of aggregated IgG on the cells if given alone would have resulted in some germinal centre staining. It was therefore possible that some IgG was transferred in some way from the donor cells and was subsequently localized in germinal centre areas of the spleens of recipients. Further studies are required to investigate this crucial point using lymphoid cells pre-labelled with isotopically labelled precursors of DNA and RNA. Because lymphocytes were postulated to be transporting the aggregated IgG into germinal centres it was considered possible that the protein demonstrated in these areas was on lymphoid cells closely apposed to the dendritic cells[3]. When spleens which would have shown staining confined to germinal centres were teased into single cell suspensions and stained for IgG with the anti-human IgG fluorescein conjugate, many lymphocytes with a characteristic membrane fluorescence were found. It can therefore be argued that at least part of the localization of aggregated IgG in germinal centres of normal mouse spleens was due to lymphocytes with this protein on their surfaces.

If localization of aggregated human IgG occurs by a lymphocyte mediated mechanism in which circulating lymphocytes transfer it into the white pulp of the spleen where it becomes concentrated in germinal centre areas, interference with the functions of these cells should prevent this characteristic localization. Antilymphocytic serum can be considered to possess this property[8]. Mice treated with the γ-globulin prepared from a potent

Table 2. EFFECT OF ANTILYMPHOCYTIC IgG ON SPLENIC UPTAKE OF AGGREGATED ^{125}I-HUMAN IgG 24 H AFTER INTRAVENOUS INJECTION INTO Balb/c MICE

No. of mice	Treatment	Dose of human IgG (μg)	Mean splenic uptake*	Germinal centre staining

antilymphocytic serum were found to be unable to localize aggregated human IgG in the germinal centre areas of their splenic white pulp.

Table 2 shows the results of such an experiment. Antilymphocytic IgG given in two spaced injections reduced the splenic retention of aggregated ^{125}I human IgG 24 h after injection to 28 per cent of that in mice given either human IgG alone or human IgG and the same quantity of normal rabbit IgG instead of antilymphocytic IgG. This reduction of uptake was correlated with negative immunofluorescence. Another experiment (Table 3) showed that this effect of antilymphocytic IgG was dose dependent. Results not shown here indicated that significant prevention of localization of aggregated human IgG in germinal centres lasted for about 48 h after administration of 5 mg of antilymphocytic IgG.

Table 3. SPLENIC UPTAKE AND GERMINAL CENTRE LOCALIZATION OF AGGREGATED HUMAN IgG* IN PAIRS OF MICE PRE-TREATED WITH ALG

These results indicate that a large proportion of lymphocytes in the blood and spleens of normal mice can take up aggregated human IgG on to their surface membranes. The *in vitro* uptake is unlikely to involve binding of C1q because complement was not present in the medium. Presumably these cells possess specific receptors for altered gamma globulin. The nature of this receptor and the functional significance of these cells is being studied. Lymphocytes of normal mouse spleen possess receptors for specific antigen[9,12] and the present studies indicate that a large number of lymphocytes apparently possess receptors for altered human γ-globulin. It is therefore postulated that for every lymphoid cell possessing receptors specific for any given antigen there are many more with receptors for altered antibody, and it is possible that all antigen reactive lymphocytes possess receptors for altered γ-globulin. If this were so, a recruiting mechanism for induction of the immune response to an antigen would exist. Only a few antigen reacting cells need respond to their specific antigens by producing specific antibody. These antibodies would form complexes with their antigen which would in turn be the means of recruiting other cells carrying immunoglobulin receptors for altered γ-globulin. Lymphocytes carrying these complexes would become localized in the white pulp of the spleen or the cortex of lymph nodes, where they could migrate to the germinal centres. This would explain the mechanism of localization of autologous immunoglobulin in germinal centres. Thus antigen would be brought to areas where it could play a crucial, direct part in regulating the production of new cells capable of producing specific antibodies during their migration from germinal centres to the red pulp of the spleen and medullary areas of lymph nodes. The suppression of localization of aggregated human IgG by antilymphocytic IgG in these studies suggests that the cells involved form part of the recirculating pool of lymphocytes, and are either of thymic origin or are dependent on the presence of an intact thymus[13]. Such a population of cells functioning in the immune response to antigen in the manner suggested could provide a basis both for the mechanism of action of early antibody in enhancing the response to sheep erythrocytes[14] and also for the suppression of the response by antibody[15,16]. The importance of these cells in immune responsiveness to antigens is being evaluated.

Antibody Response to Tumour Xenografts in Mice treated with Antilymphocyte Serum

Antilymphocyte serum (ALS) has been shown to suppress the cell mediated response to tissue grafts[1], but its effect on the humoral response is less marked[2]. A system for assessing the effect of ALS on the humoral response to xenografts is provided by the human tumour line HeLa grown in mice treated with ALS[3]. We have therefore studied the antibody response to HeLa cells in mice treated with ALS and bearing HeLa cell tumours, using a fluorescent antibody technique.

ALS was prepared in rabbits and assessed as previously described[3]. Sera of adequate potency were pooled and stored at −20° C. Swiss mice were injected subcutaneously with 0·5 ml. of ALS three days before tumour transplantation, and with 0·25 ml. on the day of transplantation and on alternate days thereafter. HeLa cells were maintained *in vitro* as previously described[3]. Mice were injected subcutaneously in the ventral midline with 0·1 ml. of cell suspension, each mouse receiving approximately 5×10^6 cells. Tumour-bearing mice were bled at approximately 5 day intervals from day −3 to day 30; the sera were separated and stored individually at −20° C. Mice were killed on day 30, the tumours excised, snap

frozen, and stored at −20° C until they were examined for antibodies.

Antibodies to pooled normal mouse globulins were prepared in New Zealand white rabbits, and conjugated with fluorescein isothiocyanate[4]. Sections (5 μm) of excised tumour were cut on a cryostat and incubated with rabbit anti-mouse conjugate for 15 min at room temperature. Control sections were incubated with unconjugated rabbit anti-mouse γ-globulin before incubation with the conjugate.

Free serum antibodies were demonstrated using a method adapted from that of Moller[5]. Equal aliquots of viable HeLa cells from *in vitro* cultures were incubated with measured amounts of serum from tumour-bearing mice for 15 min at room temperature. The cell suspensions were washed with balanced saline solution (BSS), incubated with conjugate and washed three times with BSS to remove free conjugate. The number of cells in a total of 500 showing membrane (ring) fluorescence was then estimated for each serum, and the fluorescent index was calculated[6] as the ratio

$$\frac{\text{Percentage unstained cells after incubation with normal serum} - \text{percentage unstained with immune serum}}{\text{Percentage unstained cells after incubation with normal serum}}$$

Control cell suspensions were incubated with serum from tumour-bearing mice and unconjugated anti-mouse serum before incubation with conjugate, with normal mouse serum before incubation with conjugate, or with conjugate alone.

Bound antibodies were apparent on all excised tumours. Cells in the central necrotic areas of the tumours exhibited the diffuse fluorescence characteristic of dead cells, but particulate staining of globulin on the cell membrane was also apparent on these cells and on viable cells at the periphery. Particulate membrane staining on control sections was reduced or absent. Approximately 15 per cent of cells incubated with sera from untreated mice before injection with tumour and ALS gave fluorescent staining. Positive fluorescent indices were obtained with sera from all mice bearing progressively growing tumours; positive fluorescent indices were not, however, obtained with either of the controls. It remains to be determined whether the apparent decrease in free serum antibody titre during tumour growth is the result of an increase in the rate of absorption of antibodies by the tumour, or of the induction of tolerance by ALS, and whether tumour enhancement is occurring.

We thank Mr L. Hudson for advice during preparation of the manuscript.

Retrogenetic Expression: the Reappearance of Embryonal Antigens in Cancer Cells

VARIOUS reports of embryonal antigens in extracts of tumour tissues have appeared since 1932 (refs. 1–9). Such antigens, absent from homologous normal tissues, have been detected in colonic[6], hepatic[7] and lung cancers[8]. These findings stimulated a study of the possible universal appearance of embryonic antigens in cancer tissues.

The Swiss white mouse was chosen for the investigation for the following reasons: (1) many well characterized tumours are readily available; (2) chemical, viral and radiation induced cancerous lines are easily produced; (3) embryonal extracts from known developmental stages can be prepared with facility; (4) maximum heterogeneity of antigens may be expected in a random-bred strain; (5) test material may be obtained easily and in large quantity.

Antisera have been prepared in the rabbit, using whole mouse embryo extracts as immunizing antigen. Sera were screened by Ouchterlony agar diffusion and immuno-electrophoresis methods[10,11] against normal embryonal, neonatal and adult antigens extracted from the respective tissues, and against seventy-two extracts of malignant cells or tissues from cancerous animals.

Embryos were obtained free of maternal tissue from random bred Swiss white mice (Millerton Research Farms) after various periods of gestation. These were minced, washed in phosphate-buffered saline and homogenized in a VirTis "45" at 35,000 r.p.m. for 2 min. Tumour and normal adult tissues were similarly extracted in three times the wet cell volumes of sal-P (0·15 M NaCl, 10^{-4} M PO_4, *p*H 7·2). The homogenates were centrifuged at 1,500*g* for 10 min and the supernatants were dialysed against three changes of 500 volumes of sal-P and lyophilized. All operations were performed at 4° C.

For immunization the lyophilized embryonal material was resuspended in sterile distilled water at 15 mg/ml., and emulsified with equal volumes of Freund's adjuvant. Subcutaneous injections of 2 ml. each were administered weekly for 3 weeks, using complete adjuvant. Booster injections of 2 ml. were prepared with incomplete adjuvant and administered intramuscularly one month following the first injection. Blood was collected from the marginal ear vein weekly for 4 weeks, starting 10 days after the booster.

The cancer tissue extracts were obtained from seventy-two specimens originating in eighteen different mouse strains. The cancers arose in twelve diverse tissues following induction by viral agents in twenty-one instances (Bittner, Gross, Rauscher and Friend), and by chemical agents in twenty instances (methylcholanthrene, dimethylbenzanthracene, benzpyrene, urethane and stilboestrol); two arose following X-irradiation and twenty-nine of "spontaneous" origin were obtained from various laboratories[12–20].

Rabbit antisera to mouse embryo extracts prepared on the ninth to the nineteenth day of gestation all produced double-diffusion precipitin lines in agar with extracts of normal adult tissues as well as with extracts of tumour tissues. A composite extract of five organs (heart, lung, spleen, liver and kidney) from two female and two male adult mice was used to absorb the sera. The composite extract-absorbed serum from a rabbit immunized with 19 day embryo extract, designated AS-19, reacted to produce precipitin lines with the extracts of all seventy-two cancers, but failed to react with extracts of mouse L-cells

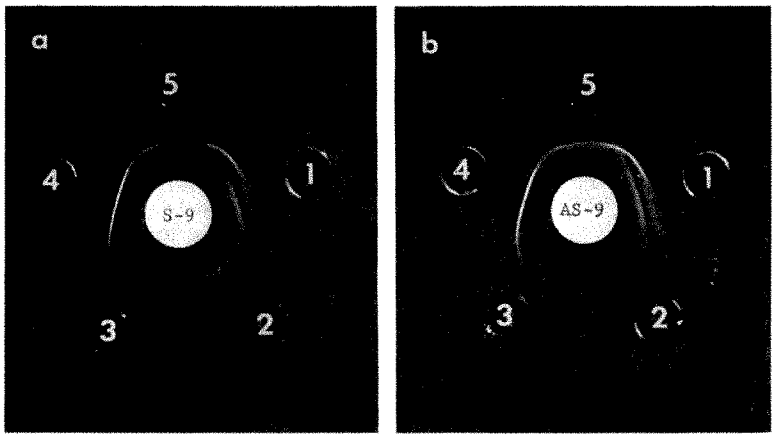

Fig. 1. Double diffusion precipitin reactions in agar gels. Immune sera in centre wells, antigen extracts in peripheral wells. 1, Embryo, 19 days; 2, spleen, normal Swiss white; 3, liver, DBA/2, solid tumour-bearing animal; 4, spleen, Swiss white leukaemic mouse (Friend); 5, skin, normal Swiss white. Wells of Micro-Ouchterlony plates (7 mm well spacings, Hyland Labs.) each received 0·005 ml. Antigens were adjusted to 10 mg protein/ml. for the tests. *a*, Unabsorbed anti-embryo immune serum; *b*, immune serum absorbed with adult extract.

and with any of the normal adult tissue extracts tested, except skin, small intestine and regenerating liver. Because the 19 day embryo contains a higher proportion of epithelial tissue than does the 9 day embryo, this would be reflected in the extracts. Accordingly, serum S-9, from a rabbit immunized with 9 day embryo extracts, was used in subsequent work. After absorption with adult antigen (composite extract) this antiserum (AS-9) was found to interact only with extracts of adult skin, the seventy-two cancer extracts, and with embryonal and neonatal extracts (Fig. 1).

Embryo-specific murine antigens reappear in adult cells following malignant conversion. These antigens were not detected in normal cells with one exception, but have been demonstrated in a variety of murine strains in which malignant transformation had been induced by viruses, chemicals or radiation, or by some unknown "spontaneous" event. These results suggest that, at least in the mouse, the reappearance and the persistence of embryonal antigens in malignant cells are universal phenomena.

Embryo-specific gene products have been identified in various tissues of cancer patients[1–8,21,22] and in polyoma virus transformed cells[23]. Embryonal polymerase activity has been described in tumours of the adult chicken[9]. Antibodies to embryonal antigens have recently been demonstrated in the sera of cancer patients[24]. These and other similar findings indicate disturbances of gene control which may be considered examples of retrogenetic expression. This is manifested by the acquisition of properties abnormal for the adult cell, such as the appearance of embryonal gene products and unrestrained growth.

Assuming the totipotency[25] of differentiated adult cells which contain an intact nucleus[26], a random disturbance in the established gene constellation may activate some dormant foetal function. This will occur with increasing probability as the ratio of embryonic to adult genes increases. If this ratio is of the order of 10^4 in mammalian cells it would be difficult to identify an unbalanced cell that lacked embryonic antigens. That no such cell line was identified among the seventy-two specimens examined in the present study is consistent with the earlier conclusion that one consequence of oncogenesis is the reappearance of embryo-specific gene products.

The completion of embryogenesis and regeneration, both proliferative phenomena, are marked by the repression of certain gene functions. The syntheses of the antigenic gene products common to both embryo and tumour tissues are each handled differently; it appears that the tumour has acquired the high proliferative activity of the embryo without its shut-off mechanisms.

The most serious dilemma concerns the occurrence of embryonal antigens in tumours and in normal skin. It may be that the tumour and embryonal antigens are not entirely identical and may yet be distinguished from those in the skin extracts when analytical procedures of greater resolution are used. Insight may be gained when the antigens involved are identified biochemically, for they may be products of derepression or they may themselves have derepressive activity.

It cannot be determined from the present investigation whether retrogenetic expression is a cause or an effect of cancerigenesis. The oncogenic event disturbs the existing controls and establishes an aberrant arrangement of activated genes characteristic of the malignant cell. What constitutes the control factors, and what controls these, remains a speculative issue.

We thank Drs F. S. Philips and E. Borenfreund for discussing the work with us and Drs D. J. Hutchison, C. Friend, K. Sugiura, F. A. Schmid and Mr R. Nowinski for providing samples. We also thank Mrs L. Benet and Mr P. Higgins for technical assistance. The work was supported by grants from the National Cancer Institute, the Atomic Energy Commission and the American Cancer Society, the First National City Bank Grant for Research from the American Cancer Society and the Health Research Council of the City of New York.

Investigation of Leucocytes from Chickens with Marek's Disease

THERE is evidence that the aetiological agent of Marek's disease is a herpes-type virus[1–4], which has been propagated successfully in chicken embryo fibroblasts (CEF), duck embryo fibroblasts (DEF) and chick-kidney cells (CKC)[1,5,6]. Virus-like particles have been found in tumours, peripheral leucocytes and plasma pellets from birds with Marek's disease[7,8]. We have made electron microscopic, fluorescent antibody and bioassay studies of leucocytes from chickens with Marek's disease.

Blood (30 ml.) collected from chickens infected with the Conn-A[9], Conn-B[10] and JM[11] strains of Marek's disease and showing clinical signs of Marek's disease was placed in centrifuge tubes containing 1,000 U of heparin. The same quantity of blood was collected from uninfected birds, identified as such by histopathological examination of brain, sciatic nerve and spinal cord. Leucocytes were separated either by leaving the blood for 2 h at 4° C, after which the plasma leucocyte suspension was removed with a pipette, or by the method of Vallee *et al.*[12]. Cells were washed twice in Tris-buffered saline and then resuspended in Eagle's basic medium with 20 per cent calf serum and 10 per cent chicken serum free of Marek's disease antibodies as determined by the agar gel precipitin test[13].

Between 3 and 4×10^6 cells/ml. in 60 ml. of medium of infected cells were placed in one side of a double sidearm spinner flask (membrane type) (Bellco Glass Inc., Vineland, New Jersey), separated by a 45 μm filter, while the other side received the same number of uninfected cells. A separate flask with uninfected cells served as a control. The spinner flasks were placed on a multi-stir magnetic stirrer adjusted to 90 r.p.m. and kept at 37° C. Infected and uninfected cells were bioassayed before incubation by inoculating 4 day old COFAL negative chicks with 0·05 ml. of cell suspension intracerebrally. Chicks were isolated for 2 weeks, then killed and examined for Marek's disease lesions as described before[5]. Subsequent samples were taken after 12, 24 and 48 h from both sides of the spinner flask for further bioassay in 1 day old chicks, fluorescent antibody studies and electron microscopic examination. To test the integrity of the separating filter, *Salmonella typhimurium* was added to one side of the spinner flask at the end of the experiment and a bacteriological examination was made on each side of the flask 12, 24 and 48 h later.

Antisera used in fluorescent antibody studies were prepared in rabbits against plasma pellets from heparinized infected whole blood prepared as described earlier[8]. Rabbits received eight injections, four intraperitoneally with complete Freund's adjuvant; two intravenously, and two intramuscularly with no adjuvant. They were bled 12 days after the last inoculation. Rabbit serum was absorbed twice for 12 h at 4° C with leucocytes from birds free of Marek's disease. Different batches of cells of the same origin were used each time. Serum was then centrifuged at 10,000*g* for 20 min and used in the indirect staining method. Culture medium from the spinner flask was centrifuged at 400*g* for 5 min.

Cells were washed twice with saline, resuspended in fresh buffer to a concentration of $1{\cdot}0 \times 10^6$ cells/ml., smeared on slides, allowed to dry, and fixed in acetone for 8 min. A drop of rabbit serum diluted 1 : 10 was placed on the smear, allowed to react for 30 min at 37° C, washed and reacted to fluorescein-tagged anti-rabbit globulin. The number of stained cells out of approximately 500 cells was recorded and the percentage of positive cells calculated.

For electron microscopic studies, cell pellets were covered with 1 per cent glutaraldehyde, dehydrated in alcohol and embedded in 'Epon'. Thick sections (0·5 μm) were cut, stained with methylene blue, and observed under the light microscope, while thin sections were examined under the electron microscope.

In vitro infected cells had a faster metabolic rate, indicated by changes in *p*H, but counts revealed no significant multiplication. Infected cells also tended to clump after 12 h in culture, and so did uninfected cells after about 24 h in the two-sided spinner flask, but not in the single sidearm flask.

Table 1. INFECTIVITY OF WHITE BLOOD CELLS FROM MAREK'S DISEASE AND NORMAL CHICKENS FOR 1 DAY OLD CHICKS AFTER BEING CULTURED IN SPINNER FLASKS SEPARATED BY A 45 μm FILTER

Experiment	Marek's disease isolate	White blood cells	h of postcultivation 0	12	24	48
(1)	Conn-A	MD	4/4*	NT†	4/4	2/4
		Normal	0/4	NT	3/4	2/4
(2)	JM	MD	3/4	NT	2/4	1/4
		Normal	0/4	NT	2/4	0/4
(3)	Conn-B	MD	4/4	NT	4/4	4/4
		Normal	0/4	NT	4/4	3/3
(4)	Conn-B	MD	4/4	4/4	NT	NT
		Normal	0/4	4/4	NT	NT

* Number of chicks with lesions/total necropsied.
† Not tested.

Four sets of results for the bioassay of the double sidearm spinner flask cultures are shown in Table 1. Marek's disease agent apparently crossed the filter and infected the normal white blood cells. Fluorescence revealed that the number of immunofluorescent-positive cells increased during culture and that the percentage of positive cells continued to change for 48 h. When cells that had clumped were isolated and stained, 95 per cent of them were immunofluorescent-positive. Only 1–2 per cent of uninfected cells were weakly fluorescent before culture, increasing to 30 per cent at the end of 48 h, while never more than 1 or 2 per cent of cells kept in separate flasks were positive. The results of fluorescent antibody tests are summarized in Fig. 1.

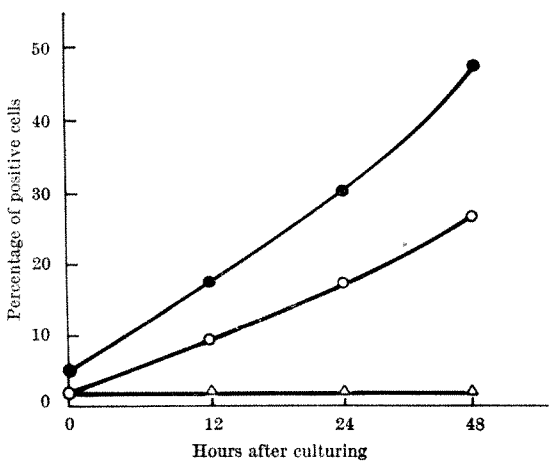

Fig. 1. Proportion of immunofluorescent-positive cells during the first 48 h in culture. ○, Side of flask with infected cells; ●, side of flask with uninfected cells; △, uninfected cells in a separate flask.

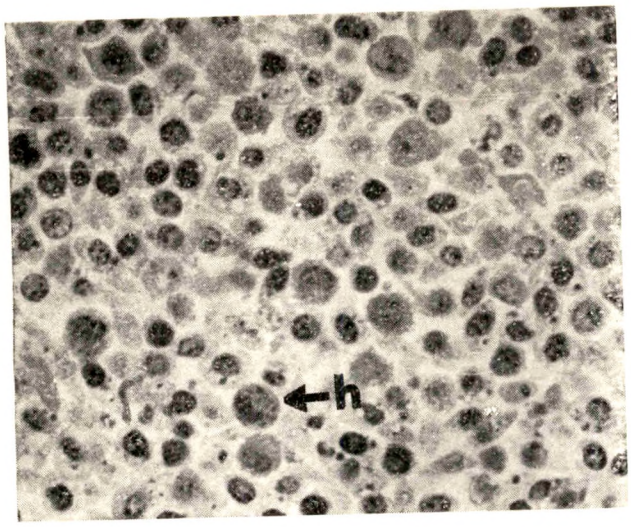

Fig. 2. Light micrograph showing a thick section from infected suspension culture. Note the number of heterophiles (h). (×160.)

When thick sections were viewed under the light microscope, most cultured cells looked similar (Fig. 2). Fresh leucocytes had no special morphological features and only after being put in culture did they change. Most cells were rounded, with round and irregular nuclei, with no cytoplasmic or nuclear inclusions.

Under the electron microscope, infected cells cultivated *in vitro* were undifferentiated with irregular nuclei, enlarged mitochondria or variable forms, sometimes containing filaments. These were cells of the heterophile type, characterized by large cytoplasmic granules and containing unidentified particles 120 to 150 nm across (Fig. 3).

Marek's disease agent has been reputed to be closely associated with cells[1], but in this study the agent seemed to cross the filter membrane and infect normal leucocytes. It is possible that all previous attempts to transmit Marek's disease with cell-free material have failed because of the methods used.

Again freshly isolated cells had no special morphological features and only changed when in culture. Infected cells clumped after at least 12 h in culture. This property has been observed in abnormal human leukaemia cells[14].

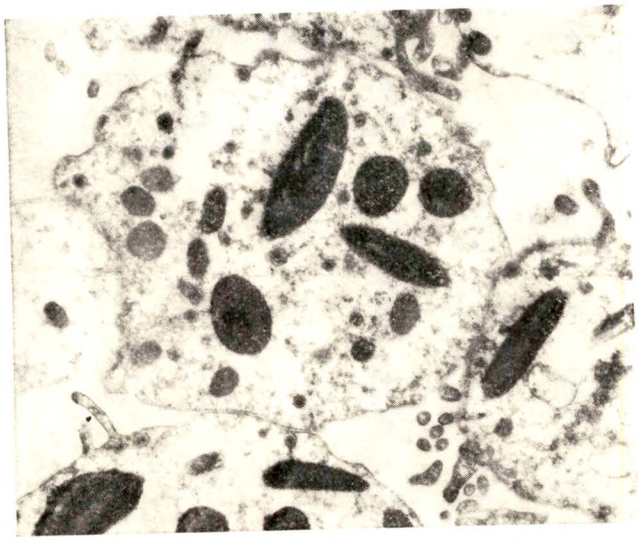

Fig. 3. Thin section of heterophile cells showing unidentified particles and long cytoplasmic projections. Infected cell culture 24 h in suspension. (×11,000.)

DeHarven[15] noted that cells that formed clumps were characterized by tight interdigitation of cytoplasmic processes. Our findings suggest no explanation for this, but because it is only an affinity displayed by infected cells, infectivity must be a contributory factor. The increase in fluorescent cells was also observed in normal leucocytes cultivated with infected cells separated by the membrane. The antigen demonstrated by immunofluorescence seemed to correlate with infection. Similar observations have been reported with Burkitt's lymphoma[16]. Work with human leukaemia cells has indicated the presence of virus particles in degenerating cells[17]. Herpes-type virus has also been suggested in frog tumours with and without outer envelopes with uncoated particles predominating[18–20]. It is interesting to note the similarity in the behaviour of the infected cultures *in vitro* (clumping, fast metabolic rate and increase in immunofluorescent-positive cells) to that described for human leukaemia cells. Further studies with chicken leucocytes infected with Marek's disease could be of great importance in understanding lymphoproliferative disorders in other species.

A most striking observation was the presence of particles exclusively to heterophile cells. Dhingra and co-workers[21] described the heterophile of birds and reptiles as the equivalent of the neutrophile in mammals. Approximately 200 thin sections of infected leucocytes were studied and only a few lymphocytes were observed to contain these particles.

Effects of an Imprinting Procedure on RNA Polymerase Activity in the Chick Brain

Exposure to an imprinting stimulus has been shown to be associated with an increase in incorporation rates of lysine into protein and uracil into RNA in the forebrain roof in one-day-old chicks' brains[1,2]. A maximum increase in RNA incorporation is seen at 76 min after the start of

the imprinting procedure and in protein incorporation at 120 min. Studies of the changes occurring in other protein synthesizing systems in response to external stimuli such as hormones have demonstrated a similar type of temporal sequence for the protein and RNA changes. In hormonal systems one of the events preceding both of these is an increase in RNA polymerase activity[3]. It seemed reasonable to test whether such an effect also occurs during imprinting in the chick. We present here preliminary results of an enquiry into the effects of the imprinting stimulus on the activity of RNA polymerase in three regions of the chick's brain.

Three batches of 'Chunky chicks' were hatched and kept in a dark incubator until they were 21–27 h old. In each batch six chicks were separately exposed for 30 min to a flashing light previously found to be highly effective as an imprinting stimulus[4]. Meanwhile six other chicks were kept in dark pens for the same length of time and at the same temperature as the experimental birds (28°–31° C). Immediately after exposure to experimental or dark control conditions the responses to the flashing light were measured for 2 min in each chick. It was then decapitated, its brain removed and dissected into three regions (forebrain roof, forebrain base and midbrain) which were frozen separately in pots on solid CO_2 and kept at −20° C until assay. The dark control birds were likewise tested and killed, their brain sections being frozen and kept for analysis.

The nuclei were removed and collected from each sample by a modification of the method of Mertelsmann[5]. The samples were homogenized separately in 4·5 ml. of medium (HM) containing 0·41 M sucrose, 1 mM $MgCl_2$, 0·4 mM KH_2PO_4, 0·4 mM K_2HPO_4, 5 mM mercaptoethanol (*p*H 6·5) for 45 s at 0–4° C, using an MSE top-drive macerator. The homogenates were filtered through two layers of 110 gauge nylon bolting cloth and the filtrate centrifuged at 2,000*g* for 10 min at 0° C. The pellets were resuspended in 4·5 ml. of HM containing 0·5 per cent 'Triton X-100' by means of a glass hand homogenizer fitted with a loose Teflon pestle. These suspensions were then centrifuged at 2,000 *g* for 10 min, the crude nuclear pellet was resuspended in 10 mM Tris buffer (*p*H 7·8), 10 mM $(NH_4)_2SO_4$, 6 mM $MgCl_2$, 1 mM disodium EDTA, 5 mM mercaptoethanol and 33 per cent of glycerol (buffer A), and the suspension centrifuged at 2,000*g* for 10 min. The final nuclear pellets were resuspended in 0·5 ml. buffer A and checked for purity under the microscope. The assays of RNA polymerase activity were performed within 3 h of the final suspension being prepared to avoid "ageing" the nuclei.

All the assays of enzymic activity were carried out in triplicate. 100 μl. aliquots of the nuclear suspensions of each sample were incubated at 37° C for 5 min in 400 μl. of assay medium containing 0·5 mM of each of ATP, CTP, GTP and UTP, and 0·167 μCi 8-^{14}C-ATP; 300 mM $(NH_4)_2SO_4$, 5 mM $MgCl_2$, 5 mM mercaptoethanol; 100 mM Tris buffer (*p*H 8·5), as used by Kato and Kurokawa[6]. Control experiments showed that, first, the reaction was linear beyond 5 min incubation time; second, the amount of radioactivity incorporated was directly proportional to the quantity of nuclei present as measured by DNA; third, the substrates were not rate-limiting. The reactions were stopped by the addition to each tube of 0·5 ml., 10 per cent trichloroacetic acid (TCA) containing 2 M sodium pyrophosphate at 0° C and the precipitates filtered onto Whatman GF/C glass fibre filters. These were washed successively with 5 per cent TCA, chloroform–ethanol (3:1) and ether, and the filters counted in a butyl-PBD–toluene–methoxyethanol scintillant. A 100 μl. aliquot was taken from each nuclear suspension and its DNA content determined[7]. The incorporation of radioactive nucleotide into the recovered RNA was expressed as the average of d.p.m. incorporated per μg of DNA present in the assay.

To eliminate batch differences between experiments the samples from one dark control brain were processed in parallel with those from the brain of an experimental bird. The individual values for incorporation from each sample within such a dark-experimental pair were then calculated as percentages of the mean derived from all the results of that pair. These values were pooled and their means, with standard errors, calculated. The brain regions of the experimental group were then compared statistically (Student's *t* test) with the equivalent regions in the dark control chicks (Table 1).

Table 1. RNA POLYMERASE LEVELS IN BRAIN REGIONS OF EXPERIMENTAL AND CONTROL BIRDS

Condition	Forebrain roof (per cent)	Forebrain base (per cent)	Midbrain (per cent)
Experimental	110·3±7·6 (n=15)	124·3±8·6 (n=17)	109·6±8·6 (n=17)
Dark	82·4±7·9 (n=17)	102·4±9·3 (n=17)	97·6±7·3 (n=17)
$e/d \times 100$	133·9	121·3	112·3
$P \leq$	0·02	0·09	0·30

A marked increase in RNA polymerase activity was observed in the forebrain roof of the experimental animals over that of the dark controls after 30 min exposure to the imprinting stimulus. The effect was significant in the same region of the brain, the forebrain roof, as were the increases in RNA and protein[1,2]. It was observed after an exposure to the flashing light briefer than that previously found to be necessary to obtain detectable increases in incorporation into RNA (76 min). Compared with the 34 per cent increase in the forebrain roof, there were increases of 21 and 12 per cent in the forebrain base and midbrain, respectively. This enhancement of RNA polymerase activity is reminiscent of the sequence of events which follow the stimulation of tissues by hormones[3] and is compatible with the model of intraneuronal events consequent on stimulation by an environmental "trigger" recently proposed by one of us[8]. We believe that this is the first report of an increase in RNA polymerase activity after behavioural stimulation. Because exposure to a static overhead light eventually leads to an increase in RNA synthesis in the chick brain[2]—although taking longer to do so than a flashing light—the change recorded here may be the result of non-specific visual stimulation. Further work is necessary to elucidate the details both of the specificity and the time course of the enhancement of enzyme activity.

We acknowledge support from the Medical Research Council and the Science Research Council to S. P. R. R. and from the Agricultural Research Council to P. P. G. B. We thank Dr G. Horn and Mrs A. Horn for helpful discussion and assistance with the experiments.

Motion of Spermatozoa in Fluid Streams

It is generally accepted that spermatozoa constrained to move in a fine tube swim preferentially upstream (they exhibit positive rheotaxis) when a current is established in the tube[1]. Rothschild[2] has shown that the orientation of dead sperm depends on the direction of the local velocity gradient (Fig. 1); because the head of the spermatozoon sinks more rapidly than the tail under gravity, organisms in the bottom half of a horizontal tube point head upstream while those in the top half point head downstream. Thus it was not at all clear why live spermatozoa should tend on average to swim upstream[2].

Any mechanism which could cause live spermatozoa to migrate to the lower region in a velocity gradient could account for their behaviour in fluid streams. I have therefore investigated the motion of bull sperm in horizontal glass tubes, 200–300 μm in diameter, with a microscope arranged with its axis horizontal so that motion in the vertical plane could be examined. Fresh bull semen was diluted (1 : 100) with Rothschild's medium[3]. Marked positive rheotaxis was observed for velocity gradients of 2–15 s^{-1}. Most organisms swimming upstream were found in the bottom half of the tube, although a few were observed swimming upstream in the upper half. Spermatozoa swimming downstream in the upper half could be seen sinking slowly and turning round when they reached the bottom half. Some active mechanism is therefore producing a downward migration of spermatozoa in the presence of velocity gradients.

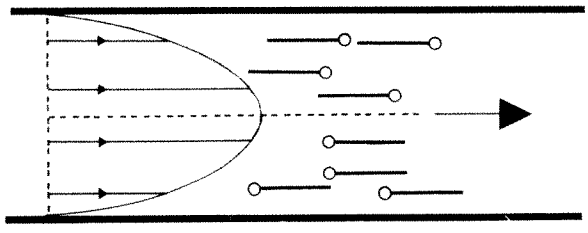

Fig. 1. The steady-state orientation of dead bull sperm when a current is established in the medium. Spermatozoa in the lower half of the tube align themselves head upstream.

Although it has been shown that spermatozoa tend to move preferentially downward (they exhibit positive geotaxis)[4,5] no estimate has been made of the magnitude of the effect. I have investigated the distribution of non-interacting randomly moving aquatic microorganisms under gravity[6], and shown that the vertical distribution in an undisturbed medium is in general exponential, with a scale height, δ, given approximately by

$$\delta = u/(2\beta) \qquad (1)$$

where u is the mean swimming velocity and β is a measure of the rate at which an immobilized organism, falling under gravity, reaches its equilibrium position (in spermatozoa, head downwards). β is defined by the relation

$$d\theta/dt = -\beta \sin\theta \qquad (2)$$

where θ is the angle between the long axis of the organism and the vertical. I have found that β for bull sperm in the diluted medium used in these experiments lies in the range 0·02–0·03 rad s^{-1} at 22° C. Assuming an average swimming velocity of 50–100 μm s^{-1} the scale height of a sperm suspension should be about 1–2 mm, that is, about 63 per cent of the sperm should be found in the bottom layer of this thickness. In practice no sedimentation is observed in dense suspensions of active sperm; because the average distance between one sperm and its nearest neighbour may be as small as 10 μm, compared with 50 μm for the sperm length, direct interactions between organisms are obviously important, and will increase the effective scale height of the distribution many times. Thus it is unlikely that positive geotaxis can account for the number differences over a height of 200–300 μm.

When a velocity gradient is established in the medium, spermatozoa will be influenced both by the gravitational torque (tending to align it vertically downwards) and the flow-orientation torque (tending to align it in the direction of the streamlines). If the velocity gradient is sufficiently large, the motion of the spermatozoa will no longer be random, and they will tend to swim in the direction of the resultant of the two torques. For a horizontal tube the downward velocity component, w, is given by

$$w = (u\beta)/\beta_v$$

where β_v is the flow-induced orientation constant defined by an equation similar to equation (2). Data[2] suggest that β_v for bull sperm is about 0·3 rad s^{-1} per unit velocity gradient. Thus in a velocity gradient of 3 s^{-1} the downward velocity is in the region 1–3 μm s^{-1}, which is an order of magnitude greater than the downward falling velocity of immobilized spermatozoa. Thus most sperm in a 300 μm diameter tube will have migrated to the lower region in about 1 min. If the velocity gradient is increased the downward migration velocity decreases, and rheotactic behaviour becomes less marked. If the velocity gradient is decreased, the spermatozoa tend to regain their normal random movement, and the downward migration again ceases. The explanation of positive sperm rheotaxis in a thin tube is that most spermatozoa which exhibit this phenomenon are in the lower half of the tube where the sense of the velocity gradient imposes this type of behaviour on them.

It is not certain whether this mechanism plays any part in directing mammalian spermatozoa along the female

reproductive tract. Vandemark and Moeller[7] found that immobilized spermatozoa appeared in the ovarian region of the bovine oviduct less than 5 min after insemination, suggesting that other mechanisms may be involved in sperm transport. Belve and McDonald[8] have shown that the net amount of fluid flow in the oviduct of the ewe is generally away from the uterus, which may explain the passage of non-motile sperm up the tube. If the cilia of the oviduct are responsible for transporting the ovum to the uterus, fluid velocity gradients will be set up at the walls which could initiate rheotaxis up the tube even if the net fluid flow is in the same direction. Because the ovum might also be expected to travel along the bottom of the oviduct in its passage to the uterus, the downward migration of spermatozoa in velocity gradients may be a mechanism by which the ovum and motile spermatozoa are brought together by purely mechanical means. In weightless conditions this guiding mechanism is inoperative, and it should be possible to assess its importance by conducting experiments in these conditions.

I thank Mr G. F. Smith for fresh bull semen.

Mechanism of Action of Luteinizing Hormone

The mechanism by which luteinizing hormone stimulates the synthesis of ovarian steroid hormones is the subject of controversy. McKerns[1] has proposed that a primary action of this gonadotrophin in rat lutein and bovine corpus luteum cells is to raise the rate of production of reduced nicotinamide–adenine dinucleotide phosphate (NADPH) by a direct stimulation of glucose-6-phosphate dehydrogenase. Savard *et al.*[2] have concluded that luteinizing hormone stimulates steroid production by an effect on protein synthesis following an increase in the intracellular concentration of cyclic-3′,5′-adenosine monophosphate. If luteinizing hormone acts by increasing the rate of production of NADPH by glucose-6-phosphate dehydrogenase (or some other cytoplasmic NADP-linked dehydrogenase) it should be possible to demonstrate a rise in the tissue concentration of NADPH when steroid synthesis is stimulated. We have made parallel measurements of the concentrations of oxidized and reduced pyridine nucleotides, and the rates of steroid synthesis in lutein tissue taken from rats before and after treatment with luteinizing hormone.

Slices of the luteinized ovaries from immature Wistar rats treated with pregnant mare serum gonadotrophin and human chorionic gonadotrophin[3,4] were incubated for 1 h at 37° C in Krebs–Ringer bicarbonate buffer containing ^{3}H-water and $^{14}C_6$-sorbitol with or without glucose (1 mg/ml.). Luteinizing hormone (NIH-LH-SII) was administered intraperitoneally (20 μg/ 100 g body weight) in saline 2 h before autopsy; control animals received saline only. Net *in vitro* synthesis of progesterone and 20α-hydroxy-pregn-4-en-3-one was determined as described previously[5], the mass of total Δ^4,3-oxo-steroids being measured on the basis of their ability to form thiosemicarbazides with high extinction coefficients at 302 nm. Oxidized[6] and reduced[7,8] pyridine nucleotides were assayed fluorimetrically in acid and alkaline extracts of tissue slices after incubation. The slices were frozen for extraction in liquid nitrogen and extracts were made in Kontes tissue grinders (Kontes Glass Co., Vineland, New Jersey). Intracellular water spaces were calculated from the ^{3}H-water and $^{14}C_6$-sorbitol contents of the tissue slice extracts as described previously; the values obtained have been used in calculating the intracellular concentrations of the pyridine nucleotides. Previous investigations have indicated that many parameters of both glucose metabolism and lipid metabolism proceed at steady state rates in the incubation conditions used in this study[4,5].

Table 1. EFFECTS OF GLUCOSE *in vitro* AND LUTEINIZING HORMONE *in vivo* ON THE CONCENTRATIONS OF PYRIDINE NUCLEOTIDES IN, AND RATES OF STEROID SYNTHESIS BY, SLICES OF RAT LUTEIN TISSUE

Luteinizing hormone *in vivo:*	−	−	+
Glucose *in vitro:*	−	+	+
NADPH*	68·4 ± 6·8 (4)	112·8 ± 8·6‡ (8)	113·2 ± 3·3 (4)
NADP+	72·9 ± 6·8 (4)	26·9 ± 2·9‡ (8)	28·8 ± 1·5 (4)
NADH	29·1 ± 2·9 (4)	85·2 ± 10·6‡ (8)	83·2 ± 4·7 (4)
NAD+	411·8 ± 25·9 (4)	424·4 ± 16·6 (8)	377·2 ± 20·8 (4)
Rate of steroid synthesis†	0·21 ± 0·02 (4)	0·20 ± 0·01 (4)	0·39 ± 0·03§ (4)

* Intracellular concentrations of pyridine nucleotides are expressed as μM (means ± s.e. for number of determinations given in parentheses).
† Rates of steroid synthesis are μmoles/g/h (means ± s.e. for number of determinations given in parentheses).
‡ $P < 0.005$ for effects of glucose *in vitro*; for other changes, $P > 0.1$.
§ $P < 0.005$ for effects of luteinizing hormone *in vivo*; for other changes, $P > 0.1$.

The pyridine nucleotide concentrations in tissue slices and the corresponding steroid release rates are shown in Table 1. Glucose *in vitro* raised the intracellular concentrations of NADPH and NADH, and lowered that of NADP+, but had no effect on the rate of steroid synthesis. No change was detected in the relatively high concentration of NAD+. Incubation with glucose raised the intracellular concentration ratios NADPH/NADP+ and NADH/NAD+ by factors of 4·4 and 2·9 respectively. By contrast with the effect of glucose *in vitro*, pretreatment of the tissue with luteinizing hormone *in vivo* significantly increased the rate of steroid synthesis but had no effect on the concentrations of the pyridine nucleotides. Thus trophic stimulation of steroid synthesis can occur in the absence of any change in the intracellular concentrations of oxidized and reduced pyridine nucleotides, and a stimulation of steroid synthesis does not always follow an increased availability of NADPH.

It has been suggested[9] that the NADPH produced in response to gonadotrophic stimulation may be localized in a compartment occupying a small fraction of the total cell volume, and that local changes in NADPH concentration may not be detectable on extraction of the whole tissue. This now seems unlikely, for if the ultimate source of mitochondrial NADPH is glucose-6-phosphate dehydrogenase (a cytoplasmic enzyme[10]) a rise in the mitochondrial NADPH concentration would involve a rise in the concentration of NADPH in the cytoplasm. Mitochondrial NADPH is required because the enzyme system responsible for converting cholesterol to steroids (the rate limiting step in steroid synthesis) is in the mitochondria[11]. We therefore conclude that a change in the concentration of cytoplasmic NADPH is not involved in the primary steroidogenic response of rat lutein tissue to luteinizing hormone. A similar conclusion was reached regarding the effect of adrenocorticotrophin on the adrenal cortex from measurements of the levels of oxidized and reduced pyridine nucleotides in adrenals from intact and hypophysectomized rats[12]. It also seems unlikely that such a change is involved in the other stimulatory effects of

luteinizing hormone observed in rat lutein tissue, such as those on the incorporation of acetate into sterol and the metabolism of glucose[5].

We thank the Endocrinology Study Section of the US National Institutes of Health for a gift of purified luteinizing hormone. The work was carried out while one of us (A. P. F. F.) was in receipt of a Science Research Council studentship.

Separation of a Hyaluronate-free Lubricating Fraction from Synovial Fluid

THE lubricating qualities of synovial fluid from animal joints have been ascribed to the presence of large hyaluronate or hyaluronate–protein complexes[1], although it has been questioned whether the protein was in fact an integral component of these macromolecules[2]. It is also uncertain whether the high relative viscosity of synovial fluid is important in building up a boundary layer of lubricant on the cartilage surface[3]. Some investigators suggest that the boundary layer is chemically bound, and that the viscosity of the lubricant is of little importance in the lubrication at the cartilage to cartilage interface[4,5].

The finding that mild hyaluronidase digestion, which reduces the viscosity of the joint fluid to that of serum, does not destroy the lubricating qualities of the synovial fluid in joints[6] favours the hypothesis that viscosity is not a determining factor in the production of a boundary lubricating layer. Although in these experiments mild hyaluronidase digestion did not destroy joint fluids lubricating advantage over buffer, severe and complete digestion with this enzyme ('HSE', Worthington, Freehold, New Jersey) did. Furthermore, tryptic digestion, which left the hyaluronate and therefore the viscosity of the fluid intact, also totally destroyed the lubricating qualities of the synovia[6], suggesting that protein might be essential in the lubricating action of joint fluid.

The implications of the hyaluronidase digestions were, however, unclear and the specificity of the hyaluronidase preparation was questioned. Worthington HSE has displayed some inconstant proteolytic activity. We therefore repeated this experiment with a purer form of the same enzyme, Worthington HSEP (6,000 USP units/mg) and also hyaluronidase obtained from Leo (Hälsongborg, Sweden, 20,000 IU/mg), in the same conditions as initially reported. These experiments showed that although 90 per cent of the hexuronic acid[7] was dialysable after treatment with enzyme, the protein content[8] and lubricating quality[9,10] of the synovial fluid were the same after digestion. In an earlier study, low molecular weight hyaluronate solutions were markedly inferior to synovial fluid as joint lubricants[11]; this was now confirmed using a high molecular weight hyaluronate[12] (molecular weight 20 million).

To test whether a protein fraction could be the active lubricant in joint fluid, the protein from the hyaluronate of joint fluid had to be separated without disrupting the physicochemical characteristics of the component macromolecules, for harsh separation would destroy all the lubricating qualities of the constituents. Density gradient sedimentation equilibration[2] was therefore carried out on cell-free bovine synovial fluid using a caesium chloride density gradient centrifugation at an initial density of 1·65 g cm^{-3}. The solution was centrifuged in a Spinco model L preparative ultracentrifuge at 46,000 r.p.m. for 64 h in a number 50 rotor. Then 1 ml. fractions were collected from each tube through a hole pierced in their bottoms. The corresponding fractions from each tube were combined and aliquots analysed for density, hyaluronic acid[7] and protein content[8]. Typical results are shown in Fig. 1. All the hyaluronate banded in the middle of the gradient at a density of 1·63 g cm^{-3}, compared with 1·66 g cm^{-3} reported by Silpananta *et al.*[2]. Most of the protein was present in the top layer of the gradient.

These fractions were combined to obtain three test lubricants as indicated in Fig. 1. Friction tests were carried out as described[9,10], after the three test lubricant solutions had been extensively dialysed against 0·15 veronal buffer (*p*H 7·2). Test lubricant A contained no hyaluronate; B contained all the hyaluronate present in the original joint fluid; C contained most of the protein present in the original synovial fluid and was hyaluronate-free. Test lubricants A and B showed no lubricating advantage over buffer; C, at the equivalent dilution, had the same lubricating qualities as whole synovial fluid (Table 1). Although the frictional values are consistent within each joint, they vary from joint to joint so that these data must be considered relative rather than absolute.

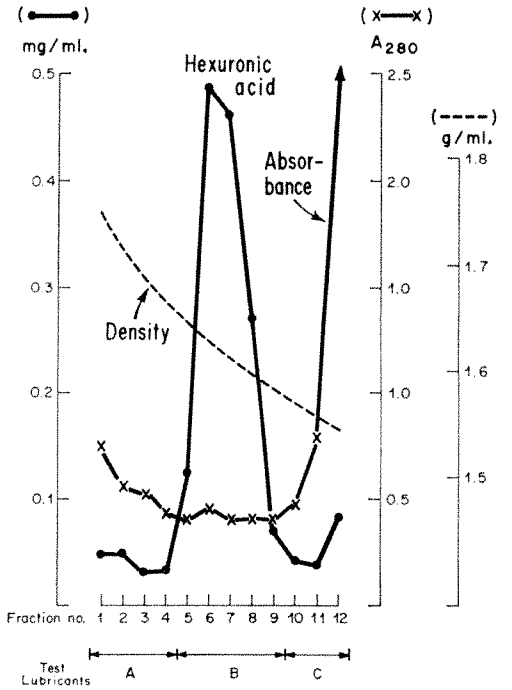

Fig. 1. Results of a density gradient sedimentation equilibrium done in cell-free bovine synovial fluid. The composition of the test lubricants is shown.

Table 1. COEFFICIENTS OF FRICTION OBTAINED WITH TEST LUBRICANTS IN BOVINE METATARSAL-PHALANGEAL JOINTS

	Joint 1	Joint 2	Joint 3
Synovial fluid	0·0021	0·0014	0·0039
Buffer	0·0046	0·0031	0·0079
Test lubricant A	0·0045	0·0033	0·0077
Test lubricant B	0·0046	0·0030	0·0077
Test lubricant C	0·0023	0·0015	0·0039

Conditions were 40 cycles/min; 250 lb load; 23° C.

The joint lubricating fraction of bovine synovial fluid is therefore a protein or glycoprotein which is free of hyaluronate. Because bovine serum fails to display similar lubricating abilities[11], it is assumed that this protein is specific to synovial fluid. Further characterization of this fraction is under way.

Branchial Reduction and Renal Stimulation of (Na^+, K^+)-ATPase by Prolactin in Hypophysectomized Killifish in Fresh Water

THE discovery, in 1959, that prolactin enables hypophysectomized killifish (*Fundulus heteroclitus*) to live in fresh water[1,2] stimulated much investigation of the osmoregulatory functions of this hormone in euryhaline teleosts[3]. The presence of prolactin, or its teleostean equivalent (paralactin), is necessary for freshwater survival in many euryhaline cyprinodonts and in some unrelated species. In others, such as the eel (*Anguilla anguilla*), prolactin participates less in electrolyte homeostasis, and hypophysectomized fish of such species can withstand fresh water. Maetz and his associates[4–6] have shown that a primary osmoregulatory function of prolactin is the reduction of extrarenal sodium outflux which is uncontrolled, or poorly controlled, after removal of the hypophysis. This becomes critical when a prolactin-dependent species, such as *F. heteroclitus*, is transferred to fresh water.

Recent investigations have implicated Na^+, K^+-activated ATPase in the osmoregulatory functions of euryhaline teleosts[7–11]. Adrenal cortical function contributes to the regulation of this enzyme[12] but, because cortisol cannot maintain freshwater survival in hypophysectomized *F. heteroclitus*[1], its osmoregulatory function in these circumstances, and in this species, is of secondary importance. We have therefore studied the effects of prolactin.

Male *F. heteroclitus*, maintained in salt water at about 15° C, were hypophysectomized in November 1969, and autopsied in February 1970. Because hypophysectomized *F. heteroclitus* fail after 5–7 days in fresh water[13], and are extremely sensitive to the stress of handling, careful planning was imperative. Control fish were transferred to dilute salt water (about 1·5 per cent salinity) for 24 h, and then to dechlorinated city water, changed daily, for three days. They were not injected with solvent, in case of early death from stress. The experimental group received five daily injections of ovine prolactin (NIH-P-S4, a preparation successfully used in an earlier investigation[2]); the dose was 5 μg (= 105 mU) per g per injection, in a volume of 0·01 ml. of 0·6 per cent NaCl. The first injection was given while the fish were in salt water, the second in diluted salt water, and the last three in fresh water. Experience has shown that prolonged pretreatment in salt water is no advantage in promoting freshwater survival. All fish were fed daily, except on the day of autopsy. Both control and experimental groups were staggered so that not more than sixteen fish were autopsied on any one day, which enabled us to do enzyme assays within a few hours.

At autopsy a small volume of blood was taken in a heparinized haematocrit tube. The remainder, in non-heparinized tubes, was allowed to clot and the serum was used for the determination of selected inorganic ions. Here we are reporting the data for Na^+ and K^+ (5 μl. samples, IL flame photometer), and for Cl^- (5 μl. samples, Aminco-Cotlove chloride titrator). Pooled homogenates of gill filaments, kidneys or intestinal mucosa were prepared from two or three fish per sample, and assayed for Na^+, K^+ and residual Mg^{3+}-activated ATPase by methods described previously[9–11].

† Mean of the means for five experiments; data from Pickford, Grant and Umminger (Table 3) (ref. 22) (s.e. added).

The principal serum electrolytes of the prolactin-treated fish were in the normal range for intact *F. heteroclitus* adapted to fresh water (Table 1). These fish appeared active and healthy, and were eating well. The control fish, after only three days in fresh water, were already showing signs of lethargy and loss of appetite, although they had not yet developed overt asthenia. The onset of these symptoms, in *F. heteroclitus*, is known to be associated with hypochloraemia[13] and a lowering of serum osmolarity[14]. In another cyprinodont, *Poecilia latipinna*, there is a fall in serum Na^+ (ref. 14) which has been suspected but not hitherto demonstrated in *F. heteroclitus*. Our results agree with these expectations.

Enzyme assays for Na^+, K^+-ATPase are summarized in Table 2. The ability of hypophysectomized *F. heteroclitus* to maintain normal levels of serum Na^+ in fresh water is correlated with a highly significant decrease in Na^+, K^+-ATPase activity in the gills, the main site of sodium

† Significantly different from the controls ($P < 0·001$).

excretion. This decrease is even greater (−65·4 per cent) than that observed previously in intact fish adapted to fresh water (−38·6 per cent)[10]. In contrast, untreated controls, near failure in fresh water, have an enzyme activity similar to that of hypophysectomized *F. heteroclitus* in salt water[9,12].

The reverse effect was observed in homogenates of kidney tissue, implying the need for increased sodium retention in fresh water. Na^+, K^+-ATPase was significantly more active in the kidneys of prolactin-treated fish. A similar increase was observed before when intact *F. heteroclitus* were adapted to fresh water[10]. There is strong support for the role of ouabain-sensitive ATPase in the regulation of sodium reabsorption in the teleostean nephron[16,17].

No change was seen in enzyme activity in the intestinal mucosa. Freshwater fish drink little[18,19], if at all[20], and intestinal sodium uptake is minimal, in contrast to the increased uptake that is correlated with drinking in salt water. The low levels of intestinal Na^+, K^+-activated ATPase observed in hypophysectomized *F. heteroclitus* in fresh water may be compared with the higher levels reported previously for such fish in salt water[12]. Adrenal corticosteroids, rather than prolactin, seem to regulate the increased enzyme activity in the intestine of salt-water-adapted *Anguilla japonica*[21] or *F. heteroclitus*[12].

Thus prolactin, which permits survival of hypophysectomized *F. heteroclitus* in fresh water, decreases the activity of the sodium transport enzyme Na^+, K^+-ATPase in the gills while reducing branchial outflux, and increases the activity of this enzyme in the kidney, so increasing sodium retention.

This investigation was supported by a grant from the US National Science Foundation and by US Public Health Service grants.

Evidence for a Second Haemoglobin α-Locus Duplication in *Macaca irus*

IN a study[1] of the haemoglobins of *Macaca irus* obtained from Thailand and Vietnam two α-chain variants, electrophoretically distinguishable from the normal type ($Hb\text{-}A^{mi}$), were found to be frequent. One, $Hb\text{-}Q^{mi}$, was anodal to $Hb\text{-}A^{mi}$ on starch gel at *p*H 8·6 and varied considerably in relative concentration when present with the latter. The fingerprint pattern of the soluble tryptic peptides was, however, indistinguishable from that of $Hb\text{-}A^{mi}$ and the difference is presumably in the insoluble peptide core. The other variant, $Hb\text{-}P^{mi}$, had the same electrophoretic mobility as $Hb\text{-}Q^{mi}$ in very fresh haemolysates but formed aggregates with ageing so that it then appeared in starch gels as a trail extending cathodally from the $Hb\text{-}A^{mi}$ position. The fingerprint of $Hb\text{-}P^{mi}$ was distinct from that of $Hb\text{-}A^{mi}$, αT3 (tryptophan positive) and αT4 (histidine positive) being absent and a new tryptophan and histidine positive peptide appearing in the neutral region. A single amino-acid substitution in α15 or 16 would probably account for this. The phenotype frequencies of these two variants in the population were consistent with their being determined by alleles at the α-locus. In addition, about 20 per cent of the animals had a minor haemoglobin component. The distinctive chain of this component was shown[2,3] to differ from the normal α-chain in at least four substitutions. In some animals the minor component was present together with $Hb\text{-}A^{mi}$ and either $Hb\text{-}P^{mi}$ or $Hb\text{-}Q^{mi}$ and it was suggested that the characteristic chain arose by duplication of the α-locus and mutational divergence.

In a collection of 231 blood specimens of *M. irus* from Malaya (provided by Dr A. C. Laursen, Glaxo Research Laboratories, Buckinghamshire, and by Dr J. Moor-Jankowsky and Mr J. Davis, Lemsip Primate Center, New York), the AQ phenotype was remarkably frequent; 184 (80 per cent) were initially scored as AQ, 39 (17 per cent) as A and 8 (3 per cent) as AP. No animals with $Hb\text{-}Q^{mi}$ alone were found. There was statistically significant heterogeneity of phenotype frequencies between the seven batches of blood, but the frequency of the AQ type was above 75 per cent in all but one. This curious frequency pattern can scarcely be due to selective elimination of homozygotes, for this would require an improbably high mortality, and it was therefore suspected that a duplication might be present. Oliver and Kitchen[4] also suggested a duplication to explain the fact that all animals in a sample of *M. speciosa* had two haemoglobins.

In one of the seven batches of material it was noticed that three specimens scored as AQ and one scored as A had a blurred band at the $Hb\text{-}A^{mi}$ position and when the haptoglobins were examined on starch gel it was seen that these four had a 2–1 m-like pattern which has been shown[1] to occur only when $Hb\text{-}P^{mi}$ is present. It there-

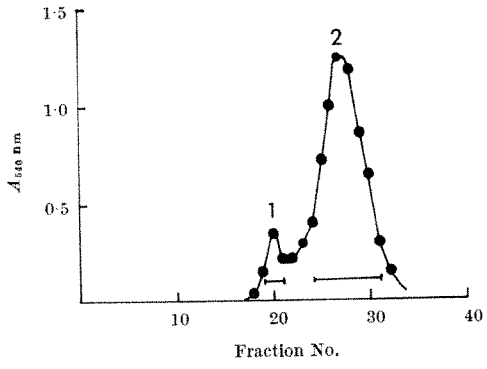

Fig. 1. Separation of *M. irus* (BX 181) haemolysate on 'Sephadex G-100'. Two fractions (1 and 2) are present.

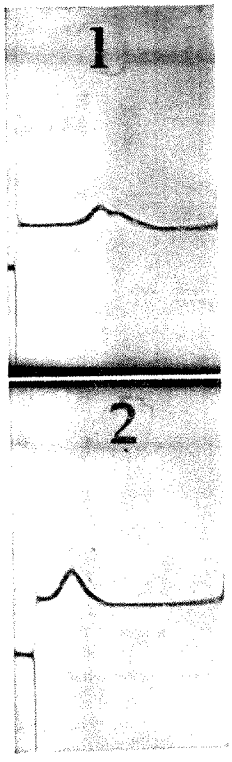

Fig. 2. Ultracentrifuge schlieren patterns of fractions 1 and 2 from 'Sephadex G-100' fractionation of BX 181 haemolysate.

fore seemed that three of these animals might each have three major haemoglobins, Hb-A^{mi}, Hb-Q^{mi} and Hb-P^{mi}.

The haemolysate from one of them (BX 181) was examined by gel-filtration on 'Sephadex G-100' at *p*H 7·0. About 10 per cent of the haemoglobin eluted with the void volume (fraction 1, Fig. 1). Ultracentrifugation of material from this fraction in 0·05 M phosphate-EDTA at *p*H 7·0 showed three peaks (Fig. 2) and the component with the smallest size had an $s_{20,w}$, of 10S, corresponding to an aggregate of at least four haemoglobin molecules. Fraction 2 showed a single symmetrical peak with an $s_{20,w}$ of 4·5S which is the same as that of human Hb-A in this solvent. On starch gel at *p*H 8·6 (Tris-EDTA–borate) material from fraction 1 appeared as a trail with its leading edge in the Hb-A^{mi} position and three sharp bands (Fig. 3*a*, *b*). Fraction 2 showed two components, one at the Hb-A^{mi} position and a stronger, more anodal one at the position of Hb-Q^{mi} (Fig. 3*c*, *d*). When fraction 2 was stored for several days at 0°–4° C and again examined on starch gel, it was found to have developed a cathodal trail suggesting that more polymer had been formed (Fig. 3*c*, *d*). It was therefore subjected to two further gel-filtrations over the course of a month and more polymerized material was recovered each time. After the third gel-filtration an aliquot of fraction 2 was left at 25° C for 2 days and then examined on starch gel. There was no cathodal trail and it was concluded that polymerization was no longer occurring. The two components of fraction 2 were then separated on a starch block at *p*H 8·6. The proportions of the haemoglobin in the A^{mi} and Q^{mi} positions were 36 and 64 per cent. The pooled polymerized material (fraction 1) comprised 40 per cent of the total haemoglobin. The three components were then fingerprinted. The polymerized material showed the changes characteristic of Hb-P^{mi} while the two components of fraction 2 were both indistinguishable from Hb-A^{mi}. These two components were also hybridized with canine haemoglobin[5]. This showed that the α and β-chain charges of the more cathodal one were the same as those of Hb-A^{mi} but that the α-chain of the more anodal one had a higher negative charge like that of Hb-Q^{mi}. This anodal component can therefore be identified provisionally as Hb-Q^{mi} on the grounds that (1) it has the same electrophoretic mobility as this variant; (2) its charge difference from Hb-A^{mi} is in the α-chain; and (3) the fingerprint pattern of the soluble tryptic peptides is indistinguishable from that of Hb-A^{mi}. It seems therefore that this animal had three major haemoglobins in the proportions 22 per cent Hb-A^{mi}, 38 per cent Hb-Q^{mi} and 40 per cent Hb-P^{mi}. The simplest explanation is that it was heterozygous for a gene producing Hb-P^{mi} and a duplication producing Hb-A^{mi} and Hb-Q^{mi}. Another specimen showing this phenotype was run on starch block and the more anodal of the two components was shown by fingerprinting to contain some Hb-P^{mi}. The fourth specimen, with a single blurred band at the Hb-A^{mi} position, was examined by gel-filtration and two fractions were obtained; the first showed the characteristic trailing pattern of Hb-P^{mi} on starch gel and the second showed only a single band at the Hb-A^{mi} position. This specimen apparently contained only Hb-P^{mi} and Hb-A^{mi}. In our earlier studies on animals from Thailand and Vietnam, polymerization of Hb-P^{mi} was virtually complete after storing the haemolysates at 0°–4° C for a few days. It is not clear why polymerization was slower in the present material.

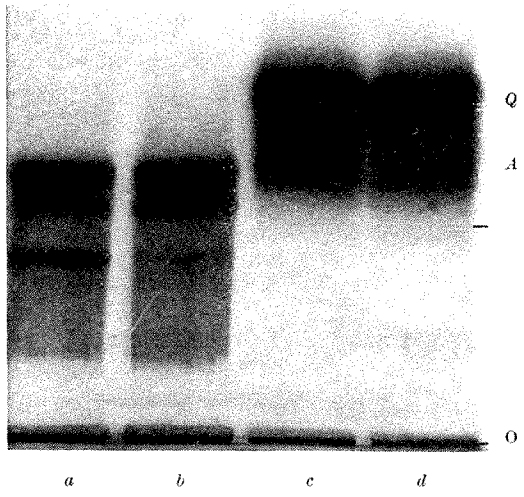

Fig. 3. 'Sephadex G-100' fractions on starch gel (Tris–EDTA–borate, *p*H 8·6). *a*, *b*, Fraction 1 showing cathodal trail extending from Hb-A^{mi} position (*A*) and three sharp bands. *c*, *d*, Fraction 2 showing Hb-Q^{mi} (*Q*) and Hb-A^{mi} components (*A*) and a slight trail of polymerized material (*t*). Specimens *b* and *d* were incubated at 25° C for 1 h.

If our interpretations are correct (and family data are desirable), *M. irus* has two different duplications. The one described here is associated with the production of Hb-A^{mi} and Hb-Q^{mi} in substantial amounts, but in the other case a minor component occurs which comprises less than 5 per cent of the total haemoglobin. The reason for this quantitative difference is obscure. The presence of a duplication may have a bearing on the striking variations in the relative concentration of Hb-Q^{mi} in the AQ phenotype, ranging from about 35 to 70 per cent of Hb-Q^{mi}. If the duplicate produces about 35 per cent of Hb-A^{mi} and 65 per cent of Hb-Q^{mi} the genotype A/AQ would be expected to produce about 32·5 per cent of Hb-Q^{mi} and the genotype AQ/AQ about 65 per cent of this haemoglobin which is in accord with these figures. If we assume Hardy–Weinberg equilibrium for the batch of forty-nine animals in which the four with Hb-P^{mi} occurred, however, and calculate the expected numbers of the genotypes we find $AQ/AQ = 10·5$ and $A/AQ = 22·5$; but nineteen were judged to have more Hb-Q^{mi} than HB-A^{mi} and fourteen less. The discrepancy is quite large, though barely significant for this small sample, and does not favour the idea that the quantitative variation

of Hb-Q^{mi} can be entirely explained by the presence of a duplication, together with two alleles producing Hb-A^{mi} and Hb-P^{mi} respectively. The assumption of Hardy–Weinberg equilibrium is, of course, open to question, because neither the genetic structure of wild macaque populations nor the sampling procedure involved in trapping is known. It should also be noted that there were wide variations in the relative concentration of Hb-Q^{mi} in the Thailand and Vietnam material in which the phenotype frequencies were consistent with equilibrium values for three simple alleles.

If the high frequencies of haemoglobin variants in *M. irus* are maintained by heterosis, like sickle-trait in man, the presence of a duplication might be an advantage since a high frequency of the AQ phenotype could then occur without entailing the production of the Q homozygote which may perhaps have lowered fitness. There is no definite evidence that malaria plays a part in maintaining haemoglobin polymorphism in certain macaque species, but it is interesting that *M. irus* from Malaya is often found to be infected with several species of simian malaria parasite whereas this is not the case in *M. mulatta* in which haemoglobin variants seem to be rare or absent.

We thank Mr David Hewett-Emmett and Miss Susan Adams for help in some of these experiments.

Hibernation and the Production of Glycerol in the Ichneumonidae

The Ichneumonidae (Hymenoptera) are a family of parasitic wasps (15,000 species in the world[1]) which deposit their eggs in larvae or pupae of other insects. Twelve genera can overwinter as free adults, and individuals of these genera may be found hibernating in rotten forest logs, between rocks and under moss carpets. It seems likely that species that survive the winter possess some physiological mechanism absent in non-hibernating species. Glycerol and sorbitol accumulate in a limited number of unrelated diapausing and non-diapausing insects subjected to temperatures resembling overwintering conditions[2]. This study was undertaken to see if (*a*) the overwintering ability of a group of closely related species is manifested by a common observable phenomenon, namely polyol accumulation, and (*b*) this phenomenon is restricted to those species which hibernate.

Specimens were collected from Massachusetts and Ohio during all seasons. Following a period at room temperature in the laboratory all specimens were cold stressed at 4° C for 3 weeks. Glycerol was extracted from individual weighed specimens with a methanol–water solution (3:1). The filtered extracts were evaporated to dryness, acetylated and analysed quantitatively by gas chromatography for glycerol triacetate[3]. Free glycerol was also identified in deacetylated extracts by paper chromatography.

* −1° C for 1 month.
† 0° C for 1 week (male).

Results are shown in Table 1. Only hibernating species are capable of low temperature induced glycerol accumulation. All values are corrected for traces of glycerol in control specimens not subjected to low temperatures. While glycerol accumulation during low temperature stress or diapause is well documented[4] its relationship to cold stress or frost hardiness (the ability of the insect to withstand freezing) is unclear. Glycerol in larvae of *Loxostage sticticalis* (L.) and adult *Camponotus* sp. does not confer frost resistance[5]. *Pyrausta nubildis* larvae, however, accumulate glycerol and can survive freezing. The formation of polyols is not essential for all insects to withstand cold stress[4].

If the ability to accumulate glycerol has survival value, it must have a physiological function. It has been shown that glycerol and other polyols help stabilize certain cold sensitive enzymes[6,7], so it is possible that glycerol protects such enzymes from inactivation in somatic cells. Another possible use for glycerol is suggested by the reproductive behaviour of these insects. Hibernating species mate in the autumn and the overwintering fertilized female stores spermatozoa in the spermatheca until spring when she leaves her hibernaculum to parasitize pupae[8]. It is believed that at this point spermatozoa are released from the spermatheca and fertilize the eggs before oviposition. Glycerol may help protect sperm during the overwintering period. (It is a well known cryoprotective agent for long term storage of bovine spermatozoa at sub-zero temperatures[9].)

Validity of the Selective Coefficient of a Behaviour Trait in Hawkmoth Larvae

In Jamaica the fifth instar larvae of the New World hawkmoth, *Erinnyis ello*, exhibit four basic colours: green, blue, green-grey and brown. The green, blue and green-grey larvae feed and rest on the leaves of their commonest food plant (*Poinsettia pulcherrima*). The brown larvae also feed on these leaves, but they rest for many hours during the day on the base of the trunk, sometimes several yards below where they feed[1]. All the larvae are preyed on during the day by wasps (*Polistes crinitus*) and to a very small extent by an anole (*Anolis lineatopus*). Because the wasps search for their prey only in the foliage of the *Poinsettia* bushes, the three forms staying constantly on its leaves suffer heavily from predation, as selection experiments in the wild have demonstrated[1]. By contrast, all the larvae which rest from time to time on the trunk of the food plant enjoy an almost complete freedom from predators.

From mortality data obtained on the campus of the University of the West Indies in Mona, Kingston, and in neighbouring gardens, a relative selective coefficient of the habit to rest on the trunk was calculated. (I take relative selective coefficient as a quantitative measure for differential survival of different larvae at one particular instar). Because the data showed a vast selective advantage of the order of $V_t = 88$ per cent (see Table 1 and refs. 2, 3, 8) and because V_t represents the first quantitative assessment of such a value for a behaviour pattern, I decided to check its validity.

Table 1. SELECTIVE COEFFICIENT V_t OF THE TRUNK RESTING HABIT IN FIFTH INSTAR LARVAE OF THE HAWKMOTH *Erinnyis ello* BY THREE DIFFERENT METHODS

Determination of m or m'	m_f or m_f'	m_t or m_t'	Determination of E or E'	$V_t = 1 - E_f/E_t$ or $V_t = 1 - E_f'/E_t'$	Refs.
(1) $m = 1 - N_a \cdot e^{-R}$	0·055	0·007	$E = 1/-\ln(1-m)$ or $E = 1/\lvert R \rvert$	0·88	4, 5, 6
(2) $m = 1 - N_a \cdot e^{-R}$	0·055	0·007	$E = 1/m$	0·87	7
(3) $m' = N_m/\mathrm{Tet}$	0·250	0·071*	$E' = 1/m'$	0·72	This paper

m, m' = mortality; E_f and E_t = life expectancy of larvae in the foliage and on the trunk of the food plant; R = risk of predation; N_a = number of larvae initially present; N_m = larvae which died. Tet = total exposure time (h).

* Initially there were 131 larvae on the trunk of *Poinsettia* bushes compared with 916 larvae in the foliage; original $m_t' = 0{\cdot}010$ was therefore weighted for equal initial numbers N_a by multiplication with 916/131.

Three different methods were used which are based on two different determinations of the mortality of the larvae per hour of daylight. Fifth instar larvae were placed singly on twigs of *Poinsettia* bushes in groups from one to forty-six per bush, the average being 6·7 per bush. Altogether 916 individuals of all four colour forms were counted in the foliage, and 131 were found on the trunk (these last had moved down from the foliage). The survivors in each group released were checked after 6·2 h ($n = 162$) and after 4·9 h ($n = 61$), respectively. (For details of the census technique and of the calculation of the mortality rate, see ref. 1.) The methods used to check the original estimate of V_t were as follows:

(1) After it had been ascertained that the mortality rate m was density independent, a constant death rate among the larvae was assumed. The basic method for the evaluation of m allowed for the variance of the group size and of the time interval between censuses. Because the mortality rates per hour differed only by chance between the four colour forms, the data for all four groups were pooled to give an overall mortality rate of $m_f = 0{\cdot}055$ and of $m_t = 0{\cdot}007$ (Table 1, 1), which differ significantly from each other ($P < 10^{-6}$) (the group on the trunk contained a small percentage of green, blue and green-grey larvae as well). The similarity of the mortality rates of the four colour forms in each respective place would be expected if the predator does not hunt by sight which is, in fact, true for the wasps. The resulting relative selective coefficient V_t of the habit to rest on the trunk was 88 per cent checked by method 2.

(2) m was calculated as in method (1), the only difference in calculating V_t being in the assessment of E which is probably less accurate[6,9]. But the ensuing selective advantage V_t of the trunk group of 87 per cent agrees closely with the value determined by (1) (Table 1, 2).

(3) While the first two methods are independent only with regard to the calculation of the respective life expectancies, the following rather crude estimation of V_t is based on another piece of information from the mortality data. Because of algebraic reasons explained elsewhere[1], twenty-seven counts from the foliage larvae with the total loss of a sample ($N_a = N_m$) have so far had to be omitted from the analysis. They can now be included in the grand total of N_m if the number of larvae per hour of daylight killed in each of the two localities is considered (Table 1, 3). Because the initial numbers N_a were different in each case, a weighting to compensate for this seemed advisable (see footnote to Table 1). The resulting selective value of 72 per cent is considerably lower than the ones obtained previously but it is based on the simplified assumption that the death rate is a linear function of time. From this it follows that the number of larvae killed after a given time is smaller than if the death rate were constant, that is, it would follow a logarithmic function as has been shown. The deviation from this function of the (simplifying) "linearity model" is negligible if m is very small, as, for example, in the trunk group; accordingly, it must be larger, where m is higher, as, for example, in the foliage group. Thus the difference between m_t' and m_f' obtained through the linearity model in this method is smaller than in the more realistic method used before. As a consequence, method (3) must lead to too low a selection coefficient which is confirmed by a comparison of the three methods in Table 1. Moreover, this V_t is especially liable to sampling error; if one assumes, for instance, that, in spite of careful searching, I overlooked only one out of the three caterpillars which disappeared from the trunk "population" the V_t value would rise to 81 per cent. Thus method 3 actually leads to an estimate of V_t which is reasonably close to the two former methods.

Consequently, the selective disadvantage of the larvae inhabiting the foliage seems so high that some strong advantage should compensate for it. This advantage might lie in the feeding behaviour of an anole. It hunts all over except in the foliage; surprisingly, it preys on non-brown larvae and rejects the brown ones[10].

Incorporation of Metabolic CO_2 into Coral Skeleton

Two possible sources for the carbonate in the calcium carbonate coral skeleton are (*a*) soluble carbonates from seawater and (*b*) carbon dioxide produced in metabolism by the living coral tissue. Although radioisotopic tracer experiments have established that carbonate from seawater is incorporated into the skeleton by many corals[1–3], evidence for incorporation of metabolic CO_2 into the skeleton is much less direct. Goreau[1] found that calcification rates measured by incorporation of radioactive carbonate from seawater were usually lower than those measured by using radioactive calcium; he proposed that the labelled carbonate might be diluted by unlabelled carbonate in coral tissue. In addition, findings that the ratios of ^{13}C to ^{12}C and of ^{18}O to ^{16}O in seawater differ from those in coral skeleton suggest that not all of the skeletal carbonate originates directly from carbonate in seawater[4–7]. To examine further the possibility that some skeletal carbonate originates from metabolic CO_2, I fed ^{14}C-labelled mouse tissue to small individuals of the coral *Fungia scutaria*, a solitary polyp containing symbiotic algae.

Table 1. ^{14}C ACTIVITY IN ORGANIC AND CARBONATE FRACTIONS OF CORAL

Days fasted after ^{14}C feeding	Per cent activity in organic carbon	Per cent activity in carbonate
4–6 (3)*	95·7	4·3
13 (4)*	91·1	8·9

* No. of corals.

To obtain labelled mouse tissue, we injected a laboratory mouse intraperitoneally with 0·5 mCi of ^{14}C-labelled protein hydrolysate in 0·1 ml. physiological saline. The mouse was killed 24 h later. Pieces of liver, kidney and intestine were fed to small corals (90–240 mm diameter, 150–1,650 mg dry weight), over a period of several days. The animals were then fasted, one group for 4–6 days, another for 13 days. At the end of the period of fasting, the tissue and skeletal components were separated as follows: each coral was placed in a small beaker and covered with concentrated ammonium hydroxide (58 per cent). The beakers were heated in a water-bath at 60°–70° C for about 1 h. The loosened tissue was easily washed off the skeleton with jets of ammonium hydroxide solution. The tissue in ammonium hydroxide was homogenized with a 'Teflon' pestle and brought to known volume. Aliquots were removed to planchets, acidified with HCl, dried, and counted on a Nuclear-Chicago gas-flow detector model 470. The skeletons were washed under a strong jet of water to remove any remaining fragments of tissue, dried in an oven at 100° C, and weighed. The clean skeletons were dissolved in 6 M HCl in evacuated flasks, and the CO_2 evolved was recovered in a small beaker containing 5 M KOH on the bottom of each flask[8]. After the skeletons had dissolved, 1 h was allowed for the CO_2 to become more completely absorbed; the flasks were then opened, and aliquots of the KOH solution were removed for counting. Approximately 95 per cent of the ^{14}C from skeletal carbonate was recovered. The acid-insoluble residue, which included the organic matrix of the skeleton, was collected on a 'Millipore' filter, dried and counted. The acid filtrate was also counted, but did not contain measurable amounts of ^{14}C. Separate control experiments showed that no measurable amount of $^{14}CO_2$ was released from tissue treated with acid. The data are presented in Table 1. Values for tissue and organic matrix were combined to give a single value for total organic ^{14}C; the matrix value was never more than 2 per cent of the total.

A portion of the activity was consistently found in the carbonate of the skeleton, offering direct evidence that metabolic CO_2 was incorporated into the skeletal carbonate. Also, the distribution of the labelled carbon in the two groups of corals was significantly different ($P < 0.05$). Among the corals fasted for a longer period (13 days), the percentage of radioactivity in skeletal carbonate was twice that of the first group (fasted 4 days), while the percentage of activity in the tissue decreased. For this difference to reflect only metabolic loss of labelled organic carbon would require that the total ^{14}C of the second group be reduced almost by half, while in fact there is no significant difference between the means for total ^{14}C in the two groups ($P = 0.33$). Alternatively, the apparent shift in distribution of the labelled carbon may be real, that is, the animals may have continued to calcify during the fasting period and, in doing so, fixed some of their metabolic $^{14}CO_2$ into skeletal carbonate. Also, some of the metabolic CO_2 may have been photosynthetically fixed by the symbiotic algae in the tissues of the coral. These two mechanisms could account for the negligible turnover of total ^{14}C in this experiment and may make possible very efficient conservation of organic carbon taken in food by the corals.

My evidence that metabolic CO_2 is deposited in coral skeleton as carbonate supports Goreau's interpretation of his experiments in which he found that calcification rates calculated from ^{14}C in skeletal carbonate were lower than those calculated from skeletal ^{45}Ca. He interpreted the lower carbonate values as being the result of isotopic dilution of the exogenous carbonate pool with unlabelled CO_2 in the coral tissue. It is important to note, however, that the relative contributions of carbonate from seawater and from metabolism are still unknown. The sources of carbonate for mineral deposition at any one instant might be expected to vary with such factors as the degree of illumination and the nutritional state of the animal.

I thank Dr Leonard Muscatine, Department of Zoology, University of California, Los Angeles, for his advice. The work was supported by the US National Science Foundation. A more complete account of this and some related work will be published later[9].

Skeletons of *Lumbricus terrestris* L. and *Arenicola marina* (L.)

FOR the theoretical investigation of their locomotion, worm-like animals have conveniently been treated as thin walled, liquid-filled cylinders[1–3]. Observation of living animals, however, suggests that rigidity of the body wall, both inherent and developed by contraction of the muscular layers, represents a more or less important component of the total force exerted on the environment.

Some references to the rigidity and elasticity of the body wall in worms appear in the literature[4–9], and Clark[10] discussed radial forces exerted by worms in relation to the presence and absence of septa; but no quantitative

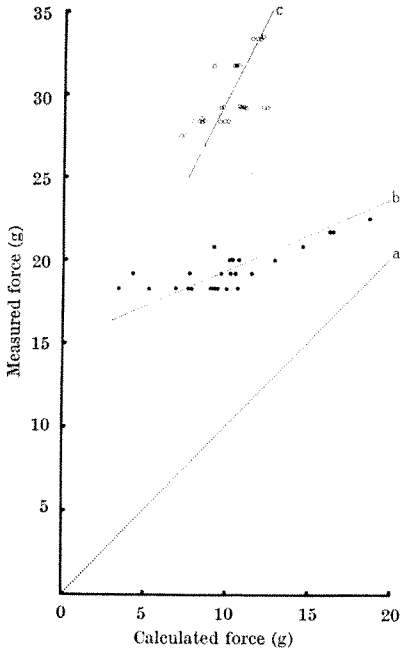

Fig. 1. Graph showing the relationship of measured forces exerted by *Lumbricus terrestris* against a movable bridge to expected forces calculated as the product of internal pressure and measured area of the worm in contact with the bridge. If the body wall had neither inherent rigidity nor internal frictional losses, all points would lie on line *a*, for measured forces would equal calculated forces. Lines *b* and *c* are for two worms (5 g and 6·3 g weight respectively) showing the range of forces encountered. Regression $P < 0.02$.

estimate of the relative importance of the internal hydrostatic and intrinsic body wall skeletal functions has been published.

In an attempt to resolve the prevailing uncertainty about the skeletal role of the body wall in worm-like invertebrates, simultaneous measurements have been made of internal pressure, externally exerted force and the area over which the force was exerted for two annelids: the terrestrial, septate earthworm *Lumbricus terrestris* L., which burrows in the earth, and the sand-burrowing, marine, effectively non-septate lugworm *Arenicola marina* (L.). The results obtained will be discussed more fully elsewhere.

Worms moving beneath a narrow 'Perspex' bridge of known area displaced it against the tension of a light myograph transducer. A Statham P23BB transducer monitored coelomic pressure in the segment central under the bridge through a fixed stainless steel cannula. Transducer output was displayed on a multichannel inkwriting recorder. From synchronized photographs of the area, A, of worm surface touching the bridge, and the recorded internal pressure, P, a force value ($P \times A$) was calculated and compared with the corresponding force value directly recorded by the myograph.

In an internally pressurized liquid-filled cylinder of which the wall has no inherent rigidity, the force against an external object flattening the wall equals internal pressure multiplied by the area of flattening. Thus measured force exerted by the cylinder in the bridge would equal calculated force, ($P \times A$), at the same instant; and measured force plotted against calculated force (Figs. 1 and 2) would yield a straight line passing through zero (lines *a*). For a real worm, however, such a plot yields lines *b* and *c* (Fig. 1) and line *b* (Fig. 2); actual forces against the bridge exceed those which could be produced by internal pressure alone. This "excess lifting force" is developed directly by contraction of the body wall musculature, and its magnitude is a measure of the "intrinsic rigidity"[8] of the muscle layers.

Excess lifting force is expressed as the percentage by which mean measured force exceeds mean calculated force. Values of excess lifting force found for *Lumbricus* and *Arenicola* are 145 and 85 per cent respectively. For *Lumbricus*, measured force and area vary reciprocally; as increased force is applied to the bridge an increase in curvature of the worm from its flattened state occurs.

Complete intersegmental septa are present in *Lumbricus* and muscle fibres within them are kept taut to resist bulging of the septa under differential pressures in locomotion[4]. Such tension must aid the circular muscles in the development of lifting force, by restricting lateral spread of the body wall in a bridge or crevice situation. Also, the thicker, and therefore shorter, is a given region of earthworm, the more septa are present in that region and so the greater is the total resistance to deviation from a circular cross-section when the worm is in the bridge apparatus, or is burrowing through and enlarging a crevice in the earth.

In contrast to *Lumbricus*, for *Arenicola*, where the trunk is without septa, the greater the force exerted against the bridge the greater the area over which it is exerted. This means that, during lifting, the body wall remains more flattened in *Arenicola* than in *Lumbricus*, and that the circumference is less reduced. Thus less stiffness is developed; the circular muscles alone, without the aid of septal elasticity and musculature, can produce relatively less excess lifting force on contraction than can the cooperating circular muscles and septa of *Lumbricus*.

Although in *Lumbricus*, lifting segments must be fully shortened to undergo their greatest dilation (because watertight septa are present and segmental volume is constant[4]), in the aseptate trunk of *Arenicola*, dilated lifting segments are usually also elongated. In this situation the dilation is achieved by longitudinal and circular contraction elsewhere in the body wall surrounding the large coelom. Such a configuration is seen during the dilation anchorage sequence of burrowing in *Arenicola*[9,11,12] wherein posterior trunk segments are short and thin and anterior trunk segments are elongated and dilated. Such simultaneous elongation and dilation minimize body wall thickness and therefore its inherent rigidity in that region. Thus *Arenicola* is far less able to develop that unidimensional lifting force necessitated by a crevice situation than is *Lumbricus*; it is, however, ideally suited for all-round enlargement of a more homogeneous substratum. Attainment of the considerable dilation required by the situation and obtainable by the system would clearly be hindered

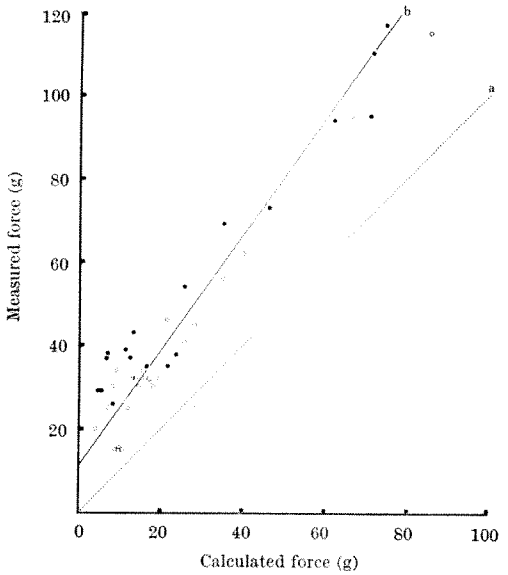

Fig. 2. Graph prepared and to be interpreted as Fig. 1, for two specimens of *Arenicola marina* (9·7 g (●) and 12·4 g (○)). Regression $P < 0.001$.

by septa limiting dilation and preventing the necessary transfer of fluid and of coelomic pressure from the posterior trunk.

Two types of penetration of the substratum can be distinguished. First, crevice burrowing, which makes use of a layer of the substratum penetrated with relative ease between two harder layers; for example, an air space in earth or an earth or sand layer between stones or roots. The body is first flattened and then exerts a lifting force at right angles to the plane of flattening (Figs. 1–6 of ref. 13). This force anchors part of the worm against elongation of the more anterior region into the crevice[9], and also enlarges the crevice. Limitation of lateral spread of the body is necessary and is much enhanced if muscular septa are present. Second, homogeneous burrowing: in a homogeneous substratum, for example sand or mud, there is complete circumferential contact with the substratum and relatively greater dilation of the burrowing animal radially in all directions. The development of excess lifting force and prevention of lateral body wall spread are inappropriate.

Thus it can be seen that the septate earthworm is better suited to, and much more likely to perform, crevice burrowing than is *Arenicola* with its open coelom; whereas *Arenicola* is well adapted for homogeneous burrowing.

I thank Professors P. G. 'Espinasse and J. G. Phillips for facilities, and Professors G. P. Wells and E. R. Trueman for reading and criticizing the manuscript. This work was carried out during tenure of an SRC research studentship at the University of Hull.

Structure of the Nuclear Pore in Higher Plants

Two recent models which have been proposed to describe the structure of the nuclear pore[1,2] have given conflicting interpretations of the structural relationship of the various pore components in animal cells. No model has satisfactorily incorporated the evidence obtained from vertical sections of a pore, and no convincing model has been proposed for the nuclear pores in plant cells. In view of the obvious significance of nuclear pores for nuclear-cytoplasmic transport, and considering the current confusion about their structure, we have investigated the three dimensional picture of the pore complex in higher plants.

We wish to describe the pore structures observed in suspension culture cells of sycamore (*Acer pseudoplatanus*) and bean (*Phaseolus vulgaris*), crown gall tumour cells of *Parthenocissus tricuspidata* and root tips of sycamore and pea (*Pisum sativum*). (A more complete report will be published elsewhere.) Tissues were processed for electron microscopy[3] and examined in either a calibrated AEI EM6B or a Philips EM 300 equipped with a tilting stage. Pea roots were examined using the freeze etch technique[4].

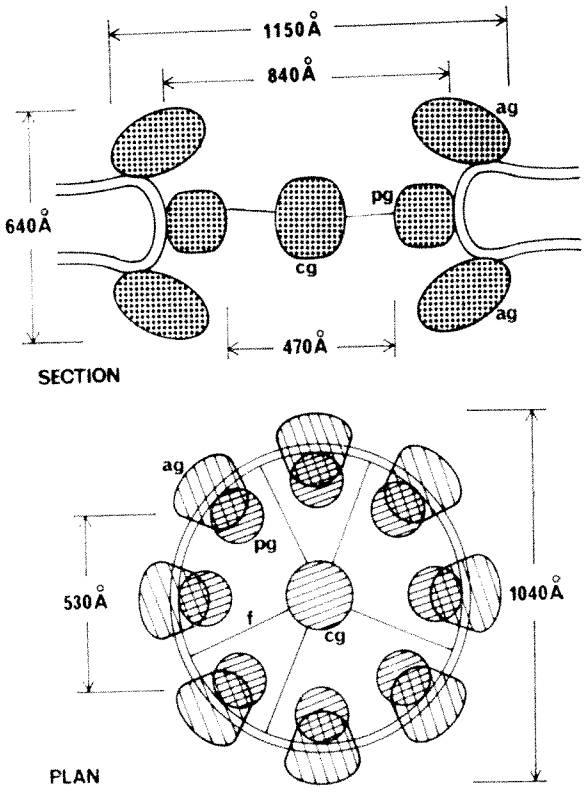

Fig. 1. Schematic diagram, drawn to scale, of the model of the nuclear pore showing its average dimensions. ag, Granular subunits of the annulus; cg, central granule; pg, peripheral granules; f, filaments.

Sectioned material revealed the following components common to all specimens (the measurements refer to the sycamore callus cells).

(*a*) The membrane boundary of the pore proper is circular. We agree with the report[2] that the octagonal appearance of the membrane seen in some negatively stained preparations[5] is a result of distortion during dehydration and spreading. The pores appear circular in the freeze etch studies. The diameter of the inside of the pore margin is 836 ± 88 Å.

(*b*) The peripheral granules, usually eight in number (visual inspection and rotation analysis), are spherical electron dense granules with a diameter of about 180 Å and a centre to centre spacing of about 250 Å. In vertical section the channel formed by the ring of granules is 472 ± 104 Å in diameter and in horizontal section is 527 ± 96 Å.

(*c*) The granular subunits of the annulus comprise two rings of eight granules, situated on the nuclear and cytoplasmic sides of the pore respectively, and attached to the membrane. Each granule appears as a flattened ovoid and together they form rings with an outer diameter of 1147 ± 83 Å in vertical section and 1037 ± 74 Å in horizontal section. The full depth of the pore complex so formed is 639 ± 71 Å.

(*d*) The central granule is present in many of the pores examined (Figs. 3 and 4). It is a large electron dense

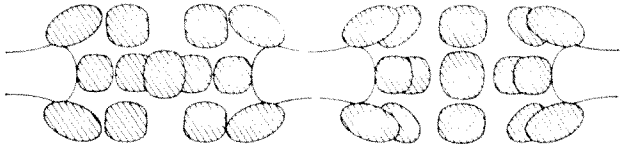

Fig. 2. Theoretical prediction of two possible projections to be seen in vertical section of a nuclear pore, assuming a section thickness of ~600 Å (silver/grey). Compare these with the actual sections in Fig. 3.

granule about 200 Å in diameter and 250 Å long, sometimes made up of subunits.

(*e*) Thin filaments (~30 Å) similar to those described in animal cells[2] can sometimes be seen in horizontal sections, connecting the central granule and the pore margin. Their number varies.

(*f*) Pore complex amorphous material fills the remainder of the area within the pore. It has an increased electron density, which suggests the presence of material acting at a barrier to free diffusion.

Taken together these features give the model shown in Fig. 1, and from this several points arise. In order to correlate the horizontal and vertical sections it must be remembered that the image obtained in the microscope is a projection of the electron density within the thickness of a section. The width of the pore complex seen in horizontal section is explicable in terms of the superposition of the peripheral granules and the granules of the two annuli above and below it. The measured widths support this argument. Similarly the variety of images obtained in vertical section can be interpreted if the thickness of the section is taken into account. A gold or silver section (600–1000 Å) will include at least five, if not all eight, sets of granules. This, depending on the line of projection, will lead to the images derived in Fig. 2, which are observed in Fig. 3. This explanation would clarify some of the pictures obtained before[1,2]. It would need a very thin grey section (~300 Å) to observe the simplified vertical section shown in Fig. 1. The correlation of the two images (vertical and horizontal section) and a check on the various measurements were made possible by examining several pores through a full 90° tilt (Fig. 4). This reveals the same pore both in horizontal and vertical section and confirms the predicted images (Fig. 2). In freeze etch pictures of the outer layer of the envelope two sorts of image are obtained, one having a "capped" appearance and one being a circular depression (Fig. 4). The former is on average 1·2 times greater in diameter than the latter, and this is explicable in terms of the fracture plane, which can either pass over the whole pore complex, including the granules of the annulus, giving the "capped" formation, or remove these (sometimes together with the peripheral granules) to give the smaller picture. This adds confirmation to the model and to the existence of the granules of the annulus. These various lines of reasoning lead to the model of Fig. 1, which in some respects resembles that of Franke and Scheer[2]. It differs in the definite presence of peripheral granules, the shape of the granules of the annulus and some of the measurements involved. Also, we only rarely see the 30 Å fibrils and associated granules. We find no evidence to support the model of Abelson and Smith[1] involving minitubules, central tubules and asymmetrically placed granules, although we support in general their view of the dynamic existence and character of the pore. What the various granules represent, beyond the knowledge that they are ribonucleoprotein[6], or how the pore operates in transport mechanisms remains obscure.

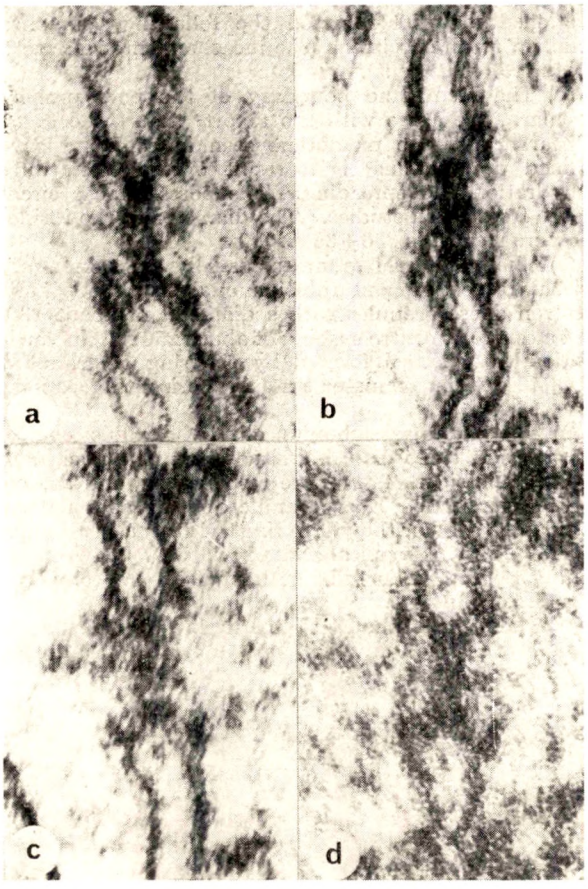

Fig. 3. *a–d*, Four different nuclear pores (sycamore) in vertical section (×160,000).

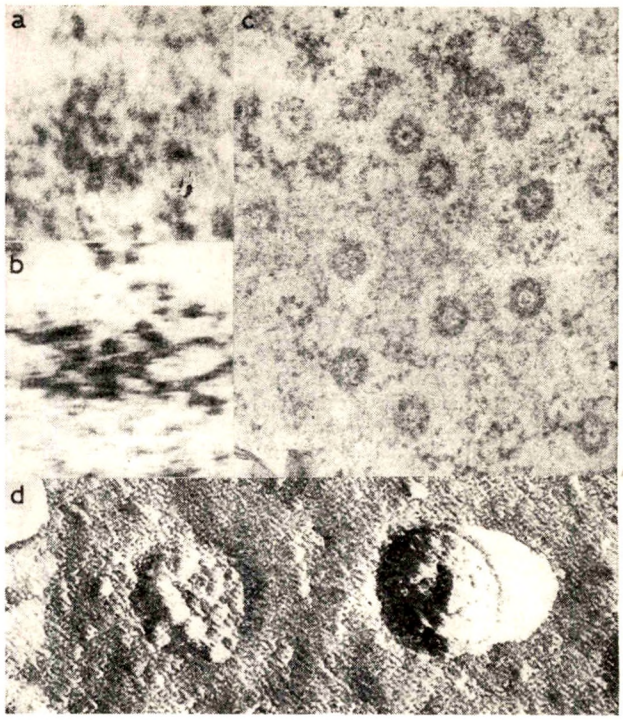

Fig. 4. The same nuclear pore (sycamore) in vertical (*a*) and horizontal (*b*) section by tilting it through 90° in the microscope (×120,000). (*c*) Horizontal sections of nuclear pores (sycamore). Most possess a central granule (×60,000). (*d*) Freeze etch picture of pea root nuclear pores, showing the two images "capped" and "hollow".

Book Reviews

SCIENTISTS AND SOCIETY

Reason Awake

Science for Man. By René Dubos. Pp. xviii + 280. (Columbia University: New York and London, July 1970.) 63*s* ($6.95); 27*s* paper.

If the 1950s can be characterized by the growth, at least in the developed countries of the West, of the scientific estate, the 1960s can be viewed as the beginning of widespread social discontent about science. We are, according to the author, living in the age of the "new pessimism" brought on by disillusionment with the wonders of science. The initial expectations of those who in the nineteenth century looked forward to a new society firmly rooted in scientific understanding stand in sharp contrast to the actual state of society that more than one hundred years of commitment to scientific and technical progress has produced. Lack of attention to the social implications of science and technology has transformed our environment beyond all recognition—so deep has been the change that the ecological balance of nature and the future of man are now seriously threatened.

The first four chapters of this book are concerned with drawing out the implications, both for science and society, of the unbridled development of technology. Thus, the central theme of the book, which derives from a set of lectures given by Professor Dubos at the Institute for the Study of Science in Human Affairs at Columbia University, is "not science *per se* but rather the penetration of science into all aspects of human life". Although the author's theme is not a new one, it is amply illustrated by references to the biological sciences rather than to the physical sciences as has usually been the case. But Dubos's chief concern is not simply to face his readers once again with a pessimistic picture of the ills of our technological society. As the central theme suggests, his concern is with the penetration of science into all aspects of human life; and this, for Dubos, means the effect of scientific technology on the intimate relationship between man and his environment. The ecological balance, according to Dubos, has been evolving over centuries. So, too, has man; his evolution, both mental and physical, is deeply involved with the development of his physical surroundings. Now, with the aid of science and technology, man has so profoundly altered the environment that his physical and mental make-up may no longer be able to cope with the rapid rate of change. But one of the principal characteristics of man is his adaptability. Throughout his evolution it has been necessary for man to adapt in order to survive biologically, but "paradoxically the greatest threat to the quality of human life is that the human species is so immensely adaptable that it can survive even the most objectionable conditions. . . . There is much evidence that tolerance of undesirable conditions is achieved at the cost of physical and mental disabilities in later life. To a large extent the so-called diseases of civilization are the delayed consequences of biological and mental stresses to which the organism has made adaptive responses that appear effective at the time but are inadequate in the long run". In chapters five and six, Dubos illustrates this thesis by drawing extensively on recent research in psychology, microbiology and the neurosciences.

Although the case for the ecological relationship between man and his environment is well made, the solution offered is less compelling. The answer to an ecological problem is an ecological solution. Man, the author argues, having grasped that his survival depends on a very delicate balance between myriads of conflicting forces must somehow attempt to "will" or plan the future so that the appropriate ecological balance is maintained or at least constrained to change more slowly.

It is refreshing, nonetheless, to see a distinguished scientist repudiate as inadequate the technological scenarios of the Hudson Institute but, alas, there is much work to be done before the ecological thinking of Dubos permeates the intellectual structures of Western society and becomes an effective alternative to the one dimensional "technological fixes" that society has so far provided to solve its problems. In a society committed to technological and economic growth as ends in themselves the battle of technology versus counter-technology must lead to the destruction both of the environment and man himself. Dubos urges us to abandon as quickly as possible the "philosophy of endless quantitative growth and opt for a social and economic 'steady state' ". Many persons may feel that to opt for such an alternative is to condone stagnation and eventually decadence. Dubos counters that ". . . a steady state is compatible with creative changes. In fact, change within a closed system will probably offer intellectual possibilities much more challenging than those offered by the kind of rampant growth that prevails at present". Accordingly, when man truly enters the age of science he will abandon his crude and destructive attempts to conquer nature by technological force. "He will instead learn to insert himself into the environment in such a manner that his ways of life and technologies make him once more at harmony with nature."

This is a thought-provoking series of essays which will be of interest to both the general reader and to the specialists who seek to understand the paradox of current disillusionment with science in a civilization dedicated to the advancement of knowledge.

Michael Gibbons

SURVEYS OF OVERCROWDING

Population Control

Edited by Anthony Allison. Pp. 240. (Penguin: Harmondsworth, Middlesex, June 1970.) 7*s*.

This collection of twelve essays is rather like a basic biology textbook; it moves from an initial discussion of protozoa, through plant, bird and animal populations to the second half which is devoted to human populations. As the editor freely admits in his introduction, such a wide ranging survey of populations will "have varying degrees of relevance to the human situation". This relevance could have been increased if there were more explicit discussion in the first half of the book, of the implications of plant and animal population fluctuations on human activity and vice versa. For example, in the paper by Leslie Brown on large mammals, it would have been interesting to know the likely ecological implications of proposals to exploit wild herds of mammals in Africa for human food consumption.

The second half of the book opens with a cogent summary of past and likely future growth of the world's human population by W. Brass, in which he notes how past predictions of population trends have not been incorrect but simply overtaken by changes, chiefly in fertility patterns which the projectors could not have been expected to foresee. There follows a discussion of the linkages between population growth and food supplies and then three papers on population regulation in the context of primitive societies, family planning programmes

in several developing countries, and contraceptive methods currently available. The final paper, by Colin Clark, is somewhat disappointing in a book which, to judge from the cover, sets out to examine population growth as "the major biological problem overshadowing the second half of the twentieth century", for about half the paper is concerned with basic factors affecting family size in past and present day societies. The emphasis, one feels, should have been on the economic and social implications of likely future developments.

The most remarkable essay is by John B. Calhoun. It links the two halves of the book physically and is a remarkable *tour de force* in that he casts his attention from the behaviour of rats in experimental habitats, through calculations of the population of western Guatemala in the sixteenth century to estimates of the optimum population of the world of 7,500 million. These are, he says, speculations which "the scientist often engages in but normally does not make public until several years later after the conclusion of studies generated by such speculation".

These speculations are based on the discovery that aggressive tendencies in rats developed at higher population densities the larger the initial size of the colony. He then goes on to argue that the totality of space that an individual is aware of around himself consists of physical space and "conceptual" space, that is, the "breadth of our insights and concerns in the arts, humanities, sciences and on the political and social scene". He sees extensions of conceptual space as compensating for reductions of physical space, but fears that there is currently occurring a reduction of both components. Overlapping conceptual space may lead to conflict even where there is no overlap of physical space. This was demonstrated by the behaviour of rats, but the sociologist might think of examples where human behaviour could tentatively be explained in such terms, such as the hostility by long standing residents to immigrants settling in their area. Although it has been shown that overcrowding existed long before new settlers arrived, nevertheless, the creation of overcrowding is frequently quoted as the justification for hostility. As Calhoun says, however, such speculations should be backed by several years of studies.

In all, this is a bitty book. If it does give, as it claims, a "biological perspective of man's predicament", this merely confirms that such a perspective is too myopic. The problems posed by population growth demand social and political perspectives and require social and political solutions.

D. R. COPE

THEORY OF POPULATIONS

Theoretical Population Biology

An international journal. Edited by J. F. Crow, N. Keyfitz, S. Karlin and R. MacArthur. Three issues per annum. (Academic: London and New York, 1970.) Private subscription $10.00; institutions $16.00.

"POPULATION" has a good chance of going to the top of the trendy protest charts. There is nothing trendy in the pejorative sense about this new journal, which aims to bring together papers on theoretical aspects of epidemiology, demography, population ecology and population genetics, although its appearance is opportune in view of the need for such a synthesis. Problems to be solved in this way include that perennial teaser, the genetic load, and the suggestion made recently in the *Lancet* (ii, 1249; 1968) that birth control will do genetic damage to the human population. There must also be rich gains in studying the relationships of genetic, evolutionary changes to the increasing exploitation of the environment, and their general effects on population dynamics or their influence on epidemics. The urgent practical implications of this kind of theory for resource conservation, animal breeding and population control are not far to seek.

A distinguished international team of editors and associate editors ensures a high standard for the journal, although in the first issue they have not succeeded in making all the papers comply with the journal's format for abstracts and summaries. Some of the contributors are a bit happy-go-lucky about explaining the meaning of their mathematical symbols to the uninitiated (later editions please note); other papers are models of clarity. Misprints are of the minor kind that will not worry anybody familiar enough with the material to be using the journal in the first place.

The reader can gain some idea of the potential scope of the journal from the contents of the first issue: the definition of a function which can be used to predict the number of competing species in a habitat at equilibrium; the building of a probabilistic model to describe a population with individuals who grow older (some theories assume instantaneous birth and death); a study of the equilibria at two genetic loci under natural selection; a solution of the rate of fixation of two linked loci in a population of finite size, and another of the effect of migration between populations on the rate of fixation at a single locus; a discussion of the evolutionary usefulness of sex, and one of the optimum strategy for animal breeding programmes.

I feel that the papers which communicate best are those which give numerical examples; indeed, it seems likely that the necessary and difficult line of communication between mathematicians and biologists will increasingly be kept open by the high-speed computer, presenting results intelligible to the non-mathematician, especially as graduates of the more worthwhile biological science courses now have some training in programming.

This deserves to become an important journal, bridging the gap between several disciplines.

JOHN R. G. TURNER

INTERNATIONAL HEALTH

Building the Health Bridge

Selections from the works of Fred L. Soper. Edited by J. Austin Kerr. Pp. xxxvii+567. (Indiana University: Bloomington and London, July 1970.) $17.50; 167*s*.

ANY book on the history of medicine that may be written at the end of this century is bound to say that one of the principal achievements of the present generation was the degree of international collaboration in the field of public health. The national responsibility for detection, notification and control of communicable diseases is now being gradually extended to international bodies. In the age of jet planes and mass travel such an approach is more suitable than the legalistic and restrictive attitude of the early phase of quarantine regulations.

This book contains forty-five selected papers from the writings of one of the great American epidemiologists and medical administrators, but it gives more than the outline of the work of Dr Fred L. Soper, formerly of the International Health Division of the Rockefellor Foundation and of the US Public Health Service, the retired director of the Pan-American Sanitary Bureau, WHO Regional Office for the Americas. The volume covers one of the most exciting, fruitful and significant periods in the recent history of international health.

After an introduction and a brief biography of Dr Soper, it opens with the story of the survey and control of hookworm in Brazil, Paraguay and other South American countries. It then deals with the eradication of yellow fever from Brazil, through the control of the peri-domestic mosquito, *Aedes aegypti*. The need for more accurate reporting of the disease led to the setting up of the

"viscerotomy" service, which collected specimens of liver tissue from all persons dying of a disease that might have been yellow fever; serological studies on large groups of inhabitants and on captured monkeys were also of immense value for the study of the distribution of the disease. The information thus provided gradually unfolded the picture of "jungle yellow fever" carried by elusive forest mosquitoes, while howler monkeys of Brazil and Panama were the sources of the virus. This fascinating story of epidemiological detection was well matched by the outstanding success of the 17D yellow fever vaccine, for prevention of the disease.

Another chapter gives the dramatic description of the invasion of Brazil and of lower Egypt by the African *Anopheles gambiae*, the subsequent epidemics of malaria and the eventual eradication of the vector from these territories. This was the origin of the notion of global eradication of malaria—a concept taken up by the World Health Organization in the following years.

The last chapters are devoted to the assertion of the belief in the feasibility of eradication of malaria, yaws, tuberculosis and smallpox from the face of the Earth. While stressing the present achievements, the book reflects Dr Soper's profession of faith that the ultimate goal of elimination of many communicable diseases can be attained by a determined and specific attack on the cycle of transmission of these infections. He feels that there is no compelling need for a previous build-up of general health infrastructure and that much can be done by medical science, quite independently of the preliminary social and economic development of underprivileged tropical countries afflicted by all the well known symptoms of the vicious circle of poverty, ignorance and disease.

Many experienced specialists of tropical public health will disagree with this oversimplified persuasion so forcibly expressed. The present consensus of opinion is that the integrated improvement of all aspects of community life offers the best chances for permanent advance of developing countries. The pursuit of some well defined health aspects should be seen not as a goal itself but as a part of the general process of orderly growth of the system of national health determined by socio-economic priorities. This should not be interpreted that economics are the key to any progress. Such an extreme view, reflected by the recent Pearson report on aid to developing countries, virtually ignored the health problems of tropical areas and created some concern among those who are aware of the present situation in the "third world".

Nobody who reads this anthology from the writings of an inspiring, courageous and often ruthless pioneer of preventive medicine on an intercontinental scale will fail to be impressed by the scope of his life-work, by his perseverance and by his vision. Those who know and admire Dr Soper not only as a foremost scientist and medical administrator but also as one of the "most unforgettable characters they have met", may regret the absence of a full page plate with his likeness; the small photograph on the back page of the blurb will not stand much wear in a book that will certainly go through many hands and will appeal to the specialist and to a general reader interested in modern trends of global epidemiology.

L. J. BRUCE-CHWATT

CHIRAL BIOLOGY

Molecular Asymmetry in Biology

By Ronald Bentley. Vol. 2. Pp. xiii + 566. (Molecular Biology: an International Series of Monographs and Textbooks.) (Academic: New York and London, June 1970.) 257*s*.

THIS second volume of *Molecular Asymmetry in Biology* is as good as the first (see review in *Nature*, **226**, 566; 1970). It deals with two major topics: stereospecificity in some important biological processes (four chapters, 344 pp.), and the determination of the configurations of some biologically important compounds (two chapters, 182 pp.). To treat either topic exhaustively would be to cover a large part of natural product chemistry and biochemistry; the particular groups considered in each case are well chosen and thoroughly discussed.

The four chapters on stereospecificity in biological processes cover dehydrogenations, reduction and related reactions; condensations with acyl-coenzyme A derivatives and hydro-lyase reactions; a variety of other reactions important in intermediary metabolism; and biosynthesis and utilization of isoprenoid compounds.

The two chapters on determination of absolute configuration deal with general types of biologically important compounds (carbohydrates, amino-acids, hydroxy-acids, lipids, nucleosides, vitamins, and the like), and a wide variety of isoprenoid and related compounds.

The book is illustrated with many good formulae and diagrams, as was the first volume, and the references are thorough. In a useful preliminary note on nomenclature, the author draws attention to some important unpublished proposals by Hanson and Hirschmann, and corrects an error in stereochemical designation in the first volume (pp. 56 and 214, [4-^{2}H]-mevalonic acid).

The two volumes of Dr Bentley's work together form an admirable introduction to steric aspects of biochemistry, and will point the way to much further interesting work.

W. KLYNE

HANDLE WITH CARE

Infections and Immunosuppression in Subhuman Primates

By H. Balner and W. I. B. Beveridge. (Proceedings of the International Symposium, Rijswijk, December 1969, organized jointly by WHO and the Radiobiological Institute, TNO, Netherlands.) Pp. 258. (Munksgaard: Copenhagen, 1970.) 120 D.Kr.

THE increasing use of subhuman primates in medical and biological research has inevitably led to problems, which were admirably summarized in 1966 by L. V. Meléndez and R. D. Hunt: "... the ecological niches of man and animal cross with increasing frequency and this undoubtedly will create or uncover new disease problems which are also important ... this is a potential threat both for human and animal health". Eleven months ago a timely international symposium was held at Rijswijk, The Netherlands, to discuss the problem and control of communicable diseases in subhuman primates and the prevention of the transfer of disease between man and animals and between animals in captivity. The lowering of resistance of the host by immunosuppressive therapy and the limitations and complications of immunosuppression were also considered in a series of authoritative papers.

It is an onerous task to single out particular contributions from this collection of uniformly excellent papers, which include reviews of tuberculosis, pathogenic enteric bacteria, group B arboviruses, simian pox viruses and more exotic infections such as green monkey disease (Marburg virus), monkey B virus, the outbreak of "monkeypox" in the Rotterdam zoo and descriptions of the epizootics caused by simian haemorrhagic fever virus. The problem of "spontaneous" infections in cell cultures derived from simian tissues, stress and latent pathogens, parasitic opportunism, infections with herpes viruses and the increase in their virulence when infecting species other than their natural host, such as the oncogenicity of *H. saimiri* and squirrel monkey heart isolate (SMHI), are important topics which are also discussed. A masterly account of spontaneous or induced hepatitis in subhuman primates is provided by F. Deinhardt, whose studies of hepatitis in marmosets form one of the

landmarks in recent research in this field. The paper on the handling of monkeys by F. T. Perkins and E. G. Hartley is an outstanding example of clarity in scientific writing, and the reader is guided step by step through the procedures which should be adopted on the reception of animals to the recapture of an escaped simian and the action to be taken if scratched or bitten. G. Mahouy and J. C. Friedmann outline the architectural and technical principles of different barrier systems for the prevention of infection from the outside and measures to reduce the possible spread of infection within a primate unit. The final chapters include superb accounts of the hazards of immunosuppression by D. W. van Bekkum, some observations of hepatic allografts and xenografts by R. Y. Calne and his associates; and R. Cortesini and his colleagues review heterotransplantation in primates.

The many photomicrographs and the photographs of the orang-utans Peek, Barbara and Nina affected by monkeypox are excellent in quality and detail. The line diagrams are clear and helpful and the tables are comprehensive.

The book is strongly recommended to all who are responsible for the care and study of non-human primates in the laboratory, in zoological gardens and animal reserves. Laboratory workers, pathologists, veterinary surgeons, microbiologists, animal house and laboratory designers, administrators responsible for the health of man and his animals and, indeed, anybody interested in the biomedical sciences will find this book an indispensable companion and a mineful of information.

A. J. ZUCKERMAN

SAVING A SHIPYARD

Fairfields

A Study of Industrial Change. By K. J. W. Alexander and C. L. Jenkins. Pp. 286. (Allen Lane (The Penguin Press): London, September 1970.) 50*s*.

IN 1965 a financial crisis hit the Fairfields shipyards in Govan on the Clyde in Scotland. The appointment of a receiver came about two-thirds of the way through the working life of the Shipbuilding Enquiry Committee which had been set up by the Board of Trade to investigate the acute crisis which faced the British shipbuilding industry. The shop stewards at Fairfields launched a vigorous and unrelenting campaign to keep the yard open. The government, as exemplified by the setting up of the shipbuilding enquiry, was interested in saving the shipbuilding industry and in stabilizing employment on the Clyde. But it was unsure—the committee not yet having reported—how to set about doing that.

The catalyst in the situation was Mr (now Sir) Iain Stewart, a Scottish businessman who had been campaigning for "new look" industrial relations on the Clyde, based upon security of earnings and a considerable extension of retraining facilities. His reaction to the threatened closure of Fairfields was that a mass pay-off affecting 2,500 workpeople would destroy any possibility of building better industrial relations in the area. The scene was now set for the unique industrial experiment that this book describes and analyses.

As George Brown said at the time in the House of Commons: "(This is) a quite new partnership between government, private enterprise and the trade unions, the motive being not just to save a recently modernized Scottish shipyard from extinction, but in addition to provide a proving-ground for new relations in the shipbuilding industry which could change the whole image of our country". Here was a unique combination of government, trade union and private enterprise capital; it was to be an industrial proving ground for new ideas and techniques in management and industrial relations.

The authors of this book were both observers and participants in the experiment at the time, and one of them was a member of the Fairfields board. This involvement itself was a unique experiment in academic research. They describe the course of events throughout the structure, at the level of union management and at that of union management within the yard. A detailed study of changing relations within the yard is made. The authors analyse salary and wage patterns, they show the impact of productivity assessments on wage negotiations, and they evaluate the overtime system and deal with problems of absenteeism. Finally, they attempt to assess the successes and failures of the experiment.

In the area of assessment they are faced with two great difficulties. The first is that the aims of the experiment were never set out clearly and comprehensively, so that criteria for judgment may themselves be disputed. But then they were dealing with a real business/work situation and not a laboratory test, and imperfections had to be accepted. The second problem is that the life of the experiment was foreshortened by the merger with other shipyards on the Upper Clyde.

Nonetheless, even if one may wish to quarrel with a particular assessment or query the basis of the judgment, one is left with the conviction that this detailed study of a unique experiment is an important academic event in itself, and that the experiment at Fairfields was worthwhile and ought to be attempted in other industries in different parts of the country in the interests of good industrial relations and cooperation, and for improved industrial efficiency.

I. KUCZYNSKI

ANOTHER REVIEW JOURNAL

Essays in Physics

Edited by G. K. T. Conn and G. N. Fowler. Vol. 1. Pp. ix+164. (Academic: London and New York, June 1970.) 30*s*; $4.50.

"WITH this issue yet another periodical in physics makes its appearance. There are already so many that some explanation, or indeed some defence, is necessary." So begins the preface to the first volume of this new publishing venture and the editors are right to be hesitant. They feel that because of the proliferation of journals in all branches of physics yet another is needed in order "to bring together straightforward accounts of ideas, methods and developments in such a way that these are accessible to as large a number of physicists as possible".

The periodical situation is really becoming intolerable, and what is needed is not a further journal explaining to us what is in the other journals, but a rationalization of the total journal system. This, one hopes, is one of the issues that the European Physical Society is tackling with vigour. In any case, surely we have enough journals of the type "Reviews of . . . ", "Progress of . . . ", "Reports on Progress in . . . ", "Advances in . . . ", "Annals of . . . ", "Comments on . . . ", not to mention "Contemporary . . . " without adding a further "Essays in . . . ".

This having been said, do the articles in this volume provide something new and of a type which does not appear in the established review and survey journals? The answer is clearly no. There are four of them: "Strong Interactions of Elementary Particles", by R. J. Eden; "Electronic Phase Transitions", by David Adler; "Optical Diffraction Methods in Crystal-structure Determinations", by H. Lipson; and "Meteorites", by G. Turner. Each article has value, and to one not well versed in the fields the last two mentioned are particularly fascinating. The point is, however, that there already exists more than a sufficiency of natural homes for each of these articles and to provide another is doing the physics community no service whatsoever.

R. J. BLIN-STOYLE

PHYSICS AND RELATIVITY

Relativity

Edited by Moshe Carmeli, Stuart I. Fickler and Louis Witten. (Proceedings of the Relativity Conference in the Midwest, Cincinnati, Ohio, June 2–6, 1969.) Pp. xii + 381. (Plenum: New York and London, 1970.) $20; 180*s*.

In 1963 R. K. Sachs said in a telling phrase, "General relativity is a legitimate, though minor, part of present fundamental physics . . . because at present it has few interactions with the remainder of physics". In this way he set the stage for a decade of development of the subject and provided a yardstick against which one can judge the steady stream of volumes of conference proceedings and collected papers which shows no sign of diminishing. The present volume reports on a national conference, but the diversity of activity in North America is sufficient to provide a view that reflects most of the recent developments in the subject.

Among others the quantization programme is reviewed by Komar and quantum gravity pursued by Klauder and Misner. A development which promises more relations with the rest of physics is foreshadowed in the Boltzmann theory paper of Anderson and in a note on the Einstein–Liouville equations by Berezdivin and Sachs. The experimental side is looked after by a report of Weber on his detection of radiation and a very valuable survey of the use of low temperature techniques by Everitt, Fairbank and Hamilton. Singularities are particularly well dealt with by Geroch, and the reader who wishes to whet his teeth may be directed towards Geroch's solution of twenty problems which he believes to be fairly difficult, and all unsolved, on pages 287–9. The fairly new topic of superspace is discussed firstly by Wheeler in a very characteristic paper called "Particles and Geometry", giving one of the usual wide-ranging views of possibilities in the subject, and in more detail by Fischer and DeWitt. Perhaps the most unusual paper is that entitled "Contribution to the History of Einstein's Geometry as a Branch of Physics" by Eugene Guth, which can be read with the greatest of interest by any physicist, including those who consider themselves experts in general relativity.

To what extent then has the subject become related with the rest of physics? The answer provided by this volume is, I think, that the process has definitely begun, but it is likely to be long and painful.

C. W. Kilmister

STELLAR SPECTROSCOPY

The Theory of Stellar Spectra

By Charles R. Cowley. (Topics in Astrophysics and Space Physics.) Pp. xi + 260. (Gordon and Breach: New York and London, May 1970.) 195*s* ($23.40) boards; 70*s* ($8.50) paper.

For approximately 100 years, astronomers have been attempting to deduce detailed information about conditions in stellar atmospheres and the abundances of the chemical elements from the appearance of stellar spectra. The physical concepts used are, on the whole, relatively simple and straightforward. For their understanding they require chiefly a knowledge of the theory of radiation of optical wavelengths and how this radiation interacts with matter in a gaseous phase. Because of the way in which the subject developed, however, the terminology of astrophysics is complex and occasionally contradictory. The result is that he who would measure and analyse stellar spectra in order to understand stars and to find clues to the origin of the chemical elements and to the history of the galaxy often has a difficult time getting into his subject.

Many of the difficulties arise because the young research worker has not had an adequate preparation in the necessary parts of the theory of radiation and of spectroscopy. This book attempts to bridge the gap between an intermediate level of college physics and the introductory stages of astrophysics. Four of the six chapters deal with relevant facets of the theory of matter and radiation, and two deal with astrophysics proper. Chapters one, three, five and six handle the theory of the line absorption coefficient, necessary parts of statistical mechanics, the semi-classical theory of line broadening, and the quantum-mechanical treatment of pressure broadening. Chapters two and four consider typical problems of spectral lines in stellar atmospheres and the classical methods of quantitative analysis of a stellar atmosphere. The book is completed with four appendices, a list of references, an extensive index of symbols used and their various definitions and a good general index.

The list of symbols used is particularly valuable because in many cases, when a particular facet of the physics of radiation is discussed, the notation of a standard textbook on the subject is maintained. This procedure leads to the same letter or symbol sometimes having two or more meanings as one proceeds through the book. Within any one section, however, the particular meaning adopted is there carefully preserved.

The author wishes his book to be a source of encouragement to the astronomer who wants to study stellar spectra without becoming too deeply involved in the non-equilibrium theory of transfer theory. This point of view is supported with statements such as "specifically we shall not concern ourselves with the details of the transfer of radiation within the spectral line" and "no one questions the use of Saha's theory of ionization in the interpretation of the spectral sequence".

I think that an introduction to astrophysics should attempt to sharpen the student's critical power by pointing out the weakness of argument underlying statements such as these and to encourage the student to think more deeply. If the student can be assumed to be prepared to accept, without preamble, derivation of the equation of transfer in general vector notation and to follow without undue struggle a discussion of theoretical line strengths (taken more or less directly from the text on *Atomic Spectra* by Condon and Shortley), he has the necessary analytical knowledge to profit by such an experience. He will then be prepared to advance towards the goal discerned by stellar spectroscopists so many years ago.

Anne B. Underhill

LIPID REVIEW

Topics in Lipid Chemistry

Vol. 1. Edited by F. D. Gunstone. Pp. ix + 451. (Logos, in association with Elek Books: London, July 1970.) 160*s*.

This volume is the first of a series intended to provide a continuing review of the chemistry, physics and technology of lipids, without omitting important biological aspects. In addition, a form of information service is offered by appending a list of relevant books and reviews, but not original papers, published in the past eight years.

Not surprisingly, in an area where the introduction of physico-chemical procedures for separation and characterization of naturally occurring lipids has initiated a vast growth of publications, the chapters tend towards either techniques themselves or the application of techniques to a particular problem. Thus there are comprehensive and authoritative reviews of the use of gas liquid chromatography for the determination of structure of fatty acid esters, of mass spectrometry, and of hydrogenation catalysts. These subjects are clearly of value on account of their generality of application and interdisciplinary

position. A chapter devoted to optically active long chain compounds brings together the techniques applicable to the study of such compounds and the information obtained. Cyclopropane and cyclopropene fatty acids are similarly reviewed in a neat and readable chapter. Milk lipids are reviewed in depth, and the large volume of analytical data accumulating in this commercially important topic makes for heavy reading. Nevertheless, even perusal of a catalogue of the milk fats of seventy-five different species can be rewarding for the general reader, if only to challenge his imagination on how to milk a black rhinoceros.

In conclusion, this volume is an excellent reference source for the specialist, and as such is to be recommended.

P. B. GARLAND

ION-MOLECULE REACTIONS

Ion Molecule Reactions

By E. W. McDaniel, V. Cermak, A. Dalgarno, E. E. Ferguson and L. Friedman. (Wiley Interscience Series in Atomic and Molecular Collisional Processes.) Pp. xiii + 374. (Wiley (Interscience): New York and London, August 1970.) 190*s*.

THE subject which this book treats has in the past few years been expanding so rapidly that a comprehensive review by notable specialists in the field is most welcome. If a verdict may be placed before the evidence, the book may at once be said to be a contribution to the literature which will be an important reference for many years, although other volumes on the same subject should be produced. Perhaps the only serious criticism which can be offered is that, after starting the project in 1964, some portions at least were probably completed by 1968, and a considerable and regrettable delay in its general availability seems to have occurred.

After a short introductory chapter, there follows in the second chapter a comprehensive review of the experimental method relevant to the study of ion-molecule reactions. The use and accurate control of electron bombardment and other similar ion sources is first described, followed by accounts of their adaptation to the measurement of rate coefficients of suitable reactions. Next follows a section on the sampling of ions from electrical discharges and afterglows. These systems, which in some cases mimic the conditions of the upper atmosphere, must be very specially controlled in order to produce reliable values of rate coefficients. These problems of control and some of the solutions adopted are fully described. The section on the "flowing afterglow" technique is of notable length and completeness.

The chapter continues with a section on drift tube techniques which includes a full treatment of the problem of diffusion in conditions of low E/P with simultaneous reaction of the ions. There is then a section describing what would now be called the earlier work of the relatively new field of ion cyclotron resonance. The chapter concludes with a lengthy and valuable review of the information obtained using beam techniques. This includes the description of classical kinematics which is needed for a proper understanding of the results.

The experimental tone of chapter two is continued in chapter four, which gives a review of existing data under the heading "Reaction Rates from Ionospheric and Airglow Data". This chapter, however, quotes only two references dated later than 1967, and those readers wishing for fully up to date information will have to search further.

The fifth chapter is headed "Ion-molecule Chemistry" and seeks to bring these reactions more fully into the gaze of chemists by discussing them in terms of heats of formation of the ions, orders of reaction and the dependence of rate coefficient on energy. A discussion of dependence of rate on system temperature is notably absent from the subject.

The compilation of "Quantitative Data" in chapter six lists all known data on cross-sections and/or rate coefficient, and for each reaction supplies also the "Langevin" rate coefficient for comparison. Tables are given for four classes of reaction. There is then a section in which graphical data on various reactions are assembled. This chapter shows several references dated 1969, plus several results "unpublished" or "to be published", and provides a very valuable collection.

The third chapter is reserved for special mention, because this treatment of the theory of ion-molecule collisions is probably the material least expected by a potential reader already well versed in the subject. Running to nearly a hundred pages, or a quarter of the book, it gives a treatment based on quantum theory which is full without being overwhelming, and is very well timed in its appearance. Improvements in experimental technique have, over several years, made the classical Langevin treatment seem inadequate. The patchwork which has thus developed may, with such a stimulus as the introduction of this chapter provides, evolve into a more coherent and generally satisfactory discussion of the phenomena.

P. F. KNEWSTUBB

FAMOUS INEQUALITIES

Finite Sections of Some Classical Inequalities

By Herbert S. Wilf. (Ergebnisse der Mathematik und ihrer Grenzgebiete, Band 52.) Pp. vii + 83. (Springer-Verlag: Berlin and New York, 1970.) 28 DM; $7.70.

THE problem here investigated may be elucidated by a simple example. For positive a_n, it is known that

$$\sum_1^\infty \{(a_1 + a_2 + \ldots + a_n)/n\}^2 \leq 4 \sum_1^\infty a_n^2$$

where the constant 4 is best possible, that is, cannot be replaced by a smaller number. If now the sums are taken not to ∞ but to an integer N, say, then we may hope to replace 4 by a constant $k(N)$, where $k(N) \to 4$ as $N \to \infty$. The examination of the character of $k(N)$ for a number of the classical inequalities brings together several analytical techniques: asymptotic methods, Toeplitz forms and integral kernels, functional analysis with operators which are not necessarily linear. Hilbert's famous inequality

$$\sum_{m,n}^\infty \{a_m a_n/(m + n)\} < \pi \sum^\infty a_m^2$$

belongs essentially to linear operator theory, and a great deal is known about its corresponding $k(N)$; for instance,

$$k(N) = \pi - \pi^5/2(\log N) + O\{(\log \log N)/(\log N)^3\}$$

On the other hand, non-linear theory is involved in Carlemann's inequality

$$\sum^\infty (a_1 a_2 \ldots a_n)^{1/n} < e \sum^\infty a_n$$

and here the first discussion of the appropriate $k(N)$ is to be found in a delicate and ingenious argument given by de Bruijn in 1963.

The author has provided a concise and lucid account of the present state of knowledge, with a useful bibliography. The young postgraduate worker interested in "hard" analysis will find here many suggestions for further research.

Government Research

SIR,—Your comments on "Green Paper to Burn" (*Nature*, **228**, 1; 1970) raise again the question of the government's relations with industrial research. A fair amount has been said on the subject, but there is one form of analysis that I have not seen applied simply and directly.

This arises from categorizing research activities in the dimension that ranges from long term, fundamental and speculative work through applied research to development. Such classification can in fact be done quite straightforwardly in terms of the time expected to elapse before the work in question will be applied outside the laboratory. The time scale stretches from about one year for development that will be used very soon to the nearly pure research looking ten or more years ahead. (Work at the ultra-short end of the spectrum could hardly be called R or D.)

Generalizing for the overall national picture, I suggest that industry is looking after 1–2 years work and the universities are covering work at 5–10 years range: with the recent expansion of universities, we need not be unduly worried over shortage of long-term effort.

The serious gap occurs in the intermediate region, research looking, say, 3–6 years ahead. This is the area where spin-off from defence research was most applicable and where the old look of research associations was aimed. Only a few industrial laboratories are long-sighted enough to reach this territory, and the current tendency for research associations and the UKAEA laboratories to look for short-term income is making them also neglect this middle range of applied research.

I have myself come across two projects recently which, under the climate of a few years ago, could have been funded largely with government money. They were recognized to be promising, but because they were somewhat speculative and could only come to fruition in three or four years' time, industry, with its present tight purse-strings, was reluctant to put up the necessary finance. I suspect that these are typical of many cases formulated and unformulated.

Of course, there are honourable exceptions and, of course, diagnosis is easier than cure. But I believe that Britain's technological health will be endangered until this particular weakness in the R and D structure is recognized and attempts made to remedy it.

Yours faithfully,

B. E. NOLTINGK

"Windwhistle",
Nutcombe Lane,
Dorking, Surrey.

A Congress is a Congress is a Congress

SIR,—In view of the opinions expressed in *Nature* (**228**, 13; 1970) on international meetings, you may be interested in the "case history" of the Second International Congress of Parasitology which took place on September 6–12, 1970, in Washington DC and which involved some 1,600 participants from many parts of the world.

The organizers of this congress wanted it to be different from any previous similar gatherings by proposing a greater informality of the meetings and a full opportunity for free and ample discussion. This was attempted by parcelling up the proceedings of the congress into a large number of small "colloquia" on a well defined subject.

In addition there were eight formal meetings under the banner of "Technical Reviews" dealing with topics of wider interest (taxonomy, genetics and evolution of parasites; pathology of parasitic infections; phytonematology; pharmacology of antiparasitic agents; immunity; seroepidemiology; physiology and biochemistry of parasites; drug activity against trematodes).

In organizing the congress the selected chairmen of seventy-five colloquia approached a number of participants with requests for relevant papers. Other unsolicited contributions on the same subjects were grouped accordingly. 980 papers submitted to the congress were published in advance in three special issues of the *Journal of Parasitology* and distributed to the participants at the time of registration.

Chairmen of colloquia urged the participants not to present their papers formally but to make a single point, thus stimulating the discussion. Moreover, participants were not committed to any specific colloquium and were given free rein to follow only their personal interests. All this was done to avoid the general criticism of large international meetings that too little time is left for discussions.

The final result of this unconventional convention was hailed as a success by a majority of the participants. No doubt the new formula worked well in some colloquia and was less effective in others, especially when several chairmen were unsure how to apply it. There were complaints that a large number of colloquia and their simultaneous running were responsible for a degree of frustration in people whose interests were overlapping and who were anxious to be exposed to the greatest possible amount of cross-fertilization.

It seems that the degree of intercommunication achieved by a gathering of scientists is not proportional to the numbers assembled, and that there is a critical limit beyond which even the informal exchange of views becomes difficult. There is no uniform or infallible method applicable to a large congress intending to preserve the intimacy and the free give and take of a small meeting. The Second International Congress of Parasitology was undoubtedly a courageous and an interesting attempt to square this particular circle. The next congress will take place in Munich in 1974. *Qui vivra, verra!*

Yours faithfully

L. J. BRUCE-CHWATT

Keppel Street (Gower Street),
London WC1E 7HT.

Biological Membranes

SIR,—Your Molecular Biology Correspondent, in commenting (*Nature*, **227**, 1294; 1970) on some interesting recent model studies relevant to biological membranes, leaves the impression that it is a new idea of general importance in transport studies that the relative energies of hydration of the alkali cations may be responsible for their differing affinities for anionic or polar sites. I would like to correct this impression by drawing attention to the extensive studies by Eisenman[1] of the origins of ionic specificity which include a quantitative treatment of the dependence of ionic specificity on hydration energy. Eisenman's work during the last decade has been superbly reviewed, with special reference to its validity in biology, by Diamond and Wright[2].

Yours faithfully,

MARTIN DAVIES

Department of Biology,
University of York,
Heslington, York.

Announcements

University News

Mr J. E. L. Farradane has been appointed the first director of the Centre for Information Science of the **City University.**

Dr G. W. Bisset, National Institute for Medical Research, has been appointed to the chair of pharmacology, St Thomas's Hospital Medical School, **University of London.** The title of professor of preventive dentistry has been conferred on **Dr M. N. Naylor** in respect of his post at Guy's Hospital Medical School and that of professor of chemistry has been conferred on **Dr Mary R. Truter** in respect of her post at University College.

Dr I. A. Menzies, University of Manchester Institute of Science and Technology, has been appointed to the new chair of materials technology in **Loughborough University of Technology.**

Professor Frank Morton has been appointed to a personal chair in chemical engineering in the **University of Manchester. Mr M. C. G. Israels** has been appointed professor (part-time) of clinical haematology and **Dr S. Thomas** has been appointed to a chair of physiology.

Appointments

Mr Bryan Rofe has been appointed director of the Antarctic Division of the **Commonwealth Department of Supply, Melbourne.**

Lord Drumalbyn has been appointed to succeed **Lord Bessborough** as deputy chairman of the **Metrication Board.**

Sir Brian Windeyer, vice-chancellor of the University of London, will be chairman of the new **National Radiological Protection Board,** established to advance knowledge and provide information on protection from radiation hazards. Members of the board include **Sir Charles Cunningham,** UKAEA; **Mr J. G. Duncan,** MRC; **Professor N. Feather,** University of Edinburgh; **Mr F. W. Fenning,** AERE; **Dr E. E. Pochin,** MRC Clinical Research Department; **Dr Derek Pringle,** Nuclear Enterprises Limited; **Professor R. E. Steiner,** University of London Postgraduate Medical School.

Miscellaneous

Professor W. T. Singleton, University of Aston in Birmingham, has been made the first Distinguished Foreign Colleague of the **American Human Factors Society.**

Mr J. M. Lumley of Monash University has been awarded a **Rutherford Scholarship** for three years for work in low temperature physics at the Cavendish Laboratory, Cambridge.

Professor G. Melchers of the Max-Planck Institut für Biologie, D 74 Tübingen, Correnstr. 41, would like to hear from anybody who is engaged in the culture of haploid plants from anthers. This information would be appreciated because an EMBO workshop on this topic is planned for next year.

Applications are invited for two **Ramsay memorial fellowships,** a British (general) fellowship and a fellowship limited to candidates educated at the Universities of Glasgow or Strathclyde or who propose to work there. The fellowships are normally tenable for two years. Further information can be obtained from the Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College London, Gower Street, London WC1.

The **Geological Society of Uganda** was established last month at Makerere University, Kampala. The society aims to encourage the study of the earth sciences, particularly of and in Uganda, and hopes to sponsor symposia and excursions. **Mr C. E. Tamale-Ssali** is president of the society, and members of council include **Professor R. Macdonald** (hon. secretary), **Dr K. Tinkler** (hon. treasurer), **Mr J. E. N. Kagule Magambo** (hon. editor), **Mr M. D. Cruikshanks** and **Mr E. S. Balaba.** Further information can be obtained from Dr K. Tinkler, PO Box 7062, Kampala, Uganda.

ERRATUM. The electronic processing mentioned by our Materials Science Correspondent (*Nature*, **228**, 19; 1970) was developed at the Standard Telecommunications Laboratories, Harlow, and not at the Services Electronic Research Laboratory.

ERRATUM. In the review "Scavenging Cells" by F. Jacoby (*Nature*, **228**, 188; 1970) the word "macrophage" on lines 1 and 2 of the third paragraph should read "macrophages".

ERRATUM. In her written answer in the House of Commons on July 20 (*Nature*, **227**, 431; 1970), Mrs Margaret Thatcher said that the Government hopes to increase the present annual number of preclinical entry places to medical schools from 2,700 to 3,700 by 1975. This was mistakenly quoted as an increase of between 2,700 and 3,700 places.

International Meetings

January 5–7, 1971, **The Impact of New Techniques on Palaeontology,** Belfast (Dr A. D. Wright, Geology Department, The Queen's University of Belfast, Belfast BT7 1NN, Northern Ireland).

January 5–7, 1971, **Solid State Physics,** Manchester (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

January 5–8, 1971, **Radiation Effects and the Mitotic Cycle,** Manchester (Dr Alma Howard, Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester M20 9BX).

January 6, 1971, **Sorption Phenomena in Vacuum,** Liverpool (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

January 6–8, 1971, **Chemical Effects at Bearing Surfaces,** Swansea (Mr P. L. Hurricks, Swansea Tribology Centre, University College of Swansea, Singleton Park, Swansea SA2 8PP).

January 7–8, 1971, **Numerical Methods for Unconstrained Optimization,** Teddington (Secretary, Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex SS1 2JY).

January 11–18, 1971, **Tropical Ecology emphasizing Organic Productivity,** New Delhi (Professor R. Misra, Department of Botany, Banaras Hindu University, Varanasi 5, Uttar Pradesh, India).

January 18–25, 1971, **Pathological Wilting in Plants,** Madras (Professor T. S. Sadasivan, Centre of Advanced Study in Botany, University Botany Laboratory, Madras 5, India).

January 27–February 3, 1971, **Plant Pathology,** New Delhi (S. P. Raychaudhuri, Division of Mycology and Plant Pathology, Indian Agricultural Research Institute, New Delhi 12, India).

February 28–March 4, 1971, **Analytical Chemistry and Applied Spectroscopy,** Cleveland (Dr W. G. Fateley, Carnegie-Mellon University, 4400 Fifth Avenue, Pittsburgh, Pennsylvania 15213, USA).

February 28–March 4, 1971, **Structure and Function of Nucleic Acids,** Banff, Alberta (Dr Gordon Tener, Department of Biochemistry, University of British Columbia, Vancouver 8, Canada).

March 1–3, 1971, **Antibiotics,** Ste Marguerite, Quebec (Dr S. Rakhit, Ayerst Laboratories, PO Box 6115, Montreal, Quebec, Canada).

March 9–12, 1971, **The Exploitation of the Oceans,** Bordeaux (Secretariat du Colloque, c/o CNEXO, BP 107, Paris XVI, France).

March 16–18, 1971, **Electrical Safety in Hazardous Environments,** London (Manager, Conference Department, IEE, Savoy Place, London WC2R 0BL).

March 17, 1971, **Weather Forecasting for Agriculture and Industry,** Aberystwyth, (J. A. Taylor, Llandinam Building, University College of Wales, Penglais, Aberystwyth, Cardiganshire, Wales).

March 23–26, 1971, **Negative Ions,** Liverpool (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

March 24–26, 1971, **Structure and Growth of Thin Films,** Southampton (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

March 29–31, 1971, **Non-ionizing Radiation Safety,** Cincinnati (Laser Laboratory, Children's Hospital Research Foundation, Cincinnati, Ohio 45229, USA).

March 29–April 2, 1971, **Statistical Mechanics,** Chicago (Professor Stuart A. Rice, James Franck Institute, University of Chicago, 5640 Ellis Avenue, Chicago, Illinois 60637, USA).

March 30–31, 1971, **Electrochemical Engineering,** Newcastle upon Tyne (Professor J. D. Thornton, University of Newcastle upon Tyne, Merz Court, Claremont Road, Newcastle upon Tyne NE1 7RU).

March 31–April 1, 1971, **Meat in the Future—Problems and Solutions,** London (General Secretary, Institute of Biology, 41 Queen's Gate, London SW7).

April 1–3, 1971, **Applications of the Laser in Biology, Medicine and Dentistry,** Cincinnati (Laser Laboratory, Children's Hospital Research Foundation, Cincinnati, Ohio 45229, USA).

April 5–7, 1971, **Elementary Particle Physics,** Lancaster (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

April 5–8, 1971, **Conduction in Low Mobility Materials,** Eilat (D. S. Tannhauser, Department of Physics, Technion, Haifa, Israel).

April 14–16, 1971, **Electrical Conduction in Organic Solids,** Nottingham (Dr M. R. Willis, Chemistry Department, University of Nottingham, Nottingham NG7 2RD).

April 15–16, 1971, **Industrial Innovation through Contract Research,** Newcastle upon Tyne (R. G. Atkinson, International Research and Development Co. Ltd, Fossway, Newcastle upon Tyne NE6 2YD).

April 15–17, 1971, **Cereal Fodders in the Feeding of Domestic Animals,** Milan (Societa Italiana per il Progresso della Zootecnica, via Monte Ortigara 35, 20137 Milano, Italy).

April 15–21, 1971, **Radiationless Processes in Photochemistry,** Portmeiron, North Wales (Dr B. Brocklehurst, Department of Chemistry, The University Sheffield S3 7HF).

April 20–22, 1971, **Internal Flows,** Salford, (Administrative Assistant, University of Salford, 43 The Crescent, Salford M5 4WT).

April 21–29, 1971, **International Welding and Metal Fabrication Exhibition,** London (Industrial and Trade Fairs Ltd, Commonwealth House, New Oxford Street, London SW1).

May 3–7, 1971, **Man-made Lakes—their Problems and Environmental Effects,** Knoxville, Tennessee (Professor W. C. Ackerman, Scientific Committee on Water Research, Illinois State Water Survey, Box 232, Urbana, Illinois 61801, USA).

May 4, 1971, **Crop Protection,** Ghent (Symposium Secretary, Rijksfaculteit der Landbouwwetenschappen, Coupure Links 235, Ghent, Belgium).

May 8, 1971, **Stereochemistry,** Lucerne (Professor H. Musso, Institut für Organische Chemie der Universität, Richard Willstätter-Allee, 75 Karlsruhe 1, Germany).

May 17–20, 1971, **Australian Biochemical Society Conference,** Brisbane (Dr J. N. Mansbridge, Department of Biochemistry, University of Queensland, St Lucia, Queensland 4067, Australia).

May 17–21, 1971, **Remote Sensing of Environment,** Ann Arbor (Extension Service, Conference Department, University of Michigan, Ann Arbor, Michigan 48104, USA).

May 25–26, 1971, **Earthquake Engineering Research,** Vancouver (Dr S. Cherry, Earthquake Engineering Research Conference, Civil Engineering Department, University of British Columbia, Vancouver 8, BC, Canada).

British Diary

Tuesday, October 27

Correlation of River Flow Data for Yield Assessment (5.30 p.m. informal discussion) Institution of Civil Engineers, at Great George Street, London SW1.

Diabetes, Diet and Biochemistry (5.30 p.m.) Professor F. G. Young, FRS, Research Defence Society, in the Lecture Theatre of the Zoological Society of London, Regents Park, London NW1 (Thirty-ninth Stephen Paget Memorial Lecture).

Further Thoughts on W. T. Brande (5.30 p.m.) Mr Edward Ironmonger, Royal Institution Library Circle, at 21 Albemarle Street, London W1.

Genetic Polymorphism (5.30 p.m.) Professor Harry Harris, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Second of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

The Analysis of Malignancy by Cell Fusion (5 p.m.) Professor Henry Harris, FRS, Royal College of Surgeons of England, Lincoln's Inn Fields, London WC2. (Sixth Michael Cross Memorial Lecture.)

The Physics of a Polymer Molecule (5.30 p.m.) Professor S. F. Edwards, University of London, in Mechanical Engineering Lecture Theatre A, Imperial College, London SW7.

The Rational Society (5 p.m.) Professor S. J. Gould, University of London, at the London School of Economics and Political Science, Houghton Street, Aldwych, London WC2.

Wednesday, October 28

Lavoisier's "Opuscules Physiques et Chimiques", 1774 (1 p.m.) Mr Frank Greenaway, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Light Sources: Electrodeless Discharge Tubes *versus* Hollow Cathode Lamps (7 p.m. discussion meeting) Society for Analytical Chemistry, Atomic Spectroscopy Group, at the Leicester Lounge, Glasshouse Street, London W1.

Pollution Control (three-day course) in the Department of Chemistry, Liverpool Polytechnic, Byrom Street, Liverpool.

The Bibliography of Charles Darwin (6 p.m.) Mr Richard Freeman, Society for the Bibliography of Natural History, in the Men's Staff Common Room, University College London, Gower Street, London WC1.

The Brunels (5.30 p.m.) Lady Gladwyn, Institution of Civil Engineers, jointly with the British Section of the Société des Ingénieurs Civils de France, at Great George Street, London SW1.

The Thawing of Frozen Foodstuffs (6.15 p.m.) Mr D. W. Everington and Mr E. R. Cox, Society of Chemical Industry, Food Group—Food Engineering Panel, at 14 Belgrave Square, London SW1.

Thursday, October 29

Biological Aspects of Water Pollution (3 p.m. symposium) Society for Analytical Chemistry, Biological Methods Group, at the Wellcome Building, Euston Road, London NW1.

Crystallization: a Study in Molecular Engineering (5.30 p.m.) Professor J. W. Mullin, University of London, in the Engineering Theatre, University College London, Gower Street, London WC1 (Inaugural Lecture).

Economics of Solvent Extraction (2 p.m. symposium) Society of Chemical Industry, at 14 Belgrave Square, London SW1.

New Chrysanthemum Varieties Developed at Wye College (8.15 p.m.) Mr A. A. Jackson, University of London, at Swanley Hall, Withersdane, Wye College, near Ashford, Kent.

Paroxysmal Nocturnal Haemoglobinuria (5.30 p.m.) Professor J. V. Davie, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Third of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Some Reflection upon London's Passenger Transport (5.15 p.m.) Professor T. C. Barker, University of London, at Bedford College, Regents Park, London NW1.

The Application of Forensic Science to Archaeological Problems (5 p.m.) Professor R. G. Harrison, British Academy of Forensic Sciences at the Royal Society of Arts, John Adam Street, London WC2.

Theory *versus* Reality in Organizational Structure (5.30 p.m. informal discussion) Institution of Civil Engineers, at Great George Street, London SW1.

Friday, October 30

Air Pollution and its Effects on Man (9 p.m.) Mr P. J. Lawther, Roya Institution, at 21 Albemarle Street, London W1.

Photochemistry of Aromatic N-Oxide Compounds (1 p.m.) Dr C. Lohs Royal Institution, Photochemistry Discussion Group, at 21 Albemar Street, London W1.

Powder Coatings (7.15 p.m.) Mr G. T. Bassett, Oil and Colour Chemist Association, jointly with the Birmingham PVL Club, at the Hav thorns Hotel, Bristol.

Monday, November 2

Development, Use and Requirements of STOL Aircraft (5.30 p.r informal discussion) Institution of Civil Engineers, at Great Geor Street, London SW1.

Protective Coatings for Gas Pipe Lines and Storage Vessels (7 p.m Dr J. T. Harrison, in the Bullock Lecture Theatre, Hull College Technology, Hull.

The Chemical Industry and Government-Sponsored Corporatio (6.30 p.m.) Sir Frank Schon, Society of Chemical Industry, in t Scientific Societies Lecture Theatre, 23 Savile Row, London W1.

The Pharmacology of Neuromuscular Transmission (6 p.m.) Profess W. C. Bowman, University of London, at the Royal Postgradua Medical School, Du Cane Road, London W12.

What is the Future for Linkage Synthesis? (6 p.m. discussion) Instituti of Mechanical Engineers, Applied Mechanics Group, at 1 Birdca Walk, London SW1.

Ungilding the Lily

THE British Government has fired an ominous shot across the bows of the research councils in its declaration, on Tuesday this week, of the steps which are to be taken in an attempt to reduce public expenditure. Mr Anthony Barber, the Chancellor of the Exchequer, said that he was proposing to reduce the total cost of the research councils by £2 million in the year beginning next April and then to look for further savings from the recommendations of a review of the work of the research councils now being carried out by the Council for Scientific Policy (see page 400). On the face of things, at least, £2 million from one year's budget, at present running at £115 million a year, will not make much difference. It should be possible to rob Peter to pay off Paul without much trouble. At this stage, the more distant implications of Mr Barber's statement are more worrying. By all accounts, he is hoping that part of the present cost of running the research councils can be transferred from the public purse to industry, but it is exceedingly hard to see precisely what he can have in mind. Indeed, the objective of government policy in the past ten years, ever since the Trend report, has been to isolate the substantially long-term functions of the research councils from the government's more direct concern with the sponsorship of industry and of industrial innovation. It may be sensible—certainly it is consistent—for the new government to abolish the Industrial Reorganization Corporation in the belief that this is something which industry could well undertake on its own behalf. For the most part, however, the research councils are concerned with much less practical matters for which industry would be unable on strictly commercial grounds to foot the bill.

Where can Mr Barber's review body hope to find some slack? The Science Research Council is about as lean an organization as any could be. Some of its research grants are at present handed out to people with one foot in industry and another in the academic world, but this is not a large part of the council's expenditure. For the rest, the Science Research Council is a tautly organized body, chiefly preoccupied with the interests of the universities. If anything, there is a case for more and not less public support, especially with postgraduate teaching. It will be regrettable if the new government does not openly acknowledge that central government must these days assume responsibility for the cost of the research that has become a necessary part of higher education. The case of the Medical Research Council is different, for a large proportion of what it spends goes on research institutes and units the staff of which remains on the council's payroll. Very little of the research which the council supports is of such direct interest that industry could be expected to foot the bill. There may be a case for a different way of spending the money, with more research grants and fewer units, but that will not make Mr Barber's ship come home.

So are the Agricultural Research Council and the Natural Environment Research Council the chief candidates for economy? The temptation will be, of course, to wonder whether some of the Agricultural Research Council's stations—Rothamsted for example—could not raise part of their keep by means of subventions from agricultural producers to whom the research station is a blessing. The trouble, of course, is that the government's interest is to ensure that work of this kind is supported whether or not the commercial interests are willing to pay the cost continuously. To be sure, there are other parts of the Agricultural Research Council's work that may seem more vulnerable—that is something for them to worry about. Even the Natural Environment Research Council, however, has very little fat on it in spite of its ambitions to embark on ocean engineering and other vaguely industrial projects. To be sure, there might be a case for looking again at the need that the Natural Environment Research Council should exist separately from the other research councils—its arrival on the scene has not been a conspicuous success. But even such a radical reversal of the present government's plans is unlikely to save much money.

Now that Mr Barber has thrown down his gauntlet, it is important that he and his colleagues should be made to appreciate the role of public expenditure on research councils. The first objective, and a sufficient justification by itself, is the stiffening of higher education with a good backing of research. The second is to support research of a kind likely to keep the British scientific community alive and on its toes. The third is to provide British industry with a sufficiently rich source of innovation for economic growth to be sustained. None of these objectives can be neglected without serious damage, possibly in the long run. No amount of urgency to save money in the financial years immediately ahead can justify such profligacy.

Benn's House Dismantled

THE new British Government has been swift in dismantling one of the pieces of apparatus of the previous government most offensive to Conservative doctrine—the Ministry of Technology. The White Paper on the reorganization of central government, published last week (HMSO, 2*s* 6*d*), is chiefly concerned with the dismemberment of the ministry along lines which have been openly hinted at for the past six months, but particularly since the accession of Mr John Davies to the Ministry of Technology in July. First of all, the

functions of the Ministry of Technology in the making of industrial policy are to be united with the functions of the old Board of Trade in a new Department of Trade and Industry. Second, the responsibility of the old Ministry of Technology for the aerospace industry has been transferred to a new organization, the Ministry of Aviation Supply. This, however, is intended to be simply a temporary measure, for the White Paper says that the government is looking for some way to integrate all defence research development and procurement within a single organization, most probably within the Department of Defence. In the long run, this development is likely to be of crucial importance not merely for the defence laboratories with which the Labour Government never quite managed to grapple but also for the new government's policy—or method of making policy—on civil aviation. A third innovation, at least of nomenclature, is the setting up of a Department of the Environment to unite the old Ministries of Housing and Local Government, Public Building and Works, and Transport. A fourth development of some importance is the decision that in future the Ministry of Overseas Development should become part of the Department of Foreign and Commonwealth Affairs.

These changes are important not merely for what they imply for the immediate future but also because they may throw light on the way in which the new government will manage its affairs. The linking together of the industrial responsibilities of the old Ministry of Technology and the old Board of Trade is, however, a sensible step—the tension between the Board of Trade and the Ministry of Technology in Mr Wedgwood Benn's days was something of a legend. The most serious cause for anxiety under the new arrangement is that there will be a tendency for the scientific work of the government laboratories, and particularly that of the National Physical Laboratory, to be undervalued. What does the new government plan to do with this part of its inheritance? And what, in any case, is to happen with the laboratories of the Atomic Energy Authority, now presumably more unpopular than ever? Will Aldermaston, for example, finish up with the Ministry of Defence? And will Mr John Davies be happy to let Dr Walter Marshall pursue the ambition of making Harwell into a more or less self-supporting institution? No amount of paper reorganization can avoid the need to make decisions on these points.

The plan to carry out a thorough analysis of the functioning of the defence laboratories is also to be welcomed, although there is no obvious reason why at this stage the government should have assumed that defence research must ultimately be united with the Ministry of Defence. What of laboratories such as Farnborough and Malvern, now both with the Ministry of Aviation Supply? Is there not a reason for thinking that each of these laboratories has a valuable part to play in the development of civil industry in Britain? And should not each of them be edged in that direction? It is to be hoped that in the few months set aside for this examination, the government will give serious attention to the danger that its proposals may make less than full use of these important facilities for research. In the long run, there may be some value in retaining an independent organization such as the Ministry of Aviation Procurement as a device for undertaking all kinds of research and development in the semi-public sector. Telecommunications are a crying need.

The Department of the Environment is the most dubious of the new proposals, if only because it may be nothing more than an attempt to ride the bandwagon of the moment without changing anything important. To be sure, there is a need that responsibility for city planning, previously with the Ministry of Housing and Local Government, should be more closely linked with responsibility for transport planning, previously with the Ministry of Transport. It is also important that policies for the economic development of regions of the British Isles should be coordinated with those for the development of new cities. In that sense, the new arrangement may have something to contribute towards better government. But will the creation of a super-ministry make it any easier for the new government to decide on a better policy for the encouragement of economic growth outside the London region than that on which the fancy of the Labour Government fell? This is a case in which the reorganization may be taken as a sign that urgent problems have been solved or at least have been made to disappear.

The proof of the pudding will be in the eating and this is where it may be crucial to know how faithfully the government follows its own precept, spelled out in the White Paper, that there must be a better method than in the past for ordering the priorities of central government. There is, for example, to be a central policy review staff at the Cabinet Office, working not merely for the Prime Minister but for the other departments of government. There is to be a better or at least more selfconscious procedure for the review of public expenditure—one of the parts of the previous system for which the new White Paper has a few good words to say. The trouble, of course, is that no amount of good resolutions can make up for a lack of will to operate the machine efficiently. This, in the long run, is where the new government's battle will be won or lost.

Palace and Pollution

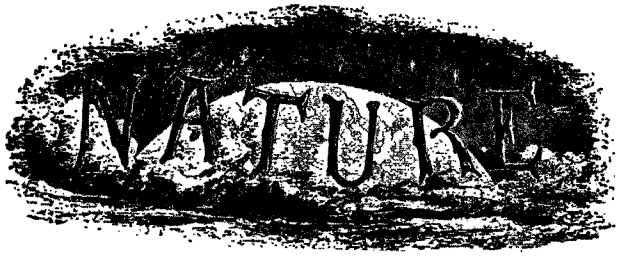
For three days of the week just past, 850 people have thronged Guildhall in London as delegates to the third conference of the organization which has for the past seven years been known as "The Countryside in 1970". To the extent that many of the participants are people whose work would normally have led to them to erect new factories, build new roads and commission new types of aircraft, the conference may indeed have done something to abate the nuisances which it has held up for public complaint. Whether the occasion, or the activities which have preceded it, will have a more lasting effect, only time will tell. On the face of things, however, the outlook is not bright. The Countryside in

1970 has been a splendid theme for harnessing the energy and the emotion of the Duke of Edinburgh to a public cause, but he must already be wondering whether he has backed the right horse.

The conference this week seems to have been a strange pantechnicon for allowing all kinds of organizations to stand up in public and declare their fondness for the proper management of the environment. Not merely the National Union of Students but the Greater London Council have been able to publish some cheerful platitudes about their special interest in the environment—the GLC, for example, busy with its gargantuan and controversial scheme for building urban motorways in London, is nevertheless able to pat itself on the back with statements such as "the GLC is taking practical measures to ensure that Londoners are given the opportunity to enjoy life to the full in a satisfactory environment" and "the problems of traffic noise, mentioned elsewhere in this paper, must also be solved". The chairman of the Natural Environment Research Council, Lord Wynne Edwards, seems to have devised the term technosphere (the complement of biosphere) as part of the jargon of the new ecology. Urban development has been widely berated, and the continuing increase of the population of Britain has been considered as an ominous threat to the amenities of British life. In spite of the practical character of many of the reports which appeared as working papers at the conference, there has been an awkward sense that conservation is next to godliness and that, in any case, the management of the environment needs some central mechanism for keeping the wayward tendencies of ordinary people within bounds. And in spite of the protests of some of the delegates, the conference has been an occasion for resurrecting old concepts such as the view that there is nothing wrong with the environment that would not be cured if people were abolished.

In discussions like these, it is customary to balance the potential benefits of some course of action against the disadvantages—pesticides kill insects but also damage (or may damage) more desirable species, for example. Roads permit movement but create noise. Plastic bottles are a convenience until they are emptied and then become a nuisance. The conference this week seems to have fought shy of the most serious problem of all—the ineradicable conflict between the wish of most people to become more prosperous and the likelihood that, if they do so, they will help to damage the environment. This, certainly, is why the solicitude of prosperous populations such as that of the United States for the environment sounds hollow to people in developing countries (and it is significant if no doubt illogical that the ban on the major uses of DDT which has been imposed in the United States does not prevent American companies from exporting this supposedly global pollutant to countries where the need for effective pesticides is as urgent as it has ever been). Within nations such as Britain, the cry for a better environment and for more care in preserving natural surroundings makes more sense to the well-to-do than to those still hoping that they may yet be able to imitate their betters by owning a car and driving it about the countryside at the weekend. This week's conference has been most seriously deficient in the way in which this essentially political issue was carefully glossed over. But what are the steps that should be taken to ensure that proper preservation of the environment does not become an obstacle to the economic advancement of those communities or sections of communities which at present are disadvantaged ?

The issue is splendidly if poignantly illustrated by the problem of the national parks, which in Britain and the United States tend nowadays to be crowded with visitors whenever there is a fine day in the summer. In both countries, schemes for restricting access to some places like these are being talked about in a desultory fashion. There is a great danger, however, that in seeking more vigorously to preserve the character of the environment as it is at present, the conservationists may be alienating those who moderately look forward to pursuits that were respectable in the thirties or even the fifties. In this sense as in many others, the conservation movement has yet to rid itself of the taint of eclecticism.



The equitable resolution of these and other dilemmas is unlikely to be acceptable to all conservationists. Because of the way in which the population of Britain has grown to more than fifty million people, and because it would be unrealistic as well as unjust to expect to contain the population within seventy million, it may for example be impossible to preserve large parts of south-east England in what might be thought of as a more or less natural condition. Isolated pockets of greenery may remain, but already there are good reasons to think that the Green Belt which the old managers of London threw about the city in the thirties is now as much a source of discontent as an indispensable physical asset. Nobody at the conference this week set out to calculate the economic cost of the city planning policies which at present restrict the development of industry and commerce within the London Green Belt and which preserve that institution intact. But may not this entail such a large economic handicap for the country as a whole that the lives of people living elsewhere are less prosperous than they might be ?

To raise these and other awkward questions does not of course imply that many of the things now being done in the name of conservation are entirely beside the point. A better understanding of what happens within the environment is entirely to be welcomed, especially when divorced from the view that "ecology is a state of mind". The view that it may also be necessary to manage the natural environment of densely populated countries such as Britain so as to permit the fullest use of the countryside for leisure rather than for agricultural production is also something to be grappled with, the National Farmers' Union permitting. But it is by no means obvious that conferences like that held this week will stimulate the hard-headed thinking necessary if methods are to be found of allowing all kinds of people to lead the lives they want to lead, within cities and outside them.

Two opposing tendencies are disquieting. There is

a risk that conservationists may be found to have embraced unnecessarily authoritarian views of what should be done to preserve the natural environment. Another possibility is that conferences like that at Guildhall this week will have allowed many people to pretend that they are on the side of the angels while caring nothing for the better management of the environment. What circumstances may urgently require is that there should be a more flexible view of the interaction between modern life and the problem of conservation. Is it not important that jet aircraft, much reviled, have nevertheless made it possible for thousands of Englishmen to spend their summer holidays on other people's less crowded beaches? And is it not important that industrial technology has provided them with the prosperity with which to pay their fare? In the long run, the narrowness of last week's conference will be its undoing. Next time round, it is to be hoped that the Duke of Edinburgh will not lend his support to the supposed conflict between technology and the environment but rather to the view that both of them can be exploited to everybody's benefit.

100 Years Ago

In a word, henceforward there must be a portion of every day taken up with teaching children by objects, specimens, or experiments, the nature of the great laws by which the universe is governed. We cannot argue here on the necessity for this knowledge. Look at that great German army, recently spoken of as the most wonderful military engine ever seen on the face of the earth. What makes it so? The intelligence of each individual of which it is composed. It is the same with wheels and pistons, spindles, hammers, chisels, and ploughs, as with guns and bayonets: the more intelligent the man is who wields or superintends them, the more successfully and prosperously will they do their work. Ten years ago Mr. Whitworth astonished the Manchester manufacturers with the account of the machines he had seen in America. "Why should we not have such machines here?" said the Manchester men. "Because," said Mr. Whitworth, "you have not intelligent hands to work them." And for these long ten years we have gone on talking about educating our working classes, and allowing priceless treasures to pass out of our hands. Every portion of Europe, as well as the United States of America, is stealing something of our rightful wealth and increasing our pauperism, because of our stolid indifference to the introduction of those branches of human knowledge which alone can properly develop the powers of industry and application, of which the English people are so wonderfully capable.

OLD WORLD

PUBLIC EXPENDITURE

Cuts in Research Grants

THE cuts in public expenditure announced last Tuesday by Mr Barber, Chancellor of the Exchequer, will be received by the research councils, the Industrial Reorganization Corporation and some parts of the social services with dismay. The budget for the research councils, now about £110 million a year, will be cut by £2 million next year, rising to about £5 million by 1974–75. The Industrial Reorganization Corporation is to be wound up completely, and many subsidies will be abolished and charges increased in the social services.

These are casualties of the government's desire to see public expenditure substantially reduced to pave the way for cuts in taxation. Mr Barber's axe has been calculated to remove £1,100 from public expenditure by 1974–75, and to reduce the annual rate of growth in public expenditure to 2·8 per cent a year, compared with a rate of 3·5 per cent which was implied by previous plans.

Although a cut of £2 million from the combined budgets of the research councils does not seem too harsh, the long-term implications are more worrying. Sir Brian Flowers, chairman of the Science Research Council, said last month, for example (*Nature*, **227**, 1284; 1970) that the growth rate of the SRC's budget is already too small for the council to support many important areas of research. It also seems less likely now that the government will be prepared to sanction British participation in the CERN project, on which the SRC has set its heart. Coupled with the announcement of cuts in the budgets of the research councils is the indication that "this field of expenditure is now being critically reviewed to establish whether activities are being carried on which might more appropriately be financed by industry, and whether there is duplication of effort". The review is being carried out by the Council for Scientific Policy, which will report to the Secretary of State for Education and Science.

It is no surprise that the government is to wind up the Industrial Reorganization Corporation. Such a measure is in line with the policy, outlined in the Queen's speech and repeatedly at the Conservative Party conference earlier this month, to liberate industry from government interference. The Conservative Party has always opposed the IRC's powers to influence industrial mergers, and winding up the corporation will result in savings next year of between £20 and £30 million.

As far as education is concerned, Mr Barber had little to say, and no mention was made of the costs of higher education. Charges for school meals will, of course, be increased, and supply of free milk to pupils over the age of seven will be discontinued, both measures being part of Mr Barber's thesis that "where the user can afford it, he should bear more of the cost and the taxpayer less". The same principle guides the government's decision to institute charges for admission to national galleries and museums. Mr Barber did, however, commit the government to spending an additional £110 million during the next four years on the social services, chiefly for new hospital facilities.

SELECT COMMITTEES

Science and Technology Reprieved

MR WILLIAM WHITELAW, Leader of the House of Commons, seems to have had a slight change of heart during the Summer recess. Although his Green Paper on the select committees of the House of Commons (HMSO, 3*s*) which was published last week reflects many of the intentions he announced last July (see *Nature*, **227**, 217; 1970), he has spared some of the specialist select committees—including the Select Committee on Science and Technology—at least for the present session.

Guided by a desire to reduce demands on members' time, while at the same time maintaining an effective machinery for scrutinizing the work of the executive, Mr Whitelaw has taken up many of the recommendations of the Select Committee on Procedure. The most important is that the Estimates Committee should be restyled into an Expenditure Committee with a membership of about 45. The new committee would "focus its attention on public expenditure rather than on the Supply Estimates and examine a wider selection of issues arising in this field".

Mr Whitelaw parts company with the Select Committee on Procedure in his proposals for the specialist select committees, however. The Green Paper suggests that the Select Committee on Nationalized Industry should be retained and that it should continue to have general oversight of the whole range of activities of the nationalized industries. Similarly, it is suggested that the Select Committee on Science and Technology should continue with its work. The Procedure Committee suggested that these committees should be scrapped, and that the proposed Expenditure Committee should take over some of their functions, but Mr Whitelaw believes that a dual system in which the three exist side by side would provide a more effective instrument for scrutinizing the work of public corporations. Also to be retained are the select committees on Race Relations and Immigration and on Scottish Affairs. But the Select Committee on Education and Science will not be reappointed; the evidence on teacher training which the committee took last session will be made available to the proposed Committee of Enquiry into the Training of Teachers.

The retention of the Select Committee on Science and Technology is something of a triumph for the pressure placed on Mr Whitelaw by some of his own backbenchers as well as by some of the opposition members of the committee. But what will happen to the enquiries on which it was engaged before the election is open to question. It seems likely, however, that the enquiry into the computer industry and into the British space research programme will be continued, while the investigation of the consequences of population growth in Britain may be scrapped or postponed.

The membership of the Select Committee on Science and Technology will also be somewhat different from that which sat before the election. Five members of the old committee failed to be re-elected last June, and the change of government means that the chairmanship of the committee will go to a Conservative member. Mr Airey Neave seems to be the most likely candidate, and Mr Arthur Palmer, chairman of the old committee, will probably be given the chairmanship of one of the subcommittees.

OIL STRIKES

Dividends from the North Sea

BRITISH PETROLEUM'S oil strike just inside the British sector of the North Sea confirms that the discovery last June of a large field in the Norwegian sector by the Philips consortium was not just an isolated freak. The strikes suggest that there is a wide distribution of oil under the North Sea. The BP strike lies about 100 miles north-west of the Philips Ekofisk field, along a line which passes through the Ekofisk field itself and several minor traces of oil found by BP and other groups. This places it in 350 feet of water (rather deeper than the Philips find) and more than 100 miles east of Aberdeen, so that many technical problems remain to be solved before Britain will feel the benefits of this discovery in terms of hard cash.

That the eventual fruits of this discovery will go in large measure to the government is beyond question —under the present taxation system, 12½ per cent of the well-head value of the oil is taken in tax, while a further 45 per cent of any eventual profits is subject to corporation tax. Moreover, 49 per cent of resulting dividends go to the government as the major shareholder in BP, and two of the blocks adjacent to BP's find are licensed by groups in which the National Coal Board is a chief partner.

In spite of the difficulties involved in bringing oil ashore compared with natural gas, the financial incentives are attractive. Oil will sell at commercial rates, whereas gas must be sold to the Gas Council, which has used its monopoly to keep the price for North Sea gas down to 2·87 pence per therm. BP is also already trying out the underwater construction of wells and has formed a partnership with Westinghouse Electric and the French groups CFP and Group Deep to design equipment suitable for oil production in deep waters.

The problem of financing a pipeline remains, however, and although BP claims that the cost should be about £25 million (equivalent to two new supertankers) this is almost certainly overoptimistic. But there will undoubtedly be other groups interested in forming a partnership comparable with the BP/Sohio deal which is providing the capital for the development of BP's Alaskan wells. There is also the possibility that the company could sell some of its Middle East interests. It seems likely that North Sea oil can be brought ashore for about two dollars a barrel, making it highly competitive with Middle East and African supplies.

Earlier claims that North Sea oil might eventually provide most of Europe's requirements seem to have been rather extravagant. The new BP field will do well simply to keep pace with domestic requirements, which are increasing by nearly 6 per cent a year. The oil could start coming ashore in commercial quantities in 1972, when it should provide about 10 per cent of Britain's requirements.

OIL POLLUTION

Inglorious Pacific Glory

THE precarious position of the tanker Pacific Glory on a shingle bank off the southern tip of the Isle of Wight raises once again the spectre of the Torrey Canyon and a country ill equipped to deal with widespread pollution. But fortunately a cogent series of emer-

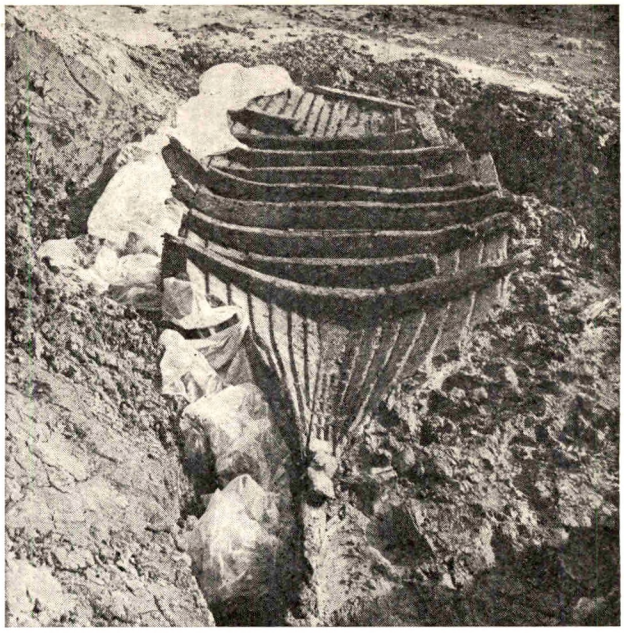
gency measures have been devised, and the picture is now one of being prepared for the worst.

Responsibility for pollution at sea divides itself into two parts; outside a one mile limit it belongs to the Department of Trade and Industry, but closer to the coast it is very much in the hands of the local authorities and therefore of the Department of the Environment. The report of a committee set up under Sir Solly Zuckerman after the disastrous spill of Easter 1967 advocated the setting up of a coordinated chain of command along the coast with responsibility for anti-pollution measures. In the case of the Pacific Glory, for example, responsibility is vested in the Marine Superintendent at the Marine Survey offices in Southampton and the overall situation, as it affects the coastline and beaches, will be overseen from an Operations Room at the Department of the Environment.

The local centres of command have been equipped with a device designed at the Warren Springs Laboratory, Stevenage, which can be fitted to an ocean-going tug. As the tug passes through the water covered with oil a wooden arrangement, which has been likened to a five barred gate, stirs up the sea and oil while detergent is sprayed from a boom on the tug. The oil is much more easily disposed of naturally by microorganisms when emulsified in fairly small drops.

Sir Solly Zuckerman's committee also recommended that a group of experts should be available in such emergencies to give advice of a scientific nature. The Central Scientific Unit set up in April at the then Ministry of Housing and Local Government under Dr Martin Holdgate is expected to provide the expertise if it should be needed.

The hope is, of course, that the Pacific Glory's oil burden can be removed without her back breaking, but the incident raises the question of the safety of large tankers, especially with the advent of the 250,000 ton giants. Internationally, however, the situation is complicated because both the Pacific Glory and the Torrey Canyon sailed under the Liberian flag of convenience with its attendant tax advantages. There was criticism of the thoroughness of the Liberian government enquiry into the Torrey Canyon disaster and the Department of Trade and Industry has now announced that a preliminary enquiry will be held into the causes of the latest incident. The powers of a possible full British Board of Enquiry are rather unclear, however, because the collision took place outside territorial waters.



After two maritime misfortunes which it seems should never have happened, it is questionable whether large tankers can any longer be allowed to ply busy seaways such as the English Channel without the kind of supervision which is now accepted in air corridors. The days when individual crews navigate their own lethal loads are surely almost past.

ARCHAEOLOGY

Oldest English Ship Unearthed

from a Correspondent

WHAT may be the oldest English ship yet traced has been unearthed during drainage works in the Seasalter marshes of Kent. It has since been measured, excavated and raised in a joint operation of the National Maritime Museum, Greenwich, and the British Museum. The boat is lodged in thick clay some 10 feet from the surface in the bank of the channel. Local archaeologists called in experts from Greenwich and the team from the British Museum that recently re-assessed the Sutton Hoo 7th century ship burial site, and part of a new ship gallery under construction at the Greenwich museum, has been set aside for the find when it has been conserved and reconstructed.

Reproduced by permission of the National Maritime Museum.

The vessel was originally about 40 feet long, of which 32 feet has survived, and 8 feet in the beam. It is clinker built in the Northern European or Viking style, and has a long curving stem which was probably repeated at the end which is lost. The robust build and size indicate that it could have carried cargo in the open sea. It was presumably rowed—there is no sign of a mast step though a jury mast might have been rigged for running before the wind.

Estimates of its age so far rest chiefly on the style in which it was built, resembling in some aspects the Viking ship tradition of the period from AD 600 to 1100 in which the Sutton Hoo ship lies. The Seasalter vessel is of generally "Northern European" construction, but it is heavier and more roughly finished than was typical. It is built from native oak. This may suggest that it was built before the Sutton Hoo ship, but alternatively it may belong to the period when Viking tradition had begun to fade or was being modified by Mediterranean influence. The date may not be fixed until carbon-14 evidence becomes available.

ENVIRONMENT

Countryside Seven Years After

As European Conservation Year reached a frenzied climax of talk, the Countryside in 1970 conference opened in London on October 26. A large concourse of people, gathered in the Guildhall, had before them an array of reports on the environment which had been in preparation since the first conference on this topic in 1963. Although some bold speakers attempted to raise debate on the reports, most seemed to feel obliged to use their few minutes to air their own, all too familiar, points of view.

The proceedings were opened by the Duke of Edinburgh who struck a political note by welcoming the recent government reorganization which created the Department of the Environment. He also advocated yet more administrative coordination, but noted that the real bar to environmental progress is likely to be the allocation and spending of the necessary funds.

Urbanization and industry dominated the first day's proceedings, and so perhaps it was to be expected that population and economic growth should have had their usual airing. The naturalist Mr Richard Fitter propounded a basic equation of conservation: $q=r/p^2$, where q is the quality of life, r represents available resources and p is the population. If r cannot be increased, Mr Fitter said, then to maintain q, the only thing to do is to keep p steady. He was supported by a call for the conference to ask the government to provide everybody in Britain with free contraceptives. There was applause for a demand for a national population policy and an end to the striving for economic growth at all costs.

The industrialists, not surprisingly, leapt to their own defence, pointing out, in the person of Mr A. E. Higginson, of the Institute of Public Cleansing, that in the manufacturing industries it is often cheaper to use fresh raw materials than to recycle wastes. In a very competitive world, he said, to the scorn of many a conservationist, the price and quality of goods are paramount. The industrialists were, of course, also quick to point out how much they have done for conservation. The Sand and Gravel Association, for example, is to give an award for the best example of restored sand and gravel workings.

But an applause meter would have shown that many of the delegates were not impressed by such industrial largesse. For once, the National Union of Students received a wide measure of support. Mr G. Searle, a member of the NUS executive, called for recycling of wastes and a firm hand on companies seeking to build factories on sites of natural beauty. Mr Searle also lamented the lack of debate in the proceedings, but doubtless it is difficult to bring new arguments to bear at this stage in the environmental crisis. It is time for action now.

FOOT AND MOUTH

Mystery Outbreak at Pirbright

Six cattle in a special holding pen outside the experimental compound, but within the security perimeter, of the Animal Virus Research Institute at Pirbright, Surrey, recently developed symptoms of foot and mouth disease. Within a few hours three more animals had contracted the infection, and shortly afterwards the entire group of eighteen animals had to be destroyed. There has been considerable speculation about the cause of the outbreak, but the source of infection is still not known, and, apart from long term projects whose progress could not be jeopardized, research has been suspended while investigations are in progress.

There seem to be three ways in which the outbreak could have arisen. First, the virus may have been brought in from outside the institute, but this frightening possibility is fortunately remote, because no other outbreaks have been reported in the area. Alternatively, the disease may have been carried physically from the experimental compound to the holding pens; again this seems unlikely because the Pirbright administration are fully aware of this danger and their security precautions are rigorous. Finally, a few virus particles may have escaped through a temporary breakdown in the filters which clean the outgoing air from the experimental compound. These filters were checked and found to be working perfectly as soon as the outbreak was confirmed, but it is well known that no biological filter can be more than 99·9 per cent efficient, and this seems the most likely source of the infection.

The chance of such an escape is a danger that all disease research stations live with, but in ten years there have been only two such incidents at Pirbright and both have been confined within the perimeter of the institute.

The role that may be played by the wind in spreading viral infections is still a matter of contention (see, for example, *Nature*, **227**, 860; 1970) and so the possibility that viral particles may be able to defeat the highly sophisticated filters developed at Pirbright is a cause for concern. But the risk to livestock on the farms surrounding Pirbright and elsewhere seems minimal. Dr J. B. Brooksby, director of the institute, pointed out last week that for 35 years the institute has carried out a full research programme, using the distinctive African variety of virus, without air filtration and with no greater incidence of infection than in the rest of the country.

PESTICIDES

More Research Required

The overwhelming impression left by the third report of the Research Committee on Toxic Chemicals (Agricultural Research Council, available from HMSO, 5*s*) is that a great deal more information will have to be collated before conclusions can be reached and the right decisions taken. The report has comforting things to say about the level of DDT in human fatty tissue but about little else. Six appendices provide a host of factual information but otherwise serve only to illustrate how difficult it is to make specific recommendations on insufficient data.

The committee's first report in 1964 placed special emphasis on the need for more research into the effects of pesticides in fresh water, and almost one third of the present report is concerned with this topic. Fresh and rain water in Britain contains small but not insignificant amounts of the chief persistent organochloride pesticides, DDT, lindane and dieldrin. The estimated amount lies between 3 and 30 parts in 10^{11}. The report concludes that such a level is within the margins of safety, but precariously so. Experiments have indicated that if the concentration of any organochloride residue should rise to more than 1 part in 10^{10}, freshwater fish and other aquatic organisms would be at considerable risk.

The report suggests three methods of approaching the problem. First, a coordinated system of surveillance should be established in collaboration with the River Authorities and the Natural Environment Research Council to plot the pattern of pesticide distribution in rivers, lakes and reservoirs. Second, the ways in which pesticides may affect organisms against which they are not directed must be examined in much greater depth. The final recommendation deals with the destruction of pesticides. It is difficult to destroy pesticides once they

have become diluted in rivers and lakes, and the report suggests that biological methods of neutralizing harmful chemicals should be sought and applied before factory wastes are voided into rivers and streams.

This last point emphasizes a new and disturbing feature of chemical pollution. The report mentions that increasingly larger amounts of the polychloro-biphenyl compounds (PCBs) are being detected, especially in bird carcasses. These are not pesticides, but are widely used in industrial processes. Neither their distribution in the environment nor their effect on living organisms is yet known in detail, but they are distantly related chemically to the organochloride pesticides, and like these compounds they are persistent, and become concentrated to a high degree in animal tissues.

The report describes some methods of pest control which might be substituted for pesticides, including the use of natural predators and sterilization, but notes that, in general, the progress made in developing these techniques has been disappointing. Pesticides remain the most economical and effective form of pest control, but further research is clearly required if the pesticides are to be controlled as effectively as the pests.

SATELLITES

Back to Nature

from our Soviet Correspondent

THE recent launch of Kosmos 368 comes as an interesting variation in a series of satellites whose payloads have been either unannounced, or which consist of physical experiments. Kosmos 368 is stated to include "scientific apparatus for testing experimental life support systems for laboratory animals, for the further study of the effect of space flight on living organisms and for the continuation of the investigation of the physical characteristics of space".

It is several years since the Soviet space programme concentrated on the orbiting of test animals. This new emphasis on life support systems, following hard on the heels of clear hints that Moon missions, let alone interplanetary missions, will remain unmanned at least in the foreseeable future (see *Nature*, **228**, 6; 1970), seems to indicate that there is to be a new attack on the problems of weightlessness. Such an attack may be a preliminary to establishing a manned space station as a base for manned exploration of the Moon or planets.

The Kosmos series of satellites, inaugurated on March 16, 1962, has long been recognized to be not only a regular programme of investigation of the upper atmosphere but also a useful label to attach to a diversity of launchings, including unmanned precursors of manned missions, failures of comsats or interplanetary probes and a number of special projects such as testing of electrical generators, automatic docking and the orbiting of dogs.

HIGHER EDUCATION

Bursting at the Seams

by our Education Correspondent

IF children now in Britain's junior schools are to be given the same opportunity of having a higher education as those now in the sixth forms of secondary schools, the number of places available in institutions of higher education must nearly double in the next ten years. By the same token, unless dramatic savings can be made in the cost of higher education, government expenditure in that sector must also nearly double by 1981. These are the chief conclusions to be drawn from reports published by the Planning Unit of the Department of Education and Science and the Scottish Education Department (*Student Numbers in Higher Education in England and Wales*, HMSO, 12*s*; *Student Numbers in Higher Education in Scotland*, HMSO, 2*s* 3*d*).

What the planning unit has done is to estimate the numbers of school leavers who are likely to achieve at least the minimum qualifications for entry into higher education during the 1970s. This estimate is then used to predict the number of places which must be made available to maintain the demand for them at its present level. The predictions are based on trends established during the 1960s and publication of these reports simply puts flesh on the skeleton which the DES has used for the past year as a basis for its discussions on the development of higher education.

The report suggests that by 1981, 835,000 full-time students will have to be accommodated in higher education establishments in Great Britain, compared with about 509,000 in 1971. The universities' share of these students, the report suggests, may be about 54 per cent, or 460,000. The costs of such an expansion are reckoned to increase expenditure on higher education in England and Wales from £590 million to £980 million over the next ten years.

These predictions are, however, simply the results of a planning exercise which seeks to point out the consequences of maintaining the demand for places at its present level. They do not imply any government commitment to higher education expansion and they make no attempt to assess the extent to which existing establishments can increase their capacity. Moreover, no account is taken of any possible changes in the structure of higher education. The chief function of the reports is therefore to provide Mrs Thatcher, Secretary of State for Education and Science, with a framework in which to plan the development of higher education and they also help to underline the urgency with which policies must be formulated.

The vice chancellors have already told the government that the number of places which existing universities can reasonably hope to provide by 1981 is 50,000 less than the DES predictions suggest should be made available (see *Nature*, **226**, 790; 1970). If the shortfall is to be taken up by establishing new universities, a commitment must therefore be made very soon; otherwise the new capacity will be established too late to affect the situation by 1980. The report also suggests that the greatest increase in demand for places is likely to be in the advanced higher education sector—the sector which includes the polytechnics whose role has still to be fully worked out.

It is the projected costs, however, that are likely to cause the most concern. The estimates suggest that expenditure on higher education will grow at 5·4 per cent a year, which means that higher education would take a larger and larger share of government expenditure. Mrs Thatcher will therefore have to convince her cabinet colleagues that the axe must not fall as heavily on higher education as on other areas, or new ways of saving on unit costs must be found. The vice

chancellors and the AUT have already rejected most of the measures canvassed by the Labour government, and Mrs Thatcher must therefore look very closely at alternative suggestions, such as introduction of a two-year degree course. The alternative is to cut back on the number of places and to restrict entry to higher education during the 1970s.

Nobel Prizes

Peace Award for Agriculturist

THE 1970 Nobel Prize for Peace, worth more than £32,000, has been awarded to Dr Norman Borlaug, geneticist and director of the Mexican International Maize and Wheat Improvement Centre (IMWIC). Although the announcement came as something of a surprise, Dr Borlaug's contribution towards easing the world's food problem makes him eminently worthy of the honour. This contribution can be measured by the number of developing countries which in recent years have greatly improved their wheat yields using the seed stocks pioneered by Dr Borlaug and his research team.

Norman Ernest Borlaug was born in Cresco, Iowa, in 1914, and received a PhD in plant pathology from the University of Minnesota in 1942. He joined the Rockefeller Foundation in 1944 and was assigned as geneticist to an agricultural project which the foundation was carrying out in collaboration with the Mexican Government. Envisaged originally as a scheme to help Mexican agriculture, IMWIC has since become well known for the practical aid it gives to stimulate cereal production in countries struggling to break out of the vicious circle of hunger and poverty.

Dr Borlaug is best known for his work on the development of dwarf wheats—high-yielding crop plants into which have been bred dwarfing genes from the Japanese 'Norin' varieties. These hybrid plants are very much shorter than normal wheat, which means that the wheat-stalk can support a heavier head of grain without collapsing.

But this is only half of the picture. Dr Borlaug had the foresight to understand that developing superior types of cereal seed was not enough. It was essential that the seed should be brought to the attention of the governments of needy countries, grown using adequate irrigation and fertilizer, and the crop skilfully harvested and distributed. He tackled the problem in two ways: by constant travelling to advise and persuade governments and industries to provide the necessary funds and facilities, and by training, in Mexico, young agricultural graduates from many of the countries which could put the newly developed seed to best use. The benefit of Dr Borlaug's vision has been felt already in India, where wheat yield has more than doubled in three years.

Two Physicists honoured

THE news that Professor Hannes Alfvén of the University of California, San Diego, has been awarded a joint share in the physics prize will come as a pleasant surprise to astronomers, who have long felt the need for such recognition of astronomy. Although the award is for physics, and not specifically for astronomy, Alfvén's work on plasma physics and magnetohydrodynamics has been used chiefly in astronomy rather than any other field. Born in Sweden in 1908, Alfvén has held many official posts in Swedish government councils and academic societies; he is a Fellow of the Royal Astronomical Society, and was awarded a Gold Medal by them in 1967 for "his fundamental work on cosmical electrodynamics".

Whilst it has been a feature of Alfvén's career that many of his ideas are considered somewhat eccentric, there have usually been elements of great value within his elaborate theories, so that piece by piece he has built up an impressive list of positive contributions to astronomy. His work is fundamental to the concept of "frozen" lines of magnetic force being held inside a plasma, a phenomena of great importance to any understanding of the processes occurring in the magnetosphere, the atmospheres of stars, and interstellar matter.

With the Nobel honours in physics falling in the past three years to nuclear or high energy physicists it comes as no surprise that Professor Louis Neel, a solid state physicist, has been selected to share this year's award. Although Professor Neel is perhaps most widely known for his pioneering work on the theory of antiferromagnetism he became involved in a very broad range of problems throughout many aspects of magnetism.

Born in Lyon in 1904, Professor Neel spent the early part of his scientific life at the University of Strasbourg, where he published two of his celebrated papers explaining the basis of antiferromagnetism.

In 1954 he became director of the Institut polytechnique. Three years later he took charge of the Centre d'Etudes Nucléaires at Grenoble, and has devoted considerable effort within the last decade to building up the large campus at the University.

It was just after the war that he published his theory of ferrimagnetism, a type of magnetism which has assumed growing importance in recent years because of the electrical properties that seem to be associated with it. Neel showed how the magnetic structure of a ferrimagnetic material, was related to, but essentially different from, that in antiferromagnets. During the immediate post-war period he also carried fundamental work on the properties of small magnetic particles, which pointed the way towards the development of modern magnetic materials. His other accomplishments include a study of the domain structure of ferromagnetic materials and work on the theory of coercivity in ferromagnets.

Biochemist for Chemistry Prize

PROFESSOR LUIS F. LELOIR receives the chemistry prize for the light which his research shed on carbohydrate metabolism, in particular the synthesis of glycogen. In the 1950s he demonstrated that the elongation of the α-1→4-glucan chain proceeded by a stepwise transfer of the glucose moiety from uridine diphosphate glucose to the non-reducing end of the polysaccharide. The wider relevance of nucleoside diphosphate sugars soon became apparent and this discovery complemented the enzymological work on phosphorylase for which C. F. and G. T. Cori and B. A. Houssay were awarded the Nobel prize for physiology and medicine in 1947. Although well known internationally, Leloir has worked almost exclusively in his own country, in a villa on the outskirts of Buenos Aires, and in far from ideal conditions. His meagre funds were to a large extent from his own resources and from a benefactor after whom his laboratory, the Fundación Campomar, is named.

NEW WORLD

Scientists and Senators against Arms Race

by our Washington Correspondent

THE scientific community may not have fielded any candidates in next week's elections but it will have at least a small voice in determining the composition of the next Senate and the way it votes on certain pertinent issues. The organs of that voice are two lobbying groups, the Council for a Livable World and the Federation of American Scientists*, both of them governed and largely supported by scientists. Up to now the two groups have been concerned almost exclusively with the arms race but the Federation is preparing to broaden its scope to include matters of more special concern to scientists such as employment and federal funding of science.

The Federation, founded after the last war by physicists concerned to see the control of atomic weapons in civilian hands, lapsed into a long quiescence once this task was done and has only come to life again since the appointment of a full time director in July this year. The Council for a Livable World has a more recent and sturdy history. Formed in 1962 by the physicist Leo Szilard with the purpose of halting the arms race, the Council focuses its efforts on the Senate, holding seminars on controversial military issues and contributing to the campaign chests of Senators or candidates who share its views. A tangible measure of the Council's strength is that this year it has 12,000 supporters and hopes to have contributed some $400,000 by election day to twelve Senate candidates.

The full time director of the Council is Thomas A. Halsted who from an office on Capitol Hill arranges the seminars, advises the Council on how it should act on particular issues, and coordinates activities with other arms control groups. Halsted is not a scientist by training but worked for two years in the US Arms Control and Disarmament Agency before becoming director of the Council in 1967. Policy decisions are taken by the Council's board of directors of which the chairman is William von E. Doering, professor of chemistry at Harvard. The twelve member board shares three of its members in common with the council of the Federation of American Scientists—Bernard T. Feld, professor of physics at MIT, who is also the president of the Council for a Livable World, Matthew S. Meselson, professor of biology at Harvard University, and George W. Rathjens, professor of political science at MIT.

The Council's campaign funds are small in relation to need and have to be spent judiciously for effect. The Council's money would be a drop in the bucket in states like New York or California but in places like Montana small sums can go far. Races where both candidates are either favourable or unfavourable to the Council's ideas are not worth investing in. A candidate's party is not a consideration but in fact the Council has supported only five Republicans and thirty-five Democrats in the four elections in which it has been involved. Thirty of the Council's forty candidates have won their races, of which perhaps the most gratifying was that of Senator McGovern who in 1962 received a contribution of $20,000 and came home by a margin of 597 votes. This year the Council is supporting candidates such as Senator Albert Gore of Tennessee, chairman of the Senate Disarmament Subcommittee and an important opponent of the anti-ballistic missile system (ABM), who is facing what is expected to be a close fight. Another ABM critic, Senator Frank Moss, is being supported for re-election in Utah, and a new candidate, Howard M. Metzenbaum, already victorious over astronaut John Glenn in a primary, has the Council's backing in the Ohio race against representative Robert Taft.

The Federation of American Scientists has also been active in the elections. This week it entered into public battle with the American Security Council, a political group targeted against liberal candidates and claiming that the United States has allowed the development of a "megatonnage gap" with the Soviet Union. But the Federation's existence as a political force lies in the future. At the moment it has only 1,500 members whose dues scarcely suffice to support the present level of activities. After many moribund years the Federation was aroused, among other things, by the noise of the ABM debate in the Senate, which showed that scientists' voices could be heard even if they did not prevail. Jeremy J. Stone, who became the Federation's full time director in July, is a mathematician with a long standing interest in the arms race and experience at the Hudson Institute and the Harvard Center of International Affairs.

In anticipation of a broader membership, the Federation has extended its interests from just arms control to matters of more particular concern to scientists. The present brochure describes the FAS as standing for six policies: arms limitation and disarmament, the reconversion of defence industry to peaceful purposes, improvements in the quality of life by the enlightened application of science, informing Congress on matters of concern to the FAS, rights of scientists in respect of travel and security regulations, and a "vigorous scientific community". Under the last heading the Federation expresses its concern with the administration and funding of science and imbalances in the supply and demand in scientific specialties.

The basic policies of the Federation are decided by the 24 member council but considerable latitude is allowed to members; individual chapters, for example, may make public pronouncements as long as they are not in conflict with general policy, and in practice the

* Council for a Livable World, 201 Massachusetts Avenue, NE, Washington DC 20002. Federation of American Scientists, 203 C Street, NE, Washington DC 20002.

director, Dr Stone, has wide discretion on day-to-day issues.

The success of the membership campaign is crucial to the Federation's future, which its recent few months of activity have at least established as promising. The Federation's lobbying efforts during the ABM debate did not take the opponents of the system to victory, or even as close to it as last year's tied vote, but at least were effective enough to draw criticism from several pro-ABM senators. The Federation was defended by Senator Cranston who praised its "invaluable" expertise.

By the nature of their business lobbying groups such as the Federation and the Council for a Livable World cannot claim any given proportion of the anti-ABM vote as being due to their efforts. But seen in retrospect there has been a significant shift in the Administration's position on ABM, to which the intensive lobbying efforts of the scientific community has certainly contributed in some measure. Halsted has recently described the "pivotal role" played by scientists in the lobbying effort: "They gave senators and congressmen confidence in their ability to counter Administration arguments; they contributed invaluable information and advice to grass-roots citizens and organizations, which they often started. . . . And the controversy in turn has had an important effect on the scientific community itself, providing the stimulus to the formation of lasting activist political organizations and alliances through which concerned scientists could become more effectively involved in discussion of public policy". The Council has been the channel through which much of the scientific evidence in the ABM debate was delivered and to that extent can take credit for what the evidence has achieved. It has at any rate received the enviable though maybe ironic accolade from Senator Charles Mathias that on issues such as arms control and ABM, "the Council for a Livable World is one of the most effective organizations in Washington . . . with the possible exception of the Pentagon".

In the coming months Halsted sees the Council's activities being directed towards getting productive results from the Strategic Arms Limitations Talks, of which the third round starts on November 2 in Helsinki. Another issue will be the Geneva protocol on chemical and biological weapons which President Nixon has asked Congress to ratify though with certain reservations. The Council at least has the advantage of having an unchanging goal in sight, the limitation of the arms race. It remains to be seen how far the Federation of American Scientists can preserve unanimity in extending its activities to the more controversial private affairs of the scientific community. What with the downturn in Federal funding of academic science and in military spending, the unemployment that this has brought in its train, and a vaguely felt but widespread disenchantment with science and technology, scientists as a group are probably more ready to be politicized than ever before. For different reasons neither the National Academy of Sciences nor professional bodies such as the American Association for the Advancement of Science can openly step down into the political arena. The Federation of American Scientists, if it plays its card right, could find itself representing a solid constituency. With admirable braggadocio it is already billing itself as the "largest lobbying arm of science".

DRUGS

Cyclamates Farce not appreciated

by our Washington Correspondent

A BRUTAL inquiry into the management of the cyclamates farce has left the Food and Drug Administration with little that could be called a reputation. Reporting on the hearings it held in June, the House Subcommittee on Intergovernmental Operations has accused the FDA of failing to protect the public against possible health hazards associated with cyclamates despite a clear legal obligation to do so, of aggravating the consequences of its lethargy by allowing the use of cyclamates in food to reach massive proportions, of contravening its own regulations by allowing foods containing cyclamates to be marketed as drugs, and of sundry other offences and misdemeanours. Many of these charges have been denied by Dr Charles Edwards, the present Commissioner of the FDA.

The salient tergiversations of the cyclamates melodrama have been as follows. On Saturday, October 18 last year, acting on the basis of evidence received by the FDA five days previously, Mr Robert Finch, the then Secretary of the Department of Health, Education and Welfare (HEW), announced that cyclamates were to be removed from the list of substances generally recognized as safe (the GRAS list). The announcement sparked off a train of equally precipitate bans in other countries, notably Britain, where hitherto respectable scientific advisory committees hastened to follow Mr Finch's footsteps without troubling to see where he was going. They, like many others, failed to appreciate the significance of what Mr Finch also said at the time, "I expect that in the future these products will be labelled as drugs, to be consumed on the advice of a physician".

A month later, on November 18, it transpired that Mr Finch had indeed correctly predicted the conclusions to be arrived at by a group of scientists known as the Medical Advisory Group. The group, appointed by HEW after Mr Finch's announcement, duly reported that cyclamated products should continue to be made available for the benefit of diabetics on a non-prescription, drug-labelled basis. Following this finding, the FDA drew up the appropriate regulations which allowed cyclamated products to be sold as before, except that they now carried a label saying they were for use only by diabetics or obese people under medical supervision.

Cyclamates enjoyed their new lease of life as drugs only until August 4 this year, when the HEW Medical Advisory Group on Cyclamates met once more and rescinded its previous decision, declaring that cyclamates should now not even be allowed as drugs. The reason given for this volte-face was that new evidence on the carcinogenic effects of cyclamates in rats brought the permissible safe level for human consumption so low that very few calories would be saved thereby, hence cyclamates were ineffective as drugs. The "new evidence" became available in the form of a FDA memorandum dated November 26, 1969, one week after the group's original decision to allow the use of cyclamates as drugs.

The FDA's conduct in the cyclamates case clearly warranted some investigation and the enquiry became the subject of hearings in June before the House Sub-

committee on Intergovernmental Operations chaired by representative L. H. Fountain (see *Nature*, **226**, 1084; 1970). In the report now published, which serves as a resonant epilogue to the drama it describes, the Subcommittee has put together a withering indictment of the FDA's role at each stage of the proceedings. The chief failings, as Mr Fountain's subcommittee sees them, can be summarized as follows:

- A report prepared by the National Research Council (the operating arm of the National Academy of Sciences) in 1955 stated that the available scientific data did not assure the unrestricted use of cyclamates by children or pregnant women. Nevertheless, when the Food Additives Amendment was passed in 1958, the FDA included cyclamates on the GRAS list, thus foregoing the opportunity afforded by the amendment of putting the onus on the manufacturers to establish the compound's safety.
- The courts have held that when there is genuine difference of opinion among qualified experts about the safety of a substance, it does not deserve a place on the GRAS list. Yet despite a recommendation by the National Research Council in 1962 that cyclamates should be restricted to dietary foods and a further report in 1968 warning against the totally unrestricted use of cyclamates, the FDA did not remove the substances from the GRAS list.
- "Lethargy appears to have played a role in FDA's inaction in this matter" and the lack of appropriate restrictions "also set the stage for unfavourable economic consequences for those who built up large inventories of cyclamate-containing products". (This conclusion may affect the fate of legislation to indemnify food manufacturers which is now pending before the House Judiciary Committee.)
- The decision to permit cyclamates to be marketed as drugs after the ban in October was taken by Mr Finch, the Secretary of HEW, not by FDA, despite the fact that responsibility for enforcing the relevant act (the Federal Food, Drug and Cosmetic Act) had been delegated to the Commissioner of the FDA.
- The HEW's Medical Advisory Group that recommended cyclamates should be available as drugs did so on the basis of scientific evidence no different from that on which the FDA had recommended they be removed from the GRAS list. In any case the real issue at this stage was whether the law permitted Mr Finch's already announced intention to allow the marketing of cyclamates as non-prescription drugs; this was a question that the Medical Advisory Group was not qualified to determine.
- In order to implement Mr Finch's decision that cyclamates should be marketable as drugs, the FDA resorted to a process that was illegal in several respects. Despite their long use in foods, cyclamates were declared to be new drugs, and marketable subject only to the filling of a new drugs application containing the required labelling. But although new drugs cannot legally be marketed without adequate evidence of their safety, the form of the regulations issued by the FDA provided that cyclamates could be approved for sale without any such supporting evidence. Since no such evidence is in fact available, the proposed use of the regulations "was obviously intended to circumvent the law". This question aside, the FDA's regulations were improper in that although they classified cyclamates as prescription drugs they also required a declaration that made the substances prescription drugs by statutory definition.
- All these actions were taken in the face of serious dissent among the FDA's medical staff who, in a position paper of January 30, clearly expressed their doubts as to the legality of the regulations: "To approve cyclamate-containing foods as safe and effective drugs within the concept of our enforcement of the New Drugs provision of the Act", the paper said, "is untenable. . . . Under the principles we strongly adhere to in permitting drugs to be marketed, these products should not be allowed on the market. To approve a New Drug Application for these products is not supportable medically or legally".
- The new evidence cited by the HEW Medical Advisory Group after its August 4 meeting as grounds for rescinding its earlier decision was all known and available to the group at the time the earlier decision was taken.
- The FDA put the wrong questions to the National Research Council panels that reported on cyclamates in 1962 and 1968. To determine if cyclamates were "generally recognized as safe" the FDA should not have asked whether the panel itself so regarded cyclamates, but whether there was a substantial difference of opinion among experts as to their safety. In fact such a difference did exist at the time the two reports were made.

The Fountain Subcommittee concludes its report with the dry observation that decisions about the safety of foods and drugs should be made in compliance with scientific and legal requirements "and without regard to economic or other extraneous considerations". The Secretary of HEW is admonished in future to let the FDA get on with its job without interference in individual cases, and both the FDA and the HEW are advised not to pass the buck on matters they can decide themselves to outside scientific advisory bodies. The present heads of those two organizations must be profoundly thankful they were not in office at the time the principal actions in the cyclamates drama were being unfolded.

In a statement issued at the same time as the report of the Fountain Subcommittee Dr Charles Edwards defended his predecessor's actions each step of which, he said, was taken with the advice of counsel: "at no time did we take a position inconsistent with the Food, Drugs and Cosmetics Act as we construe it". An even blander statement from the department of HEW actually dares to praise the Fountain Subcommittee for its constructive review of the department's actions, adding that the subcommittee's interpretation of the facts and the law are in this instance erroneous.

JOURNALS

Ap.J. loses its Star

by our Astronomy Correspondent

THE resignation of Dr S. Chandrasekhar as editor of the *Astrophysical Journal*, which has come to be regarded as the foremost of the journals that astronomers read, has set in motion changes that will mark a new era in the journal's seventy-five year history. Dr Chandrasekhar, who is professor of theoretical astrophysics at the University of Chicago, has been editor since

1952, and makes no secret of his belief that eighteen years has been too long. By all accounts his job has been arduous, and until recently Dr Chandrasekhar personally dealt with much of the technicalities of producing the 400-page monthly journal and the thinner letters section that appears separately, as well as the scientific editing. Like editors everywhere, his selection of papers for the journal is sometimes criticized. The competition for space in the *Astrophysical Journal* is strong, and last week Dr Chandrasekhar was moved to say that he has come to hate astronomers just as much as astronomers hate him. Between 25 and 30 per cent of the manuscripts submitted for the main journal have to be rejected, and the rejection rate for the more prestigious letters section which contains short items of urgent interest is 50 per cent.

Dr Chandrasekhar was sixty this year, and by resigning from the *Astrophysical Journal* now he hopes to find more time for his scientific work before he retires from the University of Chicago. His resignation comes into effect on April 1 next year. From then on new manuscripts submitted for the main part of the journal will go to Dr Helmut A. Abt, of the Kitt Peak Observatory who will be acting editor, and for the letters section to Dr D. E. Osterbrock, of the University of Wisconsin. But with the six or seven month publication delay in the main journal, Dr Chandrasekhar expects to continue his involvement with the journal until the November issue next year.

The changes that Dr Chandrasekhar's resignation will bring about arise because the University of Chicago Press which publishes the *Astrophysical Journal* wants to divest itself of its interest by the end of next year now that there will be no University of Chicago astronomers involved in running the scientific side of the journal. It is thought that the press is unhappy about continuing to publish the journal because their control over it would be lessened while they would continue to be financially responsible. It is expected that the American Astronomical Society will take over the journal, and a committee to study the changeover will probably be formed at the December council meeting. The committee will report back in the spring and the deal will have to be approved by the membership next summer.

In the past the profit for the University of Chicago Press has been the interest on a trust fund maintained at 25 per cent of the operating cost of the journal, held in reserve as a cushion against an operating deficit.

At present the role of the American Astronomical Society in the running of the *Astrophysical Journal* is as a consultant, and the council of the society appoints the five member editorial board. What usually happens is that Dr Chandrasekhar submits a list of the people he would like to fill a vacancy, and the council has made the final selection. It is not yet known who will look after the mechanics of publishing the journal, but the likeliest possibility seems to be the American Institute of Physics which already publishes the *Astronomical Journal* for the society. It would then seem appropriate for the *Astrophysical Journal* to merge with the *Astronomical Journal*, which has come to have very much the look of a poor relation, and has remained chiefly a medium for papers on celestial mechanics whereas the *Astrophysical Journal* reflects all branches of astronomy. According to a spokesman for the society, however, it is more likely that the two journals will become three by the division of the *Astrophysical Journal*. Although the letters section will continue monthly as before, the main part of the journal will appear twice a month from January. Instead of the present 400 pages per month there will be two issues of 250 pages. To begin with the mix of papers will be the same in both issues, but eventually there could be a subdivision by subject matter, involving the two issues of *Astrophysical Journal* and the *Astronomical Journal*. It appears therefore that there are the beginnings of a rationalization of the astronomy journals on the west of the Atlantic to match the merging of the European journals into *Astronomy and Astrophysics*. Although it is not always good that the number of publications open to astronomers should be reduced, the journal that stood aloof from the European merger, the British *Monthly Notices of the Royal Astronomical Society*, has recently seemed to be very much out on a limb.

PLANETS

Roll Up for the Grand Tour

NASA has begun to solicit help from the scientific community for the definition phase for the so-called grand tour missions to the outer planets. Although there is no funding yet for the two launches which are being considered—the first in 1977 to Jupiter, Saturn and Pluto, and the second in 1979 to Jupiter, Uranus and Neptune—work will have to start soon on the detailed design of the spacecraft if they are to catch the fortuitous line-up of the outer planets which makes the mission possible. An invitation for participation dated October 15 has been issued to scientists in the United States and elsewhere. The definition phase of a mission involves the selection of the basic properties of the spacecraft, its power, data handling capabilities and so on, and the best orbit to provide the most valuable return of scientific information. In the words of the NASA invitation "It will be the responsibility of the scientists selected to develop mission plans, define typical payloads, and participate in trade-off studies to maximize the value of each mission within its particular constraints".

NASA plans to hold a briefing for interested scientists in Washington on November 17, after which proposals for participation giving details of the proposed investigation and instrumentation are to be submitted by January 18. NASA hopes to have finished the selection process by March 15, and will form an imaging science team, and a radio science and celestial mechanics team. Although it is hard to recall any involvement from abroad in previous NASA definition studies, NASA is stressing that the competition is open to foreign scientists, who should forward their proposals through the National Space Agency. Letters of intent from US scientists have to be received by NASA by November 9 and from foreign scientists by November 16, and these letters do not have to be endorsed by the National Space Agency.

NEWS AND VIEWS

Deluge Unabated

THIS issue of *Nature* includes another batch of five articles about the DNA polymerase activities found in RNA tumour viruses; this completes the identification of the enzyme activities involved in producing double stranded DNA from the single stranded RNA genome. And suspicions that the DNA duplex product is integrated into the host cell genome must harden with the finding in the virion of other types of enzyme activity.

For example, Temin and his colleagues, who must marvel at the goldrush they and Baltimore started (*Nature*, **226**, 1209, 1211; 1970), now report (page 424) that Rous sarcoma virions contain at least two and probably three enzyme activities in addition to RNA dependent DNA polymerase. One is a DNA dependent DNA polymerase which Spiegelman's group has also detected in several RNA tumour viruses (*Nature*, **227**, 1029; 1970). Říman and Beaudreau report (page 427) that the DNA dependent DNA polymerase in avian myeloblastosis virions preferentially copies templates rich in guanosine and cytosine. They also confirm that these particles contain DNA, although its source is still obscure.

The third enzyme activity which Mizutani, Boettiger and Temin have detected is an endonuclease, the existence of which in Rous sarcoma virions may, they believe, explain why the double stranded DNA molecules transcribed off the endogenous viral RNA templates by the two polymerases are so much smaller than the template RNA. The idea is that any larger DNA which is made is promptly cleaved by this nuclease. Furthermore, because this DNA endonuclease activity is reduced when an ATP generating system is added to their assay brew, Mizutani *et al.* suggest that the Rous sarcoma virion also contains a ligase activity for joining DNA molecules. It is, of course, impossible to resist speculating about the roles of these four enzyme activities during the infection of cells by Rous sarcoma virus. Perhaps the two polymerases effect the synthesis of a double stranded DNA containing all the information required to specify progeny single stranded RNA genomes. The endonuclease and the ligase, the activities of which are presumably restricted in natural infections perhaps by topographical factors, might then provide the machinery required to integrate the viral DNA into the genome of the host cell. In other words the RNA tumour viruses may carry into the cell all the enzymes needed for their unique replication cycle.

Further characterization of the two polymerase activities continues apace. Levinson's group (page 433) has shown, perhaps not surprisingly, that actinomycin D inhibits DNA dependent DNA polymerase but not RNA dependent DNA polymerase. And Spiegelman's indefatigable zealots (page 430) have compared the efficiency of a wide range of synthetic nucleic acids as templates for the polymerases in six RNA tumour viruses. In brief they find that single and double stranded RNAs and double stranded DNAs act as templates for the synthesis of DNA, but synthetic RNA–DNA hybrids are by far the most effective templates. Poly dC·poly rG, for example, stimulates by very nearly two orders of magnitude more polymerization of deoxyriboside triphosphates than any natural template. As Spiegelman and his colleagues note, such effective templates will be extremely useful in monitoring the activities of the polymerases in viruses and infected cells and following the activities during purification. An intriguing possibility is that these templates could be used to try to detect the polymerase activities in other cases, such as white blood cells in patients with leukaemia. If this were to give positive results, the implications for clinical cancer research would be as important as they are obvious.

But of course any precise characterization of the polymerase activities, and for that matter the characterization of the endonuclease and putative ligase activities, depends on the development of ways of separating the active enzymes from the virions. Todaro and his colleagues report on page 435 a step in that direction. After treating murine leukaemia virions with detergent they find that the RNA dependent polymerase activity sediments with the nucleoid fraction and in a fraction with a light buoyant density. Under the electron microscope the nucleoid fraction appears to be free of envelope material and intact virions while the light fraction is seen to consist of fragments of membrane and nucleoids. These observations, together with the finding that rat anti-murine sarcoma virus serum inhibits the polymerase activity in the nucleoid fraction but not that of intact virions, indicated that the RNA dependent activity resides in the nucleoid. The polymerase enzyme(s) may well give rise to one of the group-specific antigenicities of the RNA tumour viruses which are also known to reside in the nucleoid and as Todaro and his colleagues note, by using monospecific antisera it should be possible to identify the polymerases with a particular group-specific antigen. Synthetic nucleic acid templates and group specific antisera directed against these enzyme activities look as if they will be powerful tools in the hunt for these activities, and by implication tumour viruses in human cancer cells.

What Happens inside Pulsars?

IT is now generally accepted that pulsars are associated with rotating neutron stars, but there is no really satisfactory detailed explanation of the mechanisms whereby the rotational energy of the star is transformed into the kind of radiation observed. NP 0532 in the Crab Nebula is the youngest pulsar known; it is still emitting visible and X-ray pulses as well as radio pulses and has been the object with the greatest interest to observational astronomers—and often a frustrating source of negative information which pulls the rug from under almost any detailed model put forward by the theoreticians. There was an outstanding illustration of this behaviour in September last year, when there was a sudden increase of this pulsar frequency. Having confounded much of the astronomical community by this change, NP 0532 perversely refused to suffer other similar events, even though the "starquake" model put forward to account for them required that they should occur at least once a month.

New insight into the mechanisms operating in this pulsar (and presumably in others too) is provided by the work reported on page 445 of this issue of *Nature*. Observations of the optical pulses from NP 0532 were made at the Smithsonian Astrophysical Observatory for the period September 1969 to April 1970, which includes the occasion of the marked jump in frequency. The measurements are sufficiently accurate to point to the dominant mechanism in the transfer of rotational energy into radiative energy. This accuracy is obtained by studying the pulsar over several consecutive nights. Extrapolation from the end of one night's observations to the beginning of the next is effected by a least squares fit to the pulsar's previous behaviour. The sudden jump in frequency on September 22, 1969, seems to have caused a cumulative deviation from the predicted behaviour on subsequent nights, and because this deviation is non-linear at least one other parameter than the frequency of the pulsar must have changed. There is a great deal of evidence for disturbed activity after the jump, but the overall behaviour is close to that expected of a system in which magnetic dipole radiation is the dominant mechanism.

Even better agreement with the predictions of this model is obtained when the behaviour of the pulsar just before the jump is interpreted rather differently than has been accepted previously. The original report on the frequency change from the Arecibo radio observatory described the erratic behaviour of the pulsar just before the jump as "quasi-sinusoidal", and this has been taken in some quarters as evidence for a planetary companion to NP 0532. Unfortunately, like so many experimental data, there is no unique curve fitting the observations, and in this case the changes in the data can be well fitted by two straight lines rather than one sine curve. This fitting now seems much more plausible, for, in conjunction with the magnetic dipole radiation law and assuming also a small change in the moment of the dipole (only about 1 part in 2 million), there is good agreement between the theory and subsequent observations.

Small errors forming a background noise are present throughout the data; although even the detection of this very low level noise would have seemed a triumph a few years ago, it is sufficient to prevent any possibility of using the variations in pulsar frequency caused by the Earth's movement in the Sun's gravitational field to measure accurately the gravitational redshift. In spite of this extra blow to the hopes of some theoreticians (which emphasizes the apparently capricious nature of pulsars), there may be some comfort in the suggestion that there really are starquakes on NP 0532, and that it is the frequent occurrence of rather small quakes which produces the noise.

GALAXY FORMATION

Early Protospirals

from our Observatories Correspondent

JAN OORT, who retired this year as director of the Leiden Observatory, has made important contributions to the study of the structure of our Galaxy. Recently one of his principal concerns has been the origin of the high velocity clouds of neutral hydrogen which are observed to be falling into the galactic plane at high and intermediate galactic latitudes. The clouds, which have velocities of up to about 200 km s^{-1}, have been detected by 21 cm observations made mostly at the Dwingeloo radio observatory in Holland. In the past Oort and his collaborators have discussed two possible origins for the clouds. One explanation is that they result from giant explosions in nearby spiral arms which have ejected neutral hydrogen into the galactic halo. According to this view it is largely by chance that the material is observed to be falling into the galactic plane in the vicinity of the Sun. In any case Oort has rejected this explanation (*Astronomy and Astrophysics*, **7**, 381; 1970), and instead has concluded that intergalactic gas is streaming into the Galaxy. A rough estimate of the total flow is 2×10^{17} hydrogen atoms per cm^2 of the galactic plane per million years. This corresponds to an increase of the Galaxy's mass of 0·9 per cent in 10^9 years.

Oort attempts to relate the observation of infalling hydrogen to a theory of the formation of galaxies. He first considers the origin of the angular momentum of spiral galaxies. This subject has had a controversial history. Many theoreticians suppose that galaxies formed as a result of gravitational instability soon after the decoupling of matter and radiation in the Universe. At that time the scale of the Universe was 1/1,000 of its present value. Spiral galaxies could not have contained their present angular momentum because they were too small. Starting with Hoyle in 1951, various people have explored the possibility that angular momentum was imparted to protogalaxies by extraneous couples—for example, a nearby cluster of galaxies.

Oort reports new calculations which show that this mechanism fails by two orders of magnitude to explain the present angular momentum of spirals. Consequently he suggests that protospirals were not formed by gravitational instability in a very early phase of the Universe, but that they date from a much later period when their formation was caused by large scale mass motions which at the same time provided their angular momentum. The idea that large scale "turbulence" has played an important part in the formation of galaxies was suggested in the early 1950s by von Weizäcker and Gamow.

For a protospiral to contain enough momentum it must have formed when the scale of the Universe was about 1/30 the present value. A protocloud formed at that time would initially expand with the Universe, but at a reduced rate. Consequently the actual collapse into a galaxy could occur at an epoch as late as 10^8 years after the initial "big bang". Oort points out that this is an attractive feature of this theory because counts of the extragalactic radio sources (the log N–log S relation) indicate that most of the powerful radio sources in the Universe were born at this comparatively recent epoch.

Oort speculates that the present infall of hydrogen into the Galaxy results from material initially at the outer boundaries of the cells from which protogalaxies were formed. This intergalactic gas must have a high temperature—of order 10^5 to 10^6 deg—and Oort suggests that it might be detectable through its thermal X-ray emission.

SUPERNOVAE

Clues about Pulsars

by our Cosmology Correspondent

THE frequency of supernovae has become of particular interest recently, because of its bearing on the number of pulsars expected in our Galaxy. Without this inducement to encourage detailed investigations, estimates ranging from one supernova per galaxy in 350 years to one every 15 years have been put forward by various authors. Now, a search has been carried out to find the frequency of supernovae in spiral galaxies, and this work also relates the frequency to the mass and luminosity of the galaxies in which they occur (G. A. Tammann, *Astron. Astrophys.*, **8**, 458; 1970).

Tammann has studied only Sb and Sc spirals, but all such galaxies with known luminosity classes and which are within the distance of the Virgo cluster have been investigated, having a total of forty-five supernovae. Other types of galaxy and more remote spirals have not been studied, for they have produced too few supernovae for reliable statistical analysis, but the number of supernovae seen in all galaxies out to the chosen limit during 1959–1969 gives an average of one such event per galaxy in 140 years. This must represent some upper limit, for there must have been some unobserved events. The Sb and Sc galaxies themselves behave differently, both from each other and within their own types. There is a strong dependence on luminosity class, and the frequency in Sb galaxies is down by roughly a factor of 3 on that in Sc galaxies; overall, the spirals have a higher frequency of supernovae than that found when all galaxies are included in the sample, the highest frequency found by Tammann being one in 16 years for ScI galaxies. The ratio of type II to type I supernovae seems the same for all galaxies (roughly 2:1).

Only nine of the thirteen known galaxies in which more than one supernova has occurred fall within the limits of this study, but all of these lie towards the higher luminosity classes in a way which is both significant and surprising. It would be natural to assume that brighter galaxies have more supernovae just because they contain more stars, but it seems that the correlation of supernova frequency with mass is non-linear, the frequency of events rising rather more rapidly than the mass.

Finally, and of greatest interest for investigators of pulsars, Tammann applies his results to M 31, M 33, and our Galaxy, which is generally accepted to be a type Sb or Sc. Using values intermediate between those appropriate for these two types, and taking the Galaxy's mass as 17×10^{10} $M_\odot$ gives a rate of one supernova every 26 years, with a possible error of ± 10 years (this figure is modified to one in 65 years for an Sb spiral of the same mass and one in 17 years for Sc). Overall, in spite of the incompleteness of records covering the past thousand years, this figure agrees with observation, and perhaps suggests that a new supernova is imminent. For M 31, using the latest mass estimate of 20×10^{10} $M_\odot$ the predicted rate is one event in 55 years (the only observed supernova in M 31 occurred in 1885) and for M 33 the rate should be one event in 73 years, which is at least not inconsistent with the lack of any observed supernova in that galaxy. Accepted theory suggests that the rate of star formation is greater in Sc than in Sb galaxies, which could explain the different supernova rates between the types. The interesting consequences of these differing rates on the heavy element abundances in different classes of galaxy are discussed by Tammann, and perhaps these results should be used as a basis for further observations along this line of investigation.

EARTH'S MANTLE

Rifts and Ridges

from our Geomagnetism Correspondent

CONTINENTAL rift valleys have often been regarded as the equivalents on land of the median valleys of mid-oceanic ridges. The East African rift, in particular, is usually drawn as an extension of the world wide undersea rift system, a procedure which seems to be compatible with the geometry of the system. But the evidence for this assumption is rather shaky. By implication, the East African rift should be a region of rising convection currents in the mantle, which would imply a higher than average flow of heat. Measurements of heat flow in the African rift are few; but available data suggest that the flow is not abnormal. Twenty measurements from Lake Malawi, for example, gave an average of 1·0 μcalorie cm^{-2} s^{-1}, which is well below the world average and comparable with that for the South African shield. To be sure, five other measurements were in the range 1·62 to 2·88 μcalories cm^{-2} s^{-1}, but these were easily explained as the result of a local heat source.

To the heat flow evidence must now be added geochemical evidence, for Murray (*Earth Planet. Sci. Lett.*, **9**, 34; 1970) points out that the products of volcanism in the African rift valleys differ both in composition and volume from those in the median

valleys of mid-oceanic ridges. The African rifts are sites of undersaturated, predominantly mafic volcanics erupted in comparatively small volume from single vents. Murray interprets these products as the end result of partial melting in the mantle at depths of more than 100 km. When melted, to reach the surface the liquids would have to pass through a considerable distance in which temperatures were colder than the solidus of the surrounding peridotite. In these conditions, the liquids would be fractionated at high pressures, become nepheline-normative and decrease in volume.

In regions of high heat flow, on the other hand, partial melting in the mantle would occur at depths of less than 60 km, and the liquids would thus avoid passage through peridotite at sub-solidus temperatures. Greater volumes of such magmas would reach the surface than in low heat flow areas, olivine would be the principal crystal phase to separate and, if no previous fractionation had occurred, the magmas at the surface would be tholeiitic. Accordingly, this model predicts voluminous oceanic tholeiites at mid-oceanic ridges; and these are observed. Murray's models are based on recent high pressure experimental results on the origin of basaltic magmas.

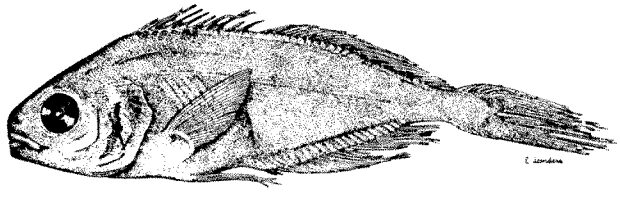
From the heat flow data and the nature and volume of the surface volcanics, Murray concludes that the upper mantle conditions below the East African rifts and mid-oceanic ridges are fundamentally different. It follows from this that because mid-oceanic ridges are regions of upwelling mantle material, the African rifts probably are not. This does not apply to the northern end of the rift valleys in Ethiopia, of course. There, heat flow is high, the volcanics are more voluminous and dredging has indicated the presence of typical oceanic tholeiites beneath the Gulf of Aden and the Red Sea. The northern end of the rifts is well established as a region of young sea floor spreading. Murray's view, however, is that the southern end cannot even be regarded as an area of "embryonic" spreading.

FISH

South African Clinids observe Rules

from our Marine Vertebrate Correspondent

THE clinids constitute the dominant group of fishes that live permanently on the shores of South Africa from south-west Africa to Natal; north of both of these provinces they are replaced by other families of shore fishes. Within this area the clinids predominate, and the composition and abundance of the thirty-three species found there vary with the changing physical conditions in the same way as those of other intertidal animals.



The late T. A. Stephenson and his colleagues, in their now classical distribution studies of the intertidal fauna and flora of South Africa, pointed out that the distribution of these fishes, as known in 1948, agreed with the general trends on that coast. The precise ranges of most species, however, were not then well known. Recent field work has produced a better understanding of their distribution, and Mary-Louise Penrith has summarized the data in a study of the distribution of the fishes of the family Clinidae in southern Africa (*Ann. S. African Mus.*, **55** (3), 135; 1970).

In general, fishes are unhelpful animals in littoral distribution studies, either on account of their mobility, or because they are very adaptable to various habitats, or because many of them possess a pelagic larval or post-larval stage. The South African clinids, however, are exceptional in that they are viviparous, sedentary animals, and speciation having proceeded lavishly might be expected to be restricted in their habitat selection. They are therefore extremely appropriate fishes for distribution studies.

Penrith has shown that their distribution corresponds very well with the faunal regions proposed by Stephenson. The west coast populations extend from Lüderitzbucht (South-West Africa) to Cape Point; a south coast group of species extends from there to East London, where the east coast group begins, extending northwards to Laurenço Marques. Some minor assemblages partly overlap these zones or are found in two adjacent zones but never more than two. Penrith concludes that because the clinids conform to the South African intertidal provinces established by other workers and these have been shown to be temperature dependent, then temperature must be a factor in their distribution also. This probably operates in two ways, the direct effect of temperature on the fish being of paramount importance, but its effect on other organisms which go towards constituting a suitable habitat is of considerable significance. An example of the latter is cited in *Clinus cottoides* which feeds on the legs of acorn barnacles. It is abundant on the south coast where dense balanoid barnacle zones are characteristic, but absent on the west coast where the balanoid zone is absent because of the different temperature.

FISH

New Nomeid

A new member of the family Nomeidae, discovered in the eastern Pacific, has been named *Psenes sio*, in honour of the Scripps Institution of Oceanography. The specimen shown here, which is immature, is 75·5 mm long and has been described by R. L. Haedrich (*Breviora*, No. 351; 1970).

PEPTIDES

New Paths to Structures

from our Molecular Biology Correspondent

PROTON magnetic resonance work on proteins, especially since the advent of the 220 MHz instrument, has often appeared to the observer as somewhat of a scramble for the spectacular, but not too arduous, *coup*. At the same time, however, some sober application has gone into the more modest area of peptide structure. From comparison of observed and calculated couplings of the protons on the α-carbon and peptide nitrogen atoms, and from other features of the spectrum, attempts have been made to deter-

mine the conformations of peptides explicitly, and in small, especially cyclic, structures, such as those of some antibiotics, considerable success has been achieved. Each compound, however, has presented its own problems, and the degree of conviction that structural conclusions have carried has depended on luck, as well as ingenuity. Some of the more glib operators in the field have also evolved what might be termed a conversational, rather than a rigorous approach to the divination of structures, and the bemusement of the outsider.

A rational general strategy, which should have wide appeal, has now been outlined by the Rockefeller group (Gibbons, Nemethy, Stern and Craig, *Proc. US Nat. Acad. Sci.*, **67**, 239; 1970). They have considered the conformation-dependence of backbone proton coupling constants in the light of the known—or at least calculated—restrictions on the peptide geometry. The various theoretical, as well indeed as the vulgarly empirical, model building routines that have been developed in different laboratories have by and large homed in nicely on the energetically favourable values for the two dihedral angles that define the conformation of a peptide chain. Each of these combinations of the angles must be associated with a particular value of the coupling constant. The latter can be derived from data on simple amide derivatives, in which substituents on the carbon determine the rotational angles, by driving the N—H bond into an optimally staggered position. The coupling constants, which in practical terms represent the splitting of the observed resonances, differ considerably. It is also possible to make use of a semi-empirical relation between the relevant dihedral angle (φ) and the coupling constant, developed by a Russian group of workers. From the values of the dihedral angles at the minima in the energy contour map, corresponding to right and left handed α-helices, pleated sheets, and so forth, coupling constants for these forms are deduced. For example the values for the right and left handed α-helix are about 2 and 8 Hz, and a typical coil value is 7 Hz. So far as can be ascertained with the sparse data at present available, predictions are consistent with experiment. The strategy then is to determine the possible dihedral angles, which according to the analytical relation are compatible with the observed coupling constants, and then eliminate those which do not correspond to favourable regions in the conformational map. Much work on model compounds is still required, and it will long be necessary to make use of evidence from other sources.

A number of important hand to mouth methods in fact remain available to assist the deduction of structures. A good example of their use, in relation to a cyclohexapeptide, ferrichrome, which is implicated in iron transport in microorganisms, comes from Llinás, Klein and Neilands (*J. Mol. Biol.*, **52**, 399; 1970). Because of the paramagnetic line-broadening induced by the iron atom which is chelated by this peptide, the aluminium analogue has been used. Introduction of the metal produces striking changes in the nuclear magnetic resonance spectrum, involving especially amide N—H proton frequencies. The solvent-dependence and temperature-dependence of the several frequencies are used to determine which groups are relatively free, and which restricted by internal hydrogen bonds, or other conformational factors, including coordination with the metal. The rough structure which is deduced for ferrichrome in solution resembles the crystal structure of a rather similar species, and involves a kind of antiparallel β-fold, which, it now seems, may be common in small cyclic peptides. Approximate calculated dihedral angles by the semi-empirical method are compatible with those observed in the X-ray model of the analogue.

DNA TUMOUR VIRUSES

Most Fastidious Viruses

from our Cell Biology Correspondent

WHEN polyoma virus or simian virus 40 transforms a cell at least some of the viral genes and their products persist in the neoplastic cell. In the case of cells transformed by SV40 the entire genome persists, whereas in cells transformed by polyoma virus it is not clear whether all or only part of the viral genome becomes stably associated with the cell. But in either event the nature of the viral genes which persist, and are apparently transcribed in transformed cells, is one of the central questions of tumour virology.

Unfortunately, although the small DNA tumour viruses are very simple structures and probably contain only about half a dozen genes, they reproduce, in extremely complex hosts, eukaryotic cells. As a result there is no way yet to select amber and ochre conditional lethal mutants which could be used to define the functions specified by the viral genome. Of course suites of temperature sensitive mutants of polyoma virus can and have been isolated but, as with all temperature sensitive mutants, they are leaky. These obstacles led Benjamin first to predict and now to isolate a third class of conditional lethal mutants of polyoma virus–host range mutants (*Proc. US Nat. Acad. Sci.*, **67**, 394; 1970).

Benjamin's ingenious idea was that it should be possible to isolate mutants of polyoma virus which fail to replicate and kill normal permissive host cells, but which can grow in such cells previously transformed by polyoma virus. This selection, of course, depends on the isolation of a murine 3T3 cell which has been transformed by polyoma virus. Normally these cells support the lytic growth of the virus and are killed, but either because the occasional cell is infected with a spontaneous mutant virus incapable of killing the cell, or because the occasional cell is itself a mutant which cannot support the lytic cycle of the virus, it is possible to isolate from an infected population rare 3T3 cells which are transformed by polyoma virus.

When Benjamin had obtained such a cell, 3T3-Py-3, he could infect it with mutagenized stocks of virus and select those viruses which grow only on 3T3-Py-3 cells. So far he has isolated four such mutants which yield less than two infectious progeny per infected 3T3 cell, but between 200 and 600 infectious particles per infected 3T3-Py-3 cell. The restricted host range of the mutants is not the result of some trivial failure in the uncoating of the virus particles or some requirement for a dividing host cell because infectious DNA isolated from the mutants has the same properties as intact mutant particles. Moreover, the mutant does not grow in stationary or dividing 3T3 cells.

The four mutants do not transform either rat embryo fibroblasts or the BHK line of hamster embryo fibroblasts, although both these types of cell are transformed by wild type virus. This result is not

altogether unexpected, because presumably Benjamin's selection procedure selects for viruses which are defective in one or more functions which are expressed in transformed cells and are also required for the lytic replication of the virus. When mutants grow in 3T3-Py-3 cells they are presumably complemented by a viral gene product or the product of a cellular gene which is depressed by transformation. Because all the mutants fail to transform non-permissive cells there is a chance that the complementing function in 3T3-Py-3 cells, which the mutants lack, plays an integral role in maintaining transformation. In other words the host range mutants may well carry mutations in a transforming gene(s).

MEMBRANES

Miniproteins or Myth?

from our Biochemical Genetics Correspondent

AN analysis of the red blood cell membrane has become an almost statutory requirement of anyone professing the name membrane biologist. The ease with which material can be isolated and purified makes the erythrocyte the favoured test system for new techniques and the touchstone for any new theory of membrane structure.

About half of the red blood cell membrane is protein, the rest being lipid and carbohydrate (44 and 7 per cent, respectively, by weight). The protein fraction displays considerable heterogeneity: Rosenberg and Guidotti, for example (*J. Biol. Chem.*, **243**, 1985; 1968), have separated and characterized several components, some—but not all—of which Berg found to be located on the outside surface of the cell (*Biochim. Biophys. Acta*, **183**, 65; 1969). More recent reports (Phillips and Morrison, *Biochem. Biophys. Res. Commun.*, **40**, 284; 1970; Lenard, *Biochemistry* **9**, 1129; 1970; Rosenberg and Guidotti, *J. Biol. Chem.*, **244**, 5118; 1969) are consistent with a system in which there are two huge proteins of approximate molecular weight 200,000, one of intermediate size (100,000) and about six smaller components (40,000–80,000)—all present in large amounts. And there are also many minor components. Most of the identified fractions—with the exception of that with a molecular weight of 100,000—do not seem to reside on the outer surface of the cell.

In the many laboratories where work has led to this picture of the red cell membrane a cry of astonishment is likely to go up at the report from Dreyer's group at Caltech (Laico *et al.*, *Proc. US Nat. Acad. Sci.*, **67**, 120; 1970) which implies that they all missed the fundamental polypeptide subunits of biological membranes, and suggests that at least 50 per cent of the protein in red cell ghosts is present in this form. The first surprise is that the molecular weight of these subunits is only 5,000—that is, each peptide can only contain at most fifty amino-acids. Some of them are believed to be glycoproteins (for which no evidence, however, is presented). Clearly they must be very small indeed, and Dreyer and his colleagues call them "miniproteins". The second surprise is that they have no N-terminal amino-acids: Dreyer *et al.* suggest that they are cyclic peptides or have blocked N-terminals. The third surprise is the aggregation phenomenon. They surmise (but do not show) that the miniprotein can aggregate to give complexes which cannot be dissociated by any known method: many of the several proteins observed by other groups are, by implication, likely to be artefacts. The only real characterization of these miniproteins Dreyer and his colleagues have carried out is fingerprinting. Miniproteins from red blood cell membranes and mitochondrial membranes give very similar fingerprints.

Unfortunately, these fingerprints were made using subtilisin to digest the miniprotein: this gives no idea of the complexity of miniprotein because of the complete lack of specificity of subtilisin. The fingerprints, then, are not very helpful. Could these miniproteins be degradation products of larger proteins—the cleavage products of a latent membrane peptidase? Dreyer *et al.* must remove this possibility before the miniprotein can be regarded as a fundamental subunit.

ENVIRONMENT

Monitoring for Malformations

from a Correspondent

WHY should anybody monitor for congenital malformations? To detect the influence on the embryo of environmental indiscretions, said Dr E. A. Murphy (Johns Hopkins University) at a symposium on the subject held in Albany, New York, on October 19 and 20. The shorter the interval between insult and recognition of injury, the easier it will be to establish causality. For this reason Drs J. R. Miller (University of British Columbia) and T. H. Shepard (University of Washington) urged monitoring of spontaneous abortions for specific malformations. The history of environmental exposures would thus be obtainable while the mother's memory was still fresh, and an excess of teratogenic effects would be potentially recognizable six to seven months earlier than if observations were limited to the outcome of pregnancies that had gone to term. Unfortunately such surveillance is costly, biased in various ways, and limited in extent.

Epidemics of environmentally induced malformations have sometimes been long delayed in gaining world wide attention; for example cerebral palsy (congenital Minamata disease) among Japanese infants whose mothers, while pregnant, ate fish contaminated with organic mercury. Dr R. W. Miller (National Cancer Institute) suggested the establishment of an international unit to deal with the global implications of such episodes, whether they occur in man or beast.

Because specific major malformations are rare, surveillance for them must be wider than can readily be achieved at present. As an alternative measure, potentially more sensitive, Drs D. W. Smith (University of Washington) and E. B. Hook (Albany Medical College) recommended further study of the relevance of minor malformations (for example abnormal palmar creases) to environmental influences. In the discussion it was suggested that a test of this relationship could be made through the study of Japanese survivors exposed *in utero* to atomic radiation, which is a known teratogen.

Vital and health records contain many unused data that would greatly aid human teratology, especially if a system for automatic linking of records were developed on a large scale. Assignment of a unique number to each child at birth for use on medical and other records would greatly ease computer processing, while preserving the

patient's privacy. Automation is also required for the mass screening of human chromosomes, obtainable at birth from blood of the umbilical cord. The development of scanning devices, which five years ago were expected to be operational in five years, has progressed rapidly according to Dr A. D. Bloom (University of Michigan), but will probably not be operational for another ten years.

Electrophoretic mass screening of blood proteins for new mutations (rare variants) would be formidable on both theoretical and practical grounds, in the view of Dr L. R. Weitkamp (University of Rochester). Screening of blood proteins by immunological reactions may offer rather more hope. The overall message of the conference, however, was that effective systematic mass screening for congenital anomalies does not seem to be imminent.

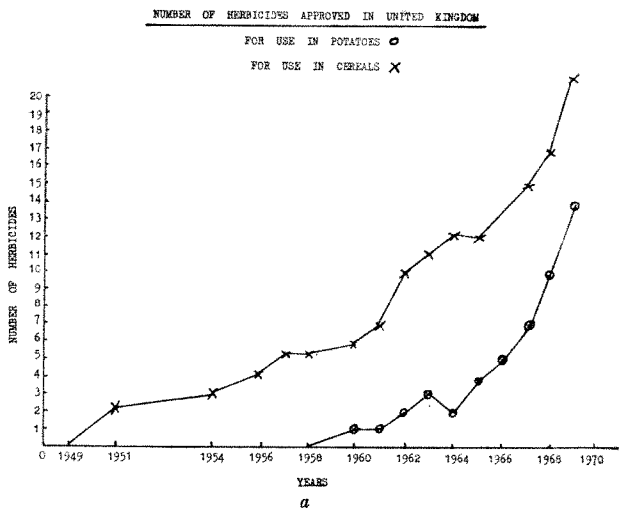
SLIDES

Away with the Fuzz

LECTURERS will be spared the embarrassment of showing fuzzy, unreadable slides if Mr Haydn Bywater, of the Weed Research Organization, Oxford, has his way. He and his colleagues have standardized a procedure for producing readable slides without the aid of a technical illustrator and elaborate equipment.

Mr Bywater writes: From a black original on white paper a finished slide is produced with white lines against a coloured background. The most critical stage is the drawing of the table or graph, which should have the minimum of lettering. Lower case lettering is easier to read.

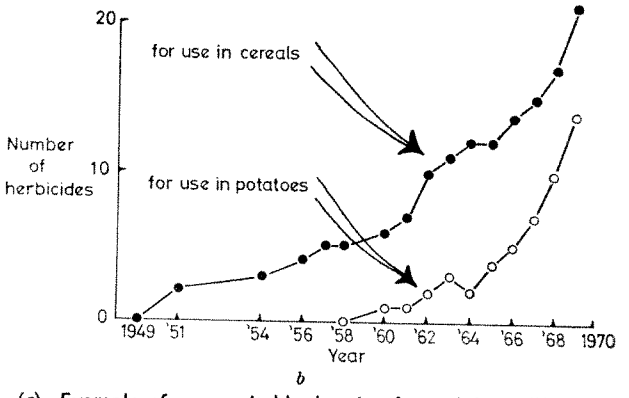
The size of the lettering is also vital. A useful standard relates size of lettering to size of screen. Thus the height of the lower case risers (that is the total height of the letter h) should be at least 1/50th of the width of the projected screen. For example, if the original drawing is 20 cm wide, the smallest lettering which can be used is $20/50 = 4$ mm tall. Therefore if a 4 mm pen stencil is used, the graph should not be larger than $4 \times 50 = 200$ mm wide. Pen stencils are easy to use, although "instant" transfer letter systems give a better result.



For solid lines black chart tapes give an even, sharp result and are easier to use than a ruling pen. A reasonable thickness of line is 1/200th of the width of the drawing, so that for a graph 20 cm wide the coordinates and other lines should not be narrower than 1 mm. The illustration shows a graph before and after redrawing for use as a slide.

The drawing is next photographed on high contrast, Kodak type 3 Kodalith film, which is available in 35 mm form as well as cut films. It can be handled in a red safelight, Wratten No. 1 or 1a. With 35 mm film the drawing must be framed correctly; a single lens reflex camera is most useful for this because the alignment can be seen through the viewfinder. Exposure should be timed accurately—with two No. 2 (500 W) Photoflood lamps 5 feet from the drawing, exposure time is 3–6 seconds at $f/22$.

The film is processed in Kodak fineline developer, with continuous agitation, for 2·5–3 minutes at 20° C, and fixed and washed as usual. Spotting, if necessary, is done on the rear (shiny) side of the film. The negatives are printed in contact with Technifax Diazochrome material KBL (blue) (Admel International, Weybridge, Surrey). Because this material is only sensitive to ultraviolet light, a darkroom is not needed. A contact printing frame can be used to expose the foil, in contact with the negatives, to direct sunlight for about 2·5 minutes. An ultraviolet printing box can also be used. Overexposure produces a weak colour background, and underexposure causes the letters to be tinted instead of transparent.



Processing is done in ammonia vapour. A dye line processing machine can be used, or the foils can be suspended in a closed container with a little 0·880 ammonia liquid; a fume chamber should be used. At normal room temperature the colour develops in 2 or 3 minutes; if the room is cold the container can be placed in warm water to speed up the development.

During printing the face of the diazo foil must be in contact with the dull side of the negative. The foil sheets are notched at the top right hand corner when facing the operator, as with photographic film. But when the full sheets are cut for printing it is impossible to tell which side is which unless care is taken to keep all pieces the same way up after cutting. When the colour has ceased to darken, the foil is cut to size and is ready for binding in a slide frame. Other colours are available, but the blue type seems to be the most acceptable to audiences. These slides have the added advantage that both the stick pointer and the illuminated pointer can be used effectively, for they are both visible against the coloured background.

Research in Muscular Dystrophy

by
J. N. WALTON
Department of Neurology,
University of Newcastle upon Tyne

Treatment of the diseases known collectively as muscular dystrophy has not proved very successful. So far, the best results have been achieved by preventive medicine, although pathological and biochemical research is beginning to yield useful information.

THE muscular dystrophies are a group of inherited degenerative diseases causing progressive weakness and wasting of muscles. The individual muscle fibre becomes necrotic, undergoes phagocytosis, and later regenerates. The most active pathological changes may be seen before there is any detectable muscle weakness[1]. Eventually the repetition of this process leads to the extensive loss of muscle fibres, with replacement by fat and fibrosis.

There are several different types of muscular dystrophy[2,3]. In man, the three most commonly encountered, in decreasing order of severity, are first the sex-linked, recessively inherited, Duchenne (pseudohypertrophic) muscular dystrophy affecting young boys, which usually causes difficulty in walking, in rising from the floor and in climbing stairs at about the age of 3 years; most patients are confined to a wheelchair by the age of 10 and die before the age of 20. Second, the autosomal recessively inherited limb-girdle muscular dystrophy is more benign but is usually severely disabling in middle life, while the dominantly inherited facioscapulohumeral type, which is the most benign of all, but which, like the limb-girdle variety, usually begins in early adult life, is often compatible with survival to a normal age, in spite of increasing disability. There is also the relatively common dystrophia myotonica in which muscular degeneration is associated with apparent delayed muscle relaxation (myotonia).

Many other conditions may give a clinical picture similar to muscular dystrophy, including polymyositis, a probable autoimmune inflammatory disorder of muscle[4,5], spinal muscular atrophy, in which there is a primary degenerative process involving the motor neurone[6,7] and various toxic and metabolic myopathies[8,9]. Treatment, prognosis and genetic counselling all depend on accurate diagnosis, and investigations are designed to identify these and many other disorders which affect voluntary muscle.

The search for an effective drug therapy for muscular dystrophy has extended widely. Enthusiastic reports of the effect of vitamins, amino-acid mixtures, nucleotides, anabolic steroids and isoniazid have all proved to be unfounded[10]. Management rests on the established practice of maintaining mobility, building up relatively unaffected muscles, preventing contractures and treating the ever-threatening respiratory infections (and, in the Duchenne type, cardiac failure due to associated cardiomyopathy). Surgical lengthening of contracted muscles and tendons is of limited value, but possibly future advances in immunosuppressive therapy and organ transplantation will allow whole muscle transplantation; it is difficult to see that this could ever be of more than limited value in view of the large numbers of muscles which are usually involved.

The greatest success in recent years in the management of muscular dystrophy has been in preventive medicine, with genetic counselling and the detection of female carriers of the gene responsible for the Duchenne type muscular dystrophy. Women who already have an affected boy and have another affected male relative in the female line of inheritance are definite carriers of the gene. They can be advised that each pregnancy has a one in four chance of producing a further affected child and a one in four chance of producing another female carrier. It is now becoming possible to determine the sex of the foetus *in utero* early in pregnancy, thereby allowing a therapeutic abortion should the foetus be male[11]. Women with a brother or uncle affected with the disease are possible carriers. The hemizygous carriers usually have little or no muscle weakness detectable clinically, but it has proved possible to detect more than 80 per cent of them by a combination of the estimation of serum creatine kinase, quantitative electromyography and muscle biopsy[10,12]. Efforts are being made to improve the rate of carrier detection by various approaches including computer analysis of the electromyographic interference pattern[13], by estimations of total body potassium and rubidium turnover[14–16], by study of the isoenzyme pattern of lactate dehydrogenase in sera and muscle[17], by a search for specific muscle antibodies[18–20], and by the investigation of electrocardiographic abnormalities[21]. The object of this research is to reduce to zero the number of carriers which go undetected, and thus to reassure female relatives of patients that they have no more chance of having an affected child than any other member of the population. Thus genetic counselling may reduce the number of boys affected with muscular dystrophy, but only to the level of the spontaneous mutation rate.

Pathological and biochemical research into muscular dystrophy is in progress, although it must be admitted that pointers to the underlying nature of the disease process are only just beginning to appear. One of the problems of investigating human muscle disease is the difficulty of obtaining sufficient material by muscle biopsy

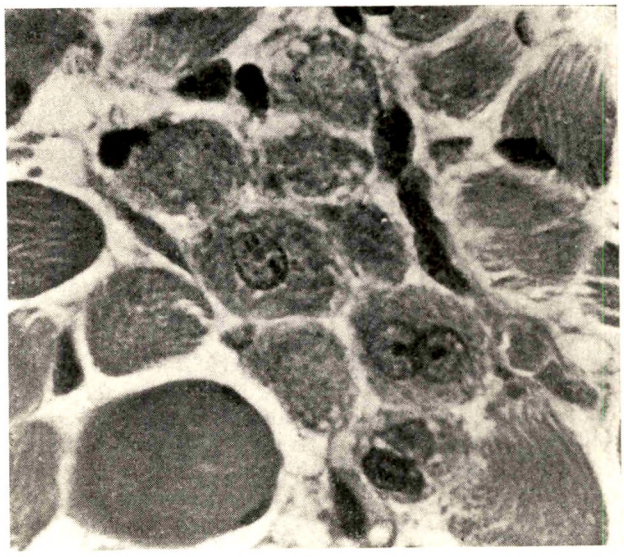

Fig. 1. A transverse section of a quadriceps biopsy obtained from an early (preclinical) case of muscular dystrophy of the Duchenne type. The group of muscle fibres in the centre of the section show sarcoplasmic basophilia with stippling of the sarcoplasm due to the sparse myofibrils; their nuclei are large and vesicular with prominent nucleoli. These histological characteristics are indicative of regenerative activity. (Stained with haematoxylin and eosin, ×640.)

for multi-disciplinary investigations. The discovery of several genetically determined muscle diseases in animals, including mouse, chicken, hamster and lamb[22], has overcome this problem to some extent. Unfortunately these disorders differ in many ways from the human disease; for example, mouse dystrophy is more like human dystrophia myotonica than Duchenne muscular dystrophy. In the latter condition, although it seems that the initial lesion is a segmental necrosis of muscle fibres, and that regeneration is active (Fig. 1), there is still doubt as to whether such regeneration is ever effective. The study of dystrophic muscle in tissue culture has aided the elucidation of this problem. Recent studies have not supported the earlier difficulty experienced in growing multinucleated muscle fibres in tissue culture from human dystrophic muscle[23]. In cultures of dystrophic mouse muscle, however, the proportion of morphologically abnormal myoblasts is greater than in control cultures, and these myoblasts do not seem to fuse into multi-nucleated muscle fibres as rapidly as normal[24–26]. Furthermore, measurements made on single cells in tissue culture, which indicate that the amount of both nucleolar and cytoplasmic RNA may be decreased both in myoblasts and fibroblasts from these cultures[26–28], may provide an explanation of these abnormalities.

Biochemistry and Electrophysiology

The search for a primary biochemical defect in the muscle of patients with muscular dystrophy is hampered by the very pathological changes that the disease produces[29]. Muscle biopsies are diluted and contaminated with biological systems derived from connective tissue, fat and macrophages. A major advance can be expected when tissue culture techniques are developed to allow the relatively pure culture of large quantities of dystrophic muscle for biochemical investigation[30]. The most striking biochemical abnormality in patients with Duchenne muscular dystrophy is the very high level of serum creatine kinase. This, however, seems to be simply an index of damage to the muscle cell, and is not due to a specific defect in creatine phosphate metabolism. In spite of the great biochemical advances recently made in understanding many forms of muscle disease, such as the glycogenoses[31,32], the biochemical basis of muscular dystrophy is still in doubt. Recent work on the activity of cathepsin in normal and dystrophic human muscle has shown that in dystrophic muscle there is a relatively greater increase in the splitting of added protein than in autolytic activity[33]. The calcium affinity of sarcotubular vesicles obtained from the muscle of patients with early Duchenne type dystrophy is less than normal[34], but these and the many other biochemical studies have not so far revealed any fundamental pathogenetic abnormality.

The histochemical characterization of muscle, and the recognition of its two principal types of fibre, has provided considerable impetus to the investigation of muscle disease[35–37]. Histochemical studies, however, suggest that both types of fibre are involved equally early in human muscular dystrophy[37,38], although occasional fibres may contain a high activity of all the enzyme systems studied[39]; in the dystrophic mouse[40], electrophysiological investigations have suggested that type II muscle fibres are affected more severely than type I.

Electrophysiological investigations of muscular dystrophy involving microelectrode studies of single muscle fibres have revealed evidence of a decreased resting membrane potential in dystrophic muscle, and of fibres or segments of fibres which are functionally denervated[41–43]. It is possible that "cracking the code" of muscular dystrophy may come from an entirely new approach, such as a consideration of the role of the motor neurone in the disease. Thus recent observations[44] have suggested that the total number of motor units in the extensor digitorum brevis muscle of the foot is greatly reduced in patients with muscular dystrophy. More attention to the "trophic" role of the motor neurone in this and other muscle diseases is clearly required. Plainly, however, much more work on the nature of the primary morphological and biochemical lesion which causes the muscle to waste must be done before the cause of the condition can be elucidated, and before hopes can be revived that an effective treatment is in sight.

Frequencies for Radio Astronomy

by
F. G. SMITH
Nuffield Radio Astronomy Laboratories,
Jodrell Bank, Cheshire

At present the scope of research in radio astronomy is limited by the allocation of frequencies, some of which have to be shared with other radio services. When the International Telecommunications Union reconsiders all frequency allocations next year, astronomers are hoping for an improvement.

THE allocation of bands of frequencies to the many radio services is a matter for agreement between nations. A series of conferences, arranged by the International Telecommunications Union (ITU), have dealt with various parts of the spectrum and with various services, so that there is now an agreed allocation for all frequency bands from 10 kHz to 40 GHz. In this agreement, the needs of scientific research must be presented, along with those of all radio services, by national administrations and not directly by the scientists. Coordination of the individual national proposals must therefore be achieved through the combined action of three international scientific unions, IAU (astronomy), COSPAR (space) and URSI (radio), which jointly delegate members to an Inter-Union Commission for the Allocation of Frequencies for Radio Astronomy and Space Science (IUCAF). This Commission discusses the scientific case for protecting various frequency bands for space research and radio astronomy, and informs scientists and administrations throughout the world of the desirable and practical steps that can be taken to improve and extend the allocations.

There will be a new World Administrative Conference of the ITU in June 1971, covering frequency allocations for all space activities, notably for satellite communications. IUCAF has made several suggestions for revising the allocations, especially for radio astronomy; these have been passed on to national administrations, and there is reason to hope that most of the IUCAF suggestions will become firm proposals with a good chance of acceptance at the conference.

Space research seems to be fairly well catered for in the existing regulations, apart from a difficulty in obtaining the use of some low frequency bands for ionospheric research. IUCAF is seeking an improvement in the protection of the "guard bands" around standard frequency transmissions for this purpose.

The more complex problem of radio astronomy is set out in the table, which lists existing allocations together with the latest IUCAF proposals. Two kinds of allocation are required: a series of bands to cover the whole spectrum at roughly octave intervals, for continuum radiation, and some individual bands to cover the most important radio spectral lines.

Some bands already allocated are shared with other services, such as "fixed and mobile", that is communications such as taxi radio. This is only possible when radio observatories and the other users are geographically widely separated; even so, sharing is often a serious limitation on the sensitivity of the radio astronomical work. There are also differences between the three "regions" of the world, defined by ITU. In any table the word "shared" covers a range of meanings. The ITU regulations include "secondary allocations", "shared allocations" and various forms of footnotes; all these are here designated as "shared".

The table represents the present state of discussions. There will be many more discussions during the coming year, and many weeks of work at the conference itself. IUCAF has asked to have an observer at the conference, so that the scientific case for the various proposals is available at all times. Fortunately many of the people concerned with formulating the next international agreement realize that the electromagnetic spectrum is a natural resource that can be despoiled as effectively as any other, and it is to be hoped that considerable improvement will be obtained in the status of frequency allocations for scientific research.

Table 1. EXISTING ALLOCATIONS OF FREQUENCIES TO RADIO ASTRONOMY AND PROPOSED CHANGES

Frequency band	Present status	Proposed changes
Approx. 10 MHz (bandwidth 20 kHz)	None	This band is needed for low-frequency observations, especially of extragalactic sources
Approx. 20 MHz (bandwidth 20 kHz)	None	As at 10 MHz. Proposals for a band at 22 MHz are expected
37·75–38·25 MHz	Shared	Improved protection is needed, although sharing may be necessary
73–74·6 MHz	Region 2 only (N. and S. America)	No extension to other regions seems possible
150·5–153 MHz	Region 1 only (Europe). Shared	No improvement seems possible
404–410 MHz	Shared	Small regional differences should be removed, giving an international allocation
606–614 MHz	Allocated to television, but so far unused	IUCAF asks for this band to be allocated to radio astronomy
1,400–1,427 MHz (the hydrogen line)	Exclusive allocation to radio astronomy	An extension to lower frequencies—down to 1,390 MHz—is needed for observation of galaxies with large redshifts
1,664·4–1,668·4 MHz (the OH line)	Shared	Protection is sought from airborne transmitters in this band, and an extension to 1,660–1,670 MHz seems possible
1,612 and 1,720 MHz (other OH lines)	None	Some local protection is sought for individual observatories observing these lines
2,690–2,700 MHz	Exclusive allocation to radio astronomy	An extension down to 2,670 MHz, on a shared basis, is requested for wide-band observations of extragalactic sources
4,990–5,000 MHz	Exclusive in Region 2 (N. and S. America), shared elsewhere	Improvement of protection, and an extension down to 4,950 MHz, both seem possible and are requested by IUCAF
10·68–10·70 GHz	Exclusive allocation to radio astronomy (with some exceptions)	An extension down to 10·60 GHz is requested
15·35–15·40 GHz	Exclusive allocation to radio astronomy (with some exceptions)	No change is proposed
19·3–19·4 GHz	Exclusive to radio astronomy, with some exceptions	This band is needed for satellite communications, and will be relinquished by radio astronomers
23·6–23·5 GHz	Proposed for exclusive allocation to radio astronomy	Replacement for the 19·3–19·4 GHz band; also covers some NH_3 and H_2O lines
31·3–31·5 GHz	Exclusive to radio astronomy with some exceptions	No change is proposed
40–240 GHz	A series of bands, for example, 88–92 GHz	It is proposed to preserve wide bands in this region initially for reception only

There are also requests for some protection to be given to observations of the three following spectral lines: formaldehyde, 4,825–4,835 MHz; formaldehyde, 14·485–14·515 GHz; water vapour, 22·21–22·26 GHz.

X-rays from Domestic Colour Television Receivers in Britain

by
M. C. O'RIORDAN
P. N. CASBOLT
Radiological Protection Service,
Belmont, Sutton,
Surrey

With British domestic colour television receivers, the genetic dose from X-rays is negligible, and the X-ray emission from individual sets is normally well within the internationally accepted limit.

RECOMMENDATIONS for limiting the emission of X-rays from domestic television receivers have existed for many years[1–3]. Throughout this period, measurements of the radiation from black-and-white sets have indicated compliance with the recommendations, and the dose to viewers was deemed negligible[4].

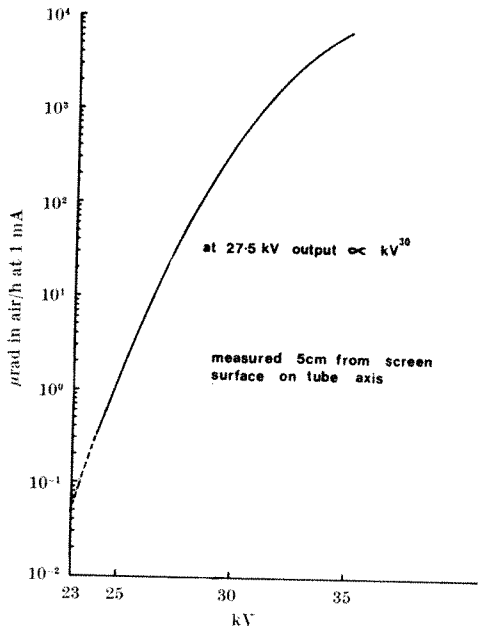

Fig. 1. Variation with tube voltage of the X-ray dose rate at 5 cm from the screen surface on the tube axis.

Colour sets operate at higher voltages than black-and-white sets, so that the possibility arises of increased emission of more penetrating X-rays. In a preliminary investigation in 1965, the Radiological Protection Service examined prototype receivers and found that manufacturers were aware of the new difficulties. Towards the end of 1969, when colour transmission on all three national channels was imminent and the production of receivers had become significant, a full-scale survey was undertaken; its objects were to estimate the radiation dose that the population is likely to receive and to determine the maximum emission from individual receivers. The survey was confined to the products of British companies, two picture tube makers and seven set makers, which supply virtually all the equipment on the British market.

The picture tube is the only source of X-rays in sets produced at present, and the maximum dose rate occurs at the front screen. Both tube companies make three sizes, but the six tubes can be reduced to two groups, thin screen and thick screen, the tubes within each group having practically identical X-ray outputs. Thin screen tubes are used by a majority of receiver manufacturers and have a greater X-ray output than thick screen tubes; but the assumption that all tubes are thin screen leads only to a slight overestimate of the dose received by the population and greatly simplifies treatment of the results. The thin screen tube with average X-ray output can be called the representative tube.

Techniques of Measurement

We made X-ray measurements chiefly with a plastic scintillation detector encased in 0·38 mm aluminium; for a limited amount of dosimetry we used a high-resolution X-ray spectrometer with a germanium (lithium) detector; the principal use of the spectrometer, however, was in matching the picture tube spectra to the spectra of the various X-ray beams used for calibration and depth dose measurements. Blank rasters were used throughout the survey to avoid fluctuating picture content.

On the basis of a study by Braestrup and Mooney[5], the International Commission on Radiological Protection (ICRP) recommends[3] that the X-ray exposure rate at 5 cm from the surface of any television set should not exceed 0·5 milliroentgens per hour, which is equivalent to a dose rate limit of 435 microrads in air per hour (μrad in air/h). Both tube companies make identical claims for X-ray emission from their products, namely that the ICRP limit is not exceeded at the maximum tube rating, which can be taken as 27·5 kV, 1 mA. Their claims were tested by haphazardly selecting one hundred thin screen tubes at each factory and measuring the dose rates 5 cm from the screen centre. The X-ray outputs were found to be an order of magnitude below the ICRP limit. The output distributions were normal in both cases and narrow spreads indicated very close control over tube production. In fact, the X-ray output 5 cm from the screen surface of the representative tube at 27·5 kV, 1 mA was 39 μrad in air/h with 30 per cent standard deviation. As is indicated in Fig. 1, X-ray output from the representative tube depends sharply on tube voltage. The output is, of course, directly proportional to tube current.

Estimating Dose Rates

Front screens are reasonably uniform in thickness, and when dose rates at the screen are measured, they too are reasonably uniform. The spatial distribution of dose rate at large distances from the tube face is, however, non-uniform, because of oblique attenuation of some X-rays in the screen. The dose rate is maximal on the tube axis and remains relatively near the axial value inside a 60° cone with apex at the screen; beyond 30° to the axis the dose rate decreases rapidly. The fall-off of the axial dose rate with distance from the screen is gradual at first, but from 70 cm outward tends to follow the inverse square law. The dose rate at 2·5 m is about a fiftieth of the dose rate at 5 cm, 2·5 m being the average viewing distance. The British Broadcasting Corporation conducted a survey of viewing habits on our behalf (B. P. Emmett, personal communication); the results indicated that the great majority of persons sat within the 60° cone. The assumption that all viewers are exposed to the axial dose rate does not therefore lead to a serious overestimate of viewer dose. The results of the survey of viewing habits are given in Table 1.

Table 1. SURVEY OF VIEWING HABITS

Persons surveyed	3,000
Households surveyed	950
Viewing distance	2·5 m
Hours viewing per year	1,000

Simulating Tissue Doses

It was not practicable to measure the dose at various depths in tissue-like material with a picture tube because of the low X-ray outputs; heavily filtered beams from a constant potential X-ray set were used instead. The spectra from both sources were matched according to equivalent or photopeak keV but, as expected, the picture tube spectra were narrower. Water was used to simulate tissue, and thermoluminescent dosimeters were used for dose measurement. Doses at depths of 1 cm and 7 cm were taken as indicative of the doses to the male and female gonads and were related to the dose at the position of the water surface; the results are given in Fig. 2. Picture tube voltage and current during normal viewing are typically 23·3 kV and 0·5 mA. Allowing for this fact, and assuming that there is a colour receiver in every household, and that male and female are equal in number and child expectancy, the annual genetically significant dose was estimated to be 0·4 microrads. The annual genetically significant dose from natural sources in Britain is about 100 millirads, with 20 per cent difference between areas of sedimentary and igneous rocks[4]. Thus the additional dose received by the public from television X-rays will be only 0·0004 per cent of that from natural sources and can therefore be regarded as negligible.

How Safe is the Viewer?

The maximum X-ray emission from individual receivers was determined at the set makers using regulation-emission charts as described by Ciuciura[6]. In test conditions of service maladjustment, or circuit failure tending to maximize X-ray emission, or both conditions combined, some manufacturers' receivers could be made to exceed the ICRP limit slightly. Picture quality was inferior even for marginally excessive dose rates. As test conditions were made more extreme, picture quality deteriorated further and sets operated merely momentarily before breakdown. The limiting output was judged to be about 5 millirads in air per hour at 5 cm from the screen, that is, approximately ten times the ICRP limit. The probability of obtaining excessive emission from a television receiver, except deliberately in severe test conditions, is, however, slight. Indeed, an evaluation of the procedures for setting up receivers during manufacture indicated that the dose rate 5 cm from the surface of any receiver leaving a factory is unlikely to exceed 15 μrad in air/h.

Some older British colour sets, no longer in production, used thermionic valves in the high voltage circuits: these were a shunt regulator tricde and a half-wave rectifier, both capable of emitting X-rays. All the valves were made by one company and have design features that minimize X-ray emission; nevertheless, in adverse operating conditions, the dose rate 5 cm from unshielded valves could reach about 100 millirads in air per hour. In all these receivers, however, the valves were placed in steel compartments of minimum thickness 0·5 mm, with the result that, in normal operating conditions, the dose rates at the surface of compartments are of the order of 1 μrad in air/h; even in abnormal conditions the dose rate outside any receiver resulting from the high voltage valves is unlikely to exceed the ICRP limit. It is essential, however, that the shielding afforded by the compartment should not be impaired.

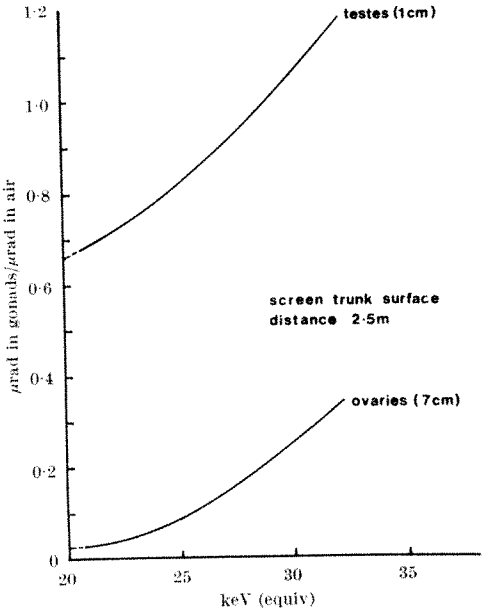

Fig. 2. Gonad dose per unit dose in air at position of trunk surface. The correspondence between keV (equiv) and picture tube kV is approximately 20–20, 25–26, 30–32, 32–35.

This work is part of a programme undertaken by the Radiological Protection Service, which is supported by the Medical Research Council and the Department of Health and Social Security. We thank Mr E. E. Smith, acting director, for initiating and supporting this survey, Messrs Sandford, Brotherton and Rose for assistance, and the television industry and the BBC for their cooperation.

Drug Pushers in the United Kingdom

by

DAVID MacSWEENEY

MRC Neuropsychiatry Unit,
West Park Hospital,
Epsom, Surrey

DENIS PARR

Herbert Hone Clinic,
Brighton, Sussex

A survey of twenty-two young narcotic addicts suggests that socially damaging forms of drug selling, or "pushing", must be discriminated from those which are socially irrelevant. This could have an important bearing on the way that current legislation is applied in Britain.

THE recent spread of drug dependence in Britain has focused attention on the selling, or "pushing", of drugs as a possible cause of this "epidemic", but there have been few studies of the drug "pusher". In a detailed study of the use of heroin in a provincial town, Kosviner *et al.*[1] found no evidence of anyone "pushing" heroin: "supplies for those not on prescription were generally obtained by different users going each week to 'score' (buy) from registered addicts in London".

For obvious reasons opportunities for studying drug pushers and their habits are severely limited. The original aim of this investigation was to compare the psychosocial characteristics of a group of heroin pushers with those of a group of heroin users who did not sell drugs. Heroin pushers were to be operationally defined as individuals making a profit of £15 or more a week from the sale of heroin.

The investigation soon ran into difficulties. Heroin pushers, as defined, were hard to discover. Heroin users were easy enough to find among our patients, but when their histories were probed they were found to contain, almost without exception, episodes of drug selling. They therefore could not be used as a satisfactory control series, even though most did not meet the operational definition of heroin pushers.

At this stage we decided to modify the study to cover the selling of addictive drugs of any kind and in any amount, and to base it on interviews with narcotic-using patients who were willing to tell us of their experiences. The operational definition of heroin pushing, and the search for a control series, were abandoned.

The Enquiry

It was difficult to arrange interviews with so mobile and unpredictable a group and the material was drawn from the following sources. D. P. interviewed ten out of fifteen narcotic addicts in a provincial town who were under his care. D. M. interviewed the other five. D. M. also interviewed five narcotic addicts or users under the care of colleagues in the London area and two ex-patients in prison.

A semi-structured form of interview was used, and absolute confidentiality was guaranteed to the subjects. Enquiries about drug-selling experiences were made with great tact and care, emphasizing past rather than current activities. It was unlikely that patients would admit selling drugs which were prescribed currently by either of us, or that even within the confidential setting of the enquiry they would give information incriminating themselves or others. Five of them, however, said that they were still engaged in selling drugs.

The Eysenck personality inventory (EPI)[2] was administered to twenty addicts and Foulds's hostility and direction of hostility questionnaire (FHDHQ)[3] was also completed in thirteen cases. No psychometric data were available in two cases. Most of the interviews were conducted in 1969.

When analysing the general characteristics of our subjects, we found that the ages of the men ranged from 19–34 (mean 22·9, median 22). In seventeen cases there was no evidence of gross parental separation or deprivation before the age of 14. Two of the subjects had been adopted in early childhood, and the parents of three others separated before the children were fourteen. Ten of them described a very marked disparity in relationships with their respective parents, nine having a much better relationship with their mothers than with their fathers, one saying that the converse was true.

The social class of father showed that this was by no means an economically deprived group of people. The British Registrar General divides the population into five classes, and of our sample the fathers of seven out of twenty were in social classes 1 or 2 (professional, semi-professional or self-employed) and nine of the remainder were in class 3 (skilled tradesmen or clerks). Two subjects were not classifiable. Seven of the subjects were or had been married, and of the fifteen single men, four had one or more children. Those currently (or immediately before entering hospital or prison) in full time employment consisted of one motor mechanic, one fitter, one painter and decorator, one car cleaner and one student. The remaining seventeen were unemployed and, of these, thirteen were drawing social security benefits. This proportion of unemployed is characteristic of addicts seen at the clinic where most attended, but may be higher than the national figure.

As far as personal drug dependence was concerned, fifteen of the subjects were, or had recently been, prescribed heroin for maintenance treatment at a National Health Service clinic. One was similarly prescribed morphine and two methadone. Three claimed to be dependent on heroin from illicit sources and one was classified as a polyaddict.

Two-thirds of the group had ceased full-time education at fifteen (the minimum school leaving age in England). One-third had some form of further full time education after fifteen. They were predominantly highly mobile, itinerant people, who changed their addresses every few weeks or months. They were also mostly separated from their family roots.

Experiences of Drug Pushing

The reported episodes of drug selling took place during 1962–70, with a peak in 1967. Subjects were asked for how long in the past they had been in the habit of selling drugs. The answers varied from 4 weeks to 8 years. In round figures, half had sold for 6 months and more, and half for less than 6 months. Two did not answer this

question. These were retrospective statements; all but five said that they had stopped pushing. Table 1 shows the drugs that were sold. It was not easy to obtain information about the source of these drugs, but over-prescribing to the patient by private doctors, before the new drug regulations came into effect in the United Kingdom in April 1968, accounted for most of the heroin.

Table 1. DRUGS SOLD BY THE SUBJECTS

No. of subjects	Drugs
7	Heroin
1	Heroin and cocaine
1	Heroin and cannabis
1	Chinese heroin
1	Morphine and methadone
5	Cannabis
4	Amphetamines, including 'Drinamyl'
2	Cannabis and LSD

In twenty cases an estimate of the average weekly profit was given. It ranged from £0·5 to £100 with a median of £12. In one other case the profit took the form of personal hemp supplies instead of cash. One subject refused to reveal his profit (Table 2). Amphetamines seem to have been the most profitable commodity in this small series. The figures speak for themselves up to a point. To judge them fairly, however, we should also show a table of the amounts spent by the same patients in buying drugs for themselves. In most cases of heroin selling, profits were ephemeral, being almost immediately spent in buying drugs to the same value for personal use.

Table 2. AVERAGE WEEKLY PROFIT

Drug	Mean (£)	Median (£)	Range (£)
Heroin	30	9	2–100
Cannabis	14	11	6–20
Amphetamines	31	45	12–75
LSD	50	—	—

Twenty subjects admitted having a criminal record when juvenile crimes were taken into account. Seventeen of them had been in trouble before they started selling drugs. Their motives for starting and ceasing to push drugs are summarized in Table 3.

Table 3. MOTIVES FOR STARTING AND STOPPING TO PUSH DRUGS

	No. of subjects
Starting	
Profit, with which to buy drugs for personal use or pay private doctors' fees	12
Profit for keep and other reasons	8
To oblige other users (and profit)	3
Self aggrandizement	4
Idealistic motives	3
Stopping	
Free treatment available in new clinics	8
Police action or pressure	5
Fear of police action	3
Distaste for transactions	3
Beaten up by rival pusher	1
Insufficient reward	1
Not applicable (still selling)	5

Psychometric Findings

The FHDHQ is designed to measure hostility or aggression, and the score expresses the total hostility reported by the subject. The direction of hostility score also indicates whether aggression is directed principally inward or outward at others.

The EPI is better known and provides a measure of neurotic tendency and of extroversion as opposed to introversion (Table 4).

The reliability of questionnaire findings in addicts is open to question for various reasons. The pushers interviewed did not, on these tests, differ from a larger group of male narcotic, needle-using addicts interviewed in Brighton. Both groups had significantly higher total hostility and neuroticism scores than normals. The scores resembled those in mixed neurotics except in that the direction of hostility was less intropunitive than in the neurotic group.

As far as heroin was concerned, our subjects said that much of their drug selling experience was a consequence of the pre-1968 overprescribing by private doctors. It seemed inevitable and natural to the otherwise impecunious addict that he should sell part of his supply of drugs in order to pay doctors' fees and keep himself. "We all had to find our script or fee money, and one would help the other out. Anybody who attended a private doctor and didn't push was a millionaire."

Table 4. RESULTS OF THE EYSENK PERSONALITY INVENTORY

		FHDHQ		EPI form A	
		Total hostility	Direction of hostility (+ = intropunitive)	Neuroticism	Extroversion
Pushers (n = 20) (present study)	Mean	18·8	+2·2	14·1	11·3
	(s.d.)	(7·5)	(7·0)	(4·7)	(3·2)
Male injecting addicts* (n = 60)	Mean	21·9	+0·1	13·3	11·3
	(s.d.)	(8·0)	(6·8)	(5·9)	(3·5)
Mixed neurotics[4]	Mean	18·4	+6·2	14·4	10·0
	(s.d.)	(7·5)	(6·7)	(5·5)	(4·3)
Normal subjects[4]	Mean	13·0	+0·5	9·1	12·1
	(s.d.)	(6·2)	(4·6)	(4·8)	(4·4)

* Unpublished work of J. A. Greenup and D. P.

Moreover, it seems to be in the make-up of the young narcotic addict to buy, sell, borrow or (according to variations in his fortune) lend small quantities of drugs to and from other users. Such transactions were seen by most of the individuals in this series as matters of mutual convenience with which society ought not to feel concerned. "It was more or less spreading it out. You might sell it one day and buy it back the next." Bartering of drugs was also extensive, particularly of injectable heroin, morphine, methadone and methylamphetamine.

The securing of maintenance supplies of drugs from National Health Service treatment centres was a common reason for abandoning drug selling. Apart from the precarious, hand to mouth life-style inseparable from private doctor prescribing, some addicts have, however, learned that the austerity of life on social security benefits can be alleviated by systematic drug selling, especially of cannabis.

Simple profit in cash or kind was the dominant motive for selling given by these subjects. The commonest attitude expressed was essentially amoral. One hemp-seller remarked: "It was an easy way out—less reprehensible than breaking and entering or personal violence, an unfortunate necessity because I'm unable to work." Most of those who had sold drugs claimed to limit sales to established users. A minority of five, however, had on occasion sold heroin or other drugs to non-users, with little concern for the consequences.

A positive wish to "turn on" non-users of drugs was expressed by only one subject, who claimed at one time to have sold amphetamines to school children. He regarded drug taking as a form of "communion with life". One sold drugs because it was "the big thing to do", another for excitement ("the glory of it"); only one for a sense of power. Another man recalled how he had for a time sought to "show the light" to other heroin addicts by getting them to take LSD and so achieve a cure of their heroin habit. In similarly mystical terms another spoke of his wish to aid "seekers of the third eye" with "the truth", through selling them good quality cannabis: he did not, however, disguise his first motive, which was profit at 100 per cent per deal.

The range of selling activities varied enormously even within this small series. Few of the subjects revealed any link with large-scale importers or other operators. The exceptions included a man who said that he had sold Chinese heroin, obtained from an agent in Soho, regularly to a clientele of four to five people, at a profit of £10–£12 weekly. The few who had dealt in sizable quantities of cannabis had evidently been in touch with suppliers trading on a very considerable scale. In the main, however, the transactions described were limited on any one occasion to quantities of drugs appropriate to one individual's immediate personal use.

Table 5. CHARACTERISTICS OF SUBJECTS ACCORDING TO TIME SPENT SELLING AND PROFIT MADE

	No.	Mean age	"Higher" education	Main drug sold: Heroin	Cannabis	LSD	Amphetamine	Profit £15 or more	"Abnormal" motives
Duration 6 months or more	9	24·0	4	3	4	2		6	4
Duration less than 6 months	11	21·6	4	5	4	2		4	2
Weekly profit £15 or more	10	22·5	3	4	4	2		(10)	4
Profit less than £15	12	25·1	5	6	6	1		—	1

The series was split into a subgroup who had sold drugs for 6 months and over, and the remainder who had sold drugs for less than 6 months. It was also split into those who claimed a weekly profit of £15 or more and those who said that their profits were less. Table 5 shows a comparison between these subgroups in respect of certain variables. By "abnormal" motives are meant motives other than simple profit or obliging (temporarily or reciprocally) other drug users. The apparent differences do not reach statistical significance. There is an interesting tendency, however, for those who were more heavily involved in selling drugs to report "abnormal" motives more often than the other subjects.

Fear of police action seemed to be a potent factor in deterring these subjects from selling drugs, and none conceived the present scale of penalties as other than extremely severe.

All of the drug selling activities in this investigation were highly illegal. In medico-social terms, however, they amount to a very wide spectrum. We are inclined to endorse the addicts' own views that much of the petty trading that goes on among themselves is socially no more harmful than the inherent patterns of their lives. The importance of trading in cannabis is debatable, and dependent on the view taken of the harmfulness of this substance and of the sort of arguments which followed the Wootton report[5]. We would speculate that, within this particular series, the most dangerous activities were the selling of amphetamines and LSD.

There is a widespread belief that a clear distinction can be drawn between the (evil) drug pusher, who is not addicted, and the (sick) addict who does not push. This belief is based on a false dichotomy, if our findings are at all representative, in that most of the young non-therapeutic addicts with whom we have been in touch have at some time sold drugs. In current legislation, public anxiety and anger about the spread of drug misuse are being expressed in still heavier penalties for trafficking. To apply such penalties indiscriminately would be to disregard the social realities of the drug scene.

We thank Drs Derek Richter and David Murray Shaw for encouragement and Drs D. Beckett and Hilary Jones for permission to interview their patients. We also thank Maryse Metcalfe and Anthony Johnson for practical suggestions and the drug pushers for giving up their time.

A DNA-dependent DNA Polymerase and a DNA Endonuclease in Virions of Rous Sarcoma Virus

by

SATOSHI MIZUTANI
DAVID BOETTIGER
HOWARD M. TEMIN

McArdle Laboratory,
University of Wisconsin,
Madison, Wisconsin 53706

The virion contains a DNA-dependent DNA polymerase which replicates duplex DNA and an endonuclease which attacks it. A ligase system may also be present.

THE replication of RNA tumour viruses seems to involve a DNA intermediate—the DNA provirus[1,2]. Virions of RNA tumour viruses contain an RNA-dependent DNA polymerase (refs. 3 and 4 and S. Spiegelman, M. Green, R. Gilden and W. Levinson, personal communication). The data reported here suggest that virions of Rous sarcoma virus contain in addition to this RNA-dependent DNA polymerase an endonuclease for DNA and a DNA-dependent DNA polymerase.

Schmidt–Ruppin virus (SRV) was prepared, purified and disrupted as before[4]. At times the virus was incubated for 20 min at 37° C with 20 μg/ml. pronase before the final sucrose density gradient centrifugation. The polymerase assay contained 10 nmoles of dATP, dCTP and dGTP, 7·5 nmoles of ATP (in 0·02 M Tris-HCl buffer (*p*H 8·0) containing 0·4 mM EDTA and 10 mM dithiothreitol), 50 nmoles of $MgCl_2$, 100 nmoles of KCl, 2·5 μg of phosphoenolpyruvate, 10 μg pyruvate kinase, 2·5 μCi of ^{3}H-dTTP (12 Ci/mmole) and 0·025 ml. of enzyme (7–10 μg of protein) in a total volume of 0·125 ml. Incubation was at 40° C. At different times samples were taken for counting as described before[4] or were extracted and analysed on sucrose or CsCl or Cs_2SO_4 gradients using standard methods. T7 (originally supplied by Dr H. Lozeron, University of Wisconsin) was grown and labelled with ^{14}C-thymidine using standard methods. DNA was extracted with phenol, and dialysed against 0·01 M NaCl–0·01 M Tris buffer (*p*H 8·0).

Disrupted virions of SRV were incubated in a standard polymerase assay until there was no further increase in ^{3}H-dTTP incorporation (2–6 h). The entire reaction mixture was then analysed on a 5–20 per cent sucrose gradient at *p*H 8·0. Twenty per cent of the counts sedimented at greater than 200S (Fig. 1*a*). If the reaction mixture was digested with pronase and the product purified on a CsCl equilibrium gradient (when there is an almost complete recovery of counts) (Fig. 1*c*) and then analysed in a neutral sucrose gradient, a broad peak of

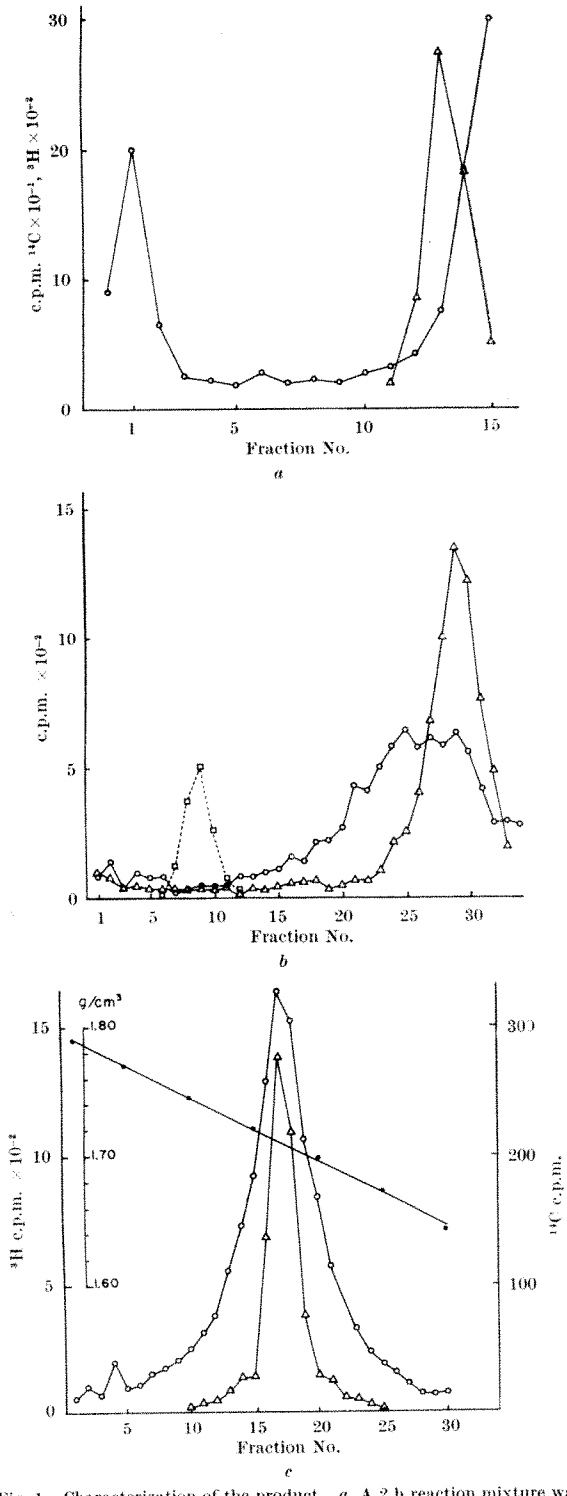

Fig. 1. Characterization of the product. *a*, A 2 h reaction mixture was layered on a 5–20 per cent sucrose gradient (0·1 M NaCl–0·01 M EDTA–0·05 M Tris-HCl buffer, *p*H 8·0) and centrifuged at 30,000 r.p.m. for 1 h in an 'SW 39' rotor. 0·3 ml. of 70 per cent sucrose was used as a cushion and ^{14}C-labelled T7 DNA was present as a marker. Drops were collected from the bottom of the tube and acid insoluble counts were determined. ○, DNA product; △, T7 DNA marker. *b*, A 6 h reaction mixture was incubated for 2 h with 200 μg/ml. pronase and centrifuged to equilibrium on a CsCl gradient. Peak fractions were pooled and dialysed against 0·015 M NaCl–0·0015 M sodium citrate. The dialysate was layered on a 5–20 per cent neutral sucrose gradient (as in *a*). ○—○, or a 5–20 per cent alkaline sucrose gradient (0·3 M NaOH–0·3 M KCl–0·01 M EDTA, *p*H 12·5), △—△, and centrifuged at 45,000 r.p.m. for 2·5 h in an 'SW 50·1' rotor. T7 DNA was used as a marker, □- - -□. Drops were collected from the bottom of the tube and acid insoluble counts determined. *c*, A 6 h reaction mixture was incubated for 2 h in 200 μg/ml. pronase mixed with ^{14}C-labelled T7 DNA and centrifuged in a CsCl gradient at 30,000 r.p.m. in an 'SW 50·1' rotor for 64 h. Drops were collected from the bottom of the tube and acid insoluble counts were determined. ○, ^{3}H counts (product); △, ^{14}C counts (T7 DNA).

5–16S material was found (Fig. 1*b*). If the phenol extracted or the overnight pronase digestion product was analysed on a neutral CsCl equilibrium density gradient, a peak with a density of 1·71 g cm^{-3} was found (Fig. 1*c*). In a neutral Cs_2SO_4 equilibrium density gradient a single peak with a density of 1·42 was found. A DNA–RNA hybrid would probably have a density of about 1·8 in CsCl and about 1·49 in Cs_2SO_4 (ref. 5).

These results suggested that the product was short double-stranded pieces of DNA. To determine the effect of denaturation on the sedimentation rate, a late reaction mixture was digested with 200 μg pronase for 1 h and analysed on an alkaline sucrose gradient (*p*H 12·5). All of the counts were found at the bottom of the tube. The same was found when the pronase-digested product was extracted with ether or heated at 100° C before analysis on the alkaline gradient. This result seems to be due to binding of single-stranded DNA to some other material, perhaps a protein. If, however, the late reaction mixture was first purified on a CsCl equilibrium gradient and then analysed on an alkaline sucrose gradient at 5–8S, peak was found (Fig. 1*b*).

To characterize further the product as double-stranded DNA, it was exposed to exonuclease I before and after denaturation with heat. It was found (Table 1) that the product was resistant to digestion by exonuclease I until after denaturation and is therefore double stranded DNA[6]. These results suggested that there might be enzyme activities other than the RNA-dependent DNA polymerase in the virion, that is a DNA-dependent DNA polymerase and an endonuclease for DNA.

Table 1. SENSITIVITY OF PRODUCT TO DIGESTION WITH EXONUCLEASE I

	Control (c.p.m.)	Exonuclease I
Native	10,800	12,000
Denatured	9,500	3,900

A standard reaction mixture was treated with 200 μg/ml. of pronase (Calbiochem) at 38° C for 2 h and then extracted with phenol. The aqueous phase was used for assay directly or after denaturation by heating in a boiling water bath for 10 min followed by rapid cooling. The assay was carried out at *p*H 9·5 for 60 min at 38° C with 23 units/ml. of exonuclease (kindly supplied by Dr R. Wells, University of Wisconsin) or buffer, and the amount of acid insoluble counts was determined.

To study the DNA-dependent DNA polymerase without disturbing its relationship to the proteins in the nucleoid, disrupted virions were pretreated with 50 μg of ribonuclease A for 60 min at 0° C to destroy the RNA template, exogenous DNA was added and a typical polymerase assay was done. It was found (Table 2) that there was a ten to fifteen-fold stimulation of incorporation of ^{3}H-dTTP by native calf thymus or *E. coli* DNA. The stimulation was reduced two-fold by denaturation. This template dependence was confirmed (personal communication from John Coffin) by the isolation by equilibrium sucrose density gradient centrifugation of a polymerase activity from ^{3}H-uridine labelled virions. This activity contained no radioactivity and banded at a density greater than that of the ribonucleoprotein nucleoids. This polymerase activity was almost completely dependent on added RNA (from mouse liver) or added DNA.

To find out more about the activity of this DNA-dependent DNA polymerase, ribonuclease-treated dis-

Table 2. EXOGENOUS DNA AS TEMPLATE

DNA added	^{3}H-dTMP incorporated (pmoles)	Ratio
None	2·3	1
Calf thymus		
Native	23	10
Denatured	13·2	5·8
E. coli		
Native	32·2	14
Denatured	20·2	8·8

Disrupted virions were pretreated with 50 μg/ml. of ribonuclease A (Worthington) for 60 min at 0° C. 1·0 μg of calf thymus DNA (Worthington) or *E. coli* DNA (obtained from Dr H. Kubinski, University of Wisconsin) in 0·015 M NaCl either native or denatured by heating in a boiling water bath for 10 min followed by rapid cooling, was added, and a standard polymerase assay was carried out for 1 h. Counting efficiency of 20 per cent was assumed.

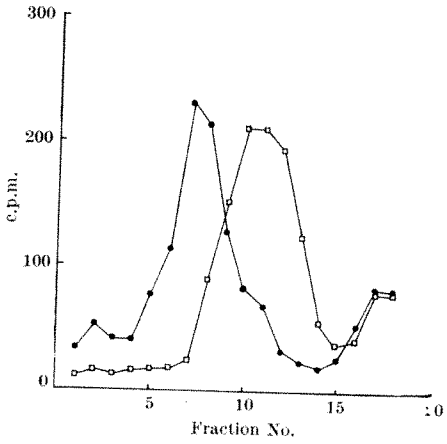

Fig. 2. Endonuclease for DNA. ^{14}C-labelled T7 DNA was incubated for 1 h at 40° C in 0·125 ml. containing pronase treated whole or disrupted virions (about 10 μg protein), treated for 30 min with 0·5 per cent sodium dodecyl sulphate 200 μg/ml. pronase, layered on neutral sucrose gradients (0·1 M NaCl–0·05 M EDTA–0·05 M Tris-HCl, *p*H 8·0) and centrifuged for 2·5 h at 45,000 r.p.m. in an 'SW 50·1' rotor. Drops were collected from the bottom of the tube and total counts were determined. ●, Non-disrupted virions; □, disrupted virions.

rupted pronase-treated virions were incubated with different single and double stranded homopolymers. Poly rA did not act as a template, and poly dT was a poor template (Table 3). Poly dA acted as a poor template in the presence of only dTTP, and also in the presence of only dATP. There is probably some small amount of contamination of poly dT in the sample so that poly dA·dT is the actual template (personal communication from R. Wells). The poly dA was a good template in the presence of both dTTP and dATP. Poly rA·dT was a fair template for poly dT and poly dA synthesis, even in the presence of only one substrate. Poly dA·dT was the best template for synthesis of both poly dT and poly dA. Synthesis was better when both dTTP and dATP were present in the reaction mixture. The activities of exogenous DNA as template were, within a factor of 10, the same as the activity of the endogenous RSV RNA as template.

To determine if the small size of the product was the result of nuclease action, virions were incubated with labelled T7 DNA and the size of the T7 DNA was analysed on sucrose gradients[7]. Incubation with whole virions reduced the *s* value of T7 DNA. To remove this external enzyme activity, virions were incubated with 20 μg/ml. pronase for 20 min at 37° C before sucrose gradient centrifugation. These virions had no endonuclease activity, unless they were disrupted with 'Nonidet' (Table 4). To determine if any exonuclease activity was present in the virions, labelled chicken DNAs were incubated with about 10 μg of disrupted virions and the amount of acid insoluble counts remaining was determined. No exonuclease activity was found.

To determine some of the requirements for the endonuclease activity inside the virions, labelled T7 DNA was incubated with disrupted pronase-treated virions and various other components of the polymerase assay, and the size of the T7 DNA was determined by sucrose gradient centrifugation (Table 4 and Fig. 2). $MgCl_2$ was required for endonuclease activity. In the presence of the ATP generating system endonuclease activity was reduced. In the presence of the dNTP alone no reduction in endonuclease activity was found. These experiments suggest that in addition to the endonuclease there may be a ligase system in the virion.

We have demonstrated that virions of Rous sarcoma virus contain several enzyme activities: an RNA-dependent DNA polymerase, a DNA-dependent DNA polymerase, and an endonuclease for DNA. All are present inside the virion as shown by their resistance to pronase digestion. It is not known whether they represent separate enzymes or separate activities of one enzyme.

Table 4. REQUIREMENTS FOR ENDONUCLEASE

System	Endonuclease
Non-disrupted virions, $MgCl_2$	−
Disrupted virions, $MgCl_2$	+
Disrupted virions	−
Disrupted virions, $MgCl_2$, dNTPs	+
Disrupted virions, $MgCl_2$, PEP, ATP, pyruvate kinase	±
Disrupted virions, $MgCl_2$, dNTPs, PEP, ATP, pyruvate kinase	±

^{14}C T7 DNA was incubated and analysed as described in the legend of Fig. 2 with the various components of a standard polymerase assay added. All virions were pronase-treated. A positive endonuclease (+) was a shift of greater than 10S (see Fig. 2). A ± reaction was a broad peak that shifted less than 10S.

The result of the action of these enzymes in a cell-free system is to make small pieces of double-stranded DNA from a single-stranded RNA template. There seems to be a transitory RNA–DNA hybrid intermediate, but double-stranded DNA is present from 1 min after the start of the reaction (unpublished data). Further, the enzyme seems to prefer an ordered DNA-like structure as template (personal communication from R. Wells). For example, poly dA·dT is a better template than poly dT, poly dA or poly rA. Poly rA·dT is a better template than poly rA (for poly dT synthesis) and a better template than poly dT (for poly dA synthesis). Native *E. coli* or calf thymus DNA are better templates than denatured *E. coli* or calf thymus DNA. With the homopolymers, poly dA, poly rA·dT, and poly dA·dT, there was more incorporation when both dTTP and dATP were present in the reaction mixture than when only one was present. These results suggest that this DNA-dependent enzyme system prefers double stranded templates, and, perhaps, copies both template strands at the same time. In short incubation times such as we have used, other DNA polymerases do not seem to have the same marked specificity for double-stranded templates[6].

In the cell-free enzyme system we have used, the endonuclease in the virions appears to cleave the double-stranded DNA as it is synthesized, and to cleave exogenous DNA.

In a completely native undisturbed system as in cells infected by virus, the actions of these enzymes might be restricted by topological factors, such as the location of the nucleoid and the presence of the viral RNA template, and so be more specific than indicated by these experimental results. The endonuclease might then act as a component of the machinery to integrate the viral double-stranded DNA into the host cell chromosome[8].

These results support the protovirus hypothesis[9] that RNA tumour viruses come from natural elements replicating DNA to DNA and DNA to RNA to DNA and controlling cell multiplication. They also raise the possibility that the difference between RNA leukaemia viruses and RNA sarcoma viruses may lie in the presence or absence and in the specificities of these enzymes. These results

Table 3. HOMOPOLYMERS AS TEMPLATE

Template	None		Poly dA·dT		Poly rA·dT		Poly dA		Poly dT	
Substrate	dTMP	dAMP	dTMP	dAMP	dTMP	dAMP	dTMP	dAMP	dTMP	dAMP
α-^{32}P-dATP	—	0·03	—	1·8	—	0·25	—	0·6	—	0·075
^{3}H-dTTP	0·045	—	2·2	—	1·65	—	0·35	—	0·06	—
α-^{32}P-dATP and ^{3}H-TTP	0·065	0·03	5·95	5·4	1·85	0·4	4·9	4·3	0·45	0·47

Values represent pmoles incorporated. Disrupted pronase-treated virions were incubated with 50 μg/ml. ribonuclease A for 60 min at 0° C. 0·4 μg of the indicated templates (kindly prepared by Dr R. Wells) and 0·2 nmoles of α-^{32}P-dATP (550 c.p.m./pmole) and/or 0·2 nmoles of ^{3}H-dTTP ($2{\cdot}65 \times 10^{4}$ c.p.m./pmole) were added and a standard polymerase assay was carried out for 1 h. Samples were counted for ^{3}H and ^{32}P, and the results calculated as pmoles of substrate incorporated, assuming a counting efficiency of 20 per cent for ^{3}H. With 10 μg of poly rA as template, no incorporation was found.

also raise the question of the role of these virus enzymes in cell DNA synthesis in infected cells and in malignant conversion by RNA tumour viruses.

Viral DNA-dependent DNA Polymerase and the Properties of Thymidine Labelled Material in Virions of an Oncogenic RNA Virus

by

JOSEF ŘÍMAN
GEORGE S. BEAUDREAU

Laboratory for Biochemical Investigation of Cancer, Institute of Organic Chemistry and Biochemistry, Czechoslovak Acadamy of Sciences, Praha

RNA tumour viruses contain a DNA-dependent DNA polymerase which preferentially uses either single or double stranded DNA rich in guanosine and cytosine as template. The virion also contains DNA of similar composition as well as A+T rich DNA.

MUCH interest has been shown recently in the RNA-dependent DNA polymerase present in various oncogenic RNA viruses[1-3]. Here we describe a DNA polymerase activity and a thymidine labelled material which we found in the virions of avian myeloblastosis (AMV). Using various DNAs as templates we have shown that AMV possesses a DNA-dependent DNA polymerase which acts preferentially on a DNA template rich in G+C to form a DNA product that has the same amount of G+C as its primer. We also demonstrate that a similar kind of DNA having a high G+C content occurs as well as that enriched in A+T in virions of AMV. Early attempts to detect DNA in oncogenic RNA viruses were not successful[4,5].

The virus particles suspended in buffer alone had no enzyme activity. A virus enzyme preparation from purified AMV (see legend to Table 1), used in this study, exhibited an endogenous incorporation of 0·4–0·6 pmoles of dTMP (or dAMP) per 24 μg of protein into polymer as described by Temin[1]. No incorporation of uridine monophosphate into ribopolymers was detectable using an assay system previously described[6] and no further stimulation was observed when RNA or DNA was added to the assay system containing ribopolynucleotides.

Table 1 shows that the enzyme activity, as measured by the incorporation of deoxyribonucleoside triphosphate into acid insoluble material, was stimulated by DNA templates obtained from bird, mammal and bacterial cells. The denatured DNAs were significantly more efficient as templates than the native preparations. The most active of the three DNAs tested was DNA from *Streptomyces chrysomalus* with a G+C content of 70 mole per cent[8]. This template was chosen on the basis of the properties of the thymidine labelled material found in the AMV. With denatured *Streptomyces chrysomalus* DNA the enzyme activity was fifteen times higher than with denatured DNAs from other sources and seventy times higher than the endogenous activity. Table 2 shows that the enzyme present in the AMV virions has the properties expected of a DNA-dependent DNA polymerase.

Omission of one of the three unlabelled deoxynucleoside triphosphates from the complete system in the presence or absence of the template DNA led to a significant decrease in the activity of the enzyme. These results indicate that a heteropolymer is being synthesized. In accordance with the properties of the G+C rich template DNA used (*Streptomyces chrysomalus* DNA), the greatest decreases in activity were measured after omission

Table 1. EFFECT OF DIFFERENT DNA PREPARATIONS ON ^{3}H-dAMP INCORPORATION INTO ACID INSOLUBLE MATERIAL

DNA preparation	Amount (μg)	G+C (mole per cent)	^{3}H-dAMP incorporation (pmoles)
Avian myeloblast, native	32	43	0·32
Avian myeloblast, heated	32	43	0·97
Avian myeloblast, alkaline treated	32	43	0·81
Calf thymus, native	40	39	0·46
Calf thymus, heated	40	39	1·00
Streptomyces chrysomalus, native	40	70	3·02
Streptomyces chrysomalus, heated	40	70	15·10
None	—	—	0·22

Enzyme preparation: AMV was isolated from leukaemic chicken plasma containing $6{\cdot}5 \times 10^{11}$ particles/ml. Plasma was purified by centrifuging twice at 2,500*g*, and the viruses were concentrated by sedimentation through a 15 per cent glycerol layer at 49,000*g* for 60 min in an 'MSE-40' centrifuge. The sedimented viruses were resuspended in 8 per cent glycerol supplemented with NaCl, Tris-HCl (*p*H 7·5) and $MgCl_2$ to a final concentration of 0·1, 0·05, and 0·0025 M respectively. They were further purified by banding at the interphase of 100 and 15 per cent glycerol layers at 63,500*g* for 90 min in an angle rotor 'SW 25·1, L2 65K' Spinco centrifuge. Such a virus preparation checked in a sucrose isopycnic density gradient centrifugation revealed a homogeneous absorbance peak as well as a peak of ATPase activity[7] at a density of 1·165 g/cm^3. The purified virus preparation containing 25 mg of protein, determined according to Warburg, was suspended in 2 × buffer TMG (1 × buffer TMG contains: 0·025 M Tris-HCl (*p*H 8·6), 0·01 M MgCl, reduced glutathione 0·005 M, 0·005 M EDTA, 0·15 M KCl and 10 per cent glycerol). To the virus suspension was added an equal volume of solution containing 'Nonidet' (Shell *P*-40) and dithiothreitol to give final concentrations of 0·25 and 0·065 per cent, respectively[1]. The protein concentration of the enzyme preparation was 12 mg/ml. The enzyme was not further purified and could be stored in an ice bath without loss in activity for 1 week. The enzyme was diluted 1:10 with buffer TMG just before the assay. Enzyme assay: the complete assay mixture (0·2 ml.) contained the following: 8 μmole Tris-HCl (*p*H 8·6), 1·6 μmoles $MgCl_2$, 12 μmoles NaCl, 0·74 μmoles reduced glutathione, 0·2 μmoles of dTTP, dCTP and dGTP (A grade, Calbiochem), $0{\cdot}12 \times 10^{-3}$ μmoles ^{3}H-dATP (Schwarz BioResearch), (2,920 c.p.m./pmole) and 20 μg of virus protein. The reaction mixture was incubated for 45 min at 37° C and the reaction was terminated by addition of sodium pyrophosphate, carrier yeast RNA and trichloroacetic acid. The acid insoluble radioactivity remaining after filtration through membrane filters was determined by scintillation spectrophotometry (Packard, model 3375), using BBOT-Packard as scintillation fluid. The radioactivity of an unincubated sample was subtracted from each value. DNAs used as internal absorbance markers for rate and equilibrium density gradient centrifugation were highly purified ribonuclease treated preparations. Calf thymus DNA and *Streptomyces chrysomalus* DNA were kindly provided by Dr J. Šponar, Biophysical Group of this institute. DNAs were denatured by heating at 100° C for 5 min in a solution of 0·01 NaCl–0·001 sodium citrate (*p*H 7). This was followed by rapid cooling of the samples in an ice bath. DNA samples were incubated in 0·1 M NaOH for 30 min at 22° C. After neutralization the samples were precipitated with ethanol at −20° C.

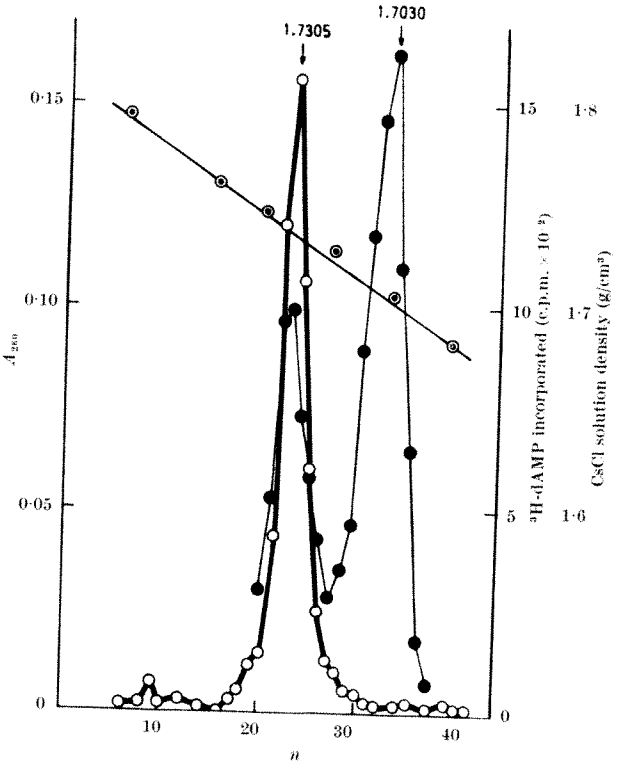

Fig. 1. Buoyant density profiles of template DNA (absorbance profile, ●); product DNA (radioactivity, ○) and marker DNA from avian myeloblasts (80 μg) with an absorbance peak at a density of 1·70. The template was heated DNA (37 μg) from *Streptomyces chrysomalus* which bands at a density of 1·73 g/cm³ CsCl. Reaction conditions were the same as in Table 1. The reaction was run for 45 min at 38° C. 60,000 c.p.m. were incorporated (16·1 pmoles of ^{3}H-dAMP) into acid-insoluble product. The reaction was terminated by adding 2·5 volumes of phenol and freezing the sample in an alcohol-solid CO_2 mixture. The sample was phenol extracted and ether extracted to remove the phenol before putting the sample on a preformed[9] CsCl gradient with DNA from myeloblasts as a marker. The CsCl gradient was centrifuged for 42 h at 37,000 r.p.m. in a Spinco 'SW 39' rotor at 15° C. The radioactivity in the sampled fractions was determined as described in the legend to Table 1; the density of CsCl solutions (○) according to Szybalski[8].

of dGTP; the next greatest decrease was after omitting dCTP. By contrast, the endogenous activity of the enzyme was more sensitive to the omission of dATP, and was less influenced by the omission of dGTP and dCTP from the assay mixture.

Table 2. DEPENDENCE OF ENZYME ON TRIPHOSPHATE AND DNA TEMPLATE

Reaction mixture	Template	^{3}H-dTMP incorporated (pmoles)
Complete	DNA	9·66
−dATP	DNA	3·21
−dGTP	DNA	1·52
−dGTP	DNA	2·10
Complete	0	0·50
−dATP	0	0·03
−dGTP	0	0·10
−dCTP	0	0·08

The complete assay mixture (0·2 ml.) contained 8 μmoles Tris-HCl (*p*H 8·6), 1·6 μmoles $MgCl_2$, 12 μmoles NaCl, 0·74 μmoles reduced glutathione, 0·2 μmoles of dATP and dCTP, and [*methyl*-^{3}H]dTTP (Schwarz BioResearch), $0{\cdot}16 \times 10^{-3}$ μmoles (3,950 c.p.m./pmole). *Streptomyces chrysomalus* DNA was added where indicated, at a level of 24 μg per assay. Isotope incorporated into acid-insoluble material was measured after 45 min incubation at 37° C as described in Table 1.

Material extracted in phenol from a reaction mixture incubated with the enzyme and *Streptomyces chrysomalus* DNA as template was analysed by isopycnic CsCl density gradient centrifugation[9]. An unlabelled myeloblastic DNA was used as the second absorbancy marker. After centrifugation, the radioactivity was situated in the same density region of the absorbance profile as that of the template DNA which, when native, has a density of 1·734 g/cm³ (Fig. 1). This finding suggested the formation of a copy corresponding to the template.

The presence of DNA was shown conclusively by the incorporation of ^{3}H-labelled thymidine into virions produced by myeloblasts cultivated[10] in conditions that eliminated mycoplasma infection (see legend to Fig. 2). The ^{3}H-thymidine label in purified undamaged virus particles was not accessible to deoxyribonuclease and the labelling kinetics were approximately linear during a 12 h labelling period (unpublished results of J. R.).

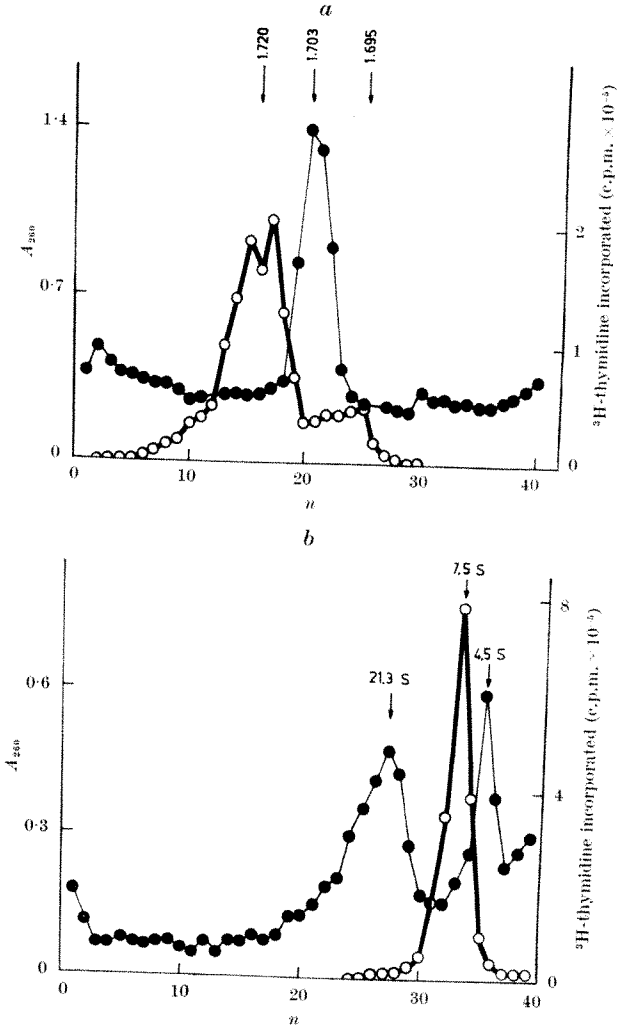

Fig. 2. *a*, Buoyant density profiles of ^{3}H-thymidine labelled material (radioactivity, ○) extracted from AMV virions and absorbance marker (chicken spleen DNA, ●, with a peak at a density of 1·70) after isopycnic CsCl density gradient centrifugation (see legend to Fig. 1). *b*, Radioactivity profile (○) of the same material on a linear (20–5 per cent) sucrose density gradient after 7 h at 25,000 r.p.m. and 4° C in Spinco rotor 'SW 25·1', with absorbance profiles (●) of chicken spleen DNA (21·3S) and *E. coli* B tRNA (4·5S). Labelling of the virus and isolation of viral ^{3}H-thymidine labelled material: 20 ml. suspension of avian myeloblasts ($7{\cdot}6 \times 10^7$ cells/ml.) were cultivated[10] for 7 days in the presence of the usual antibiotics and aureomycin (12 μg/ml.). Viruses from such cultures were void of any mycoplasma when examined by electron microscopy. The cells were labelled for 7 h with 6-^{3}H-thymidine (UVVR, Praha), 250 μCi/ml. (specific activity 25 Ci/mmole) and ^{14}C-uridine (Amersham), 4 μCi/ml. (specific activity 278 mCi/mmole). Viruses produced by leukaemic cells were concentrated and purified according to Erikson[17]. The final virus pellet was extracted with a solution containing 1 per cent sodium dodecyl sulphate (SDS), 0·01 per cent EDTA, and 0·01 M sodium citrate (*p*H 8·5) for 10 min at 22° C, then deproteinized with phenol. The phenol phase was re-extracted with 1 M NaCl. Both aqueous phases were adjusted with solid NaCl to a final concentration of 1 M and spun down with 250 μg of chicken spleen DNA at 39,000 r.p.m. in Spinco rotor 'SW 39' for 24 h at 4° C. The DNA pellet was dissolved in a 0·015 M NaCl–0·0015 M sodium citrate solution (*p*H 7), and was treated with a mixture of ribonuclease A (Worthington, 100 μg/ml.) and T, (Sankyo, 20 U/ml.). It was then inactivated at 90° C for 5 min. Ribonucleases were removed with phenol and the water phase treated with ether. Such samples were used for rate sucrose density gradient and for isopycnic CsCl gradient centrifugation. In the CsCl gradient banded viral DNA, no ^{14}C radioactivity was detected.

The ^{3}H-thymidine labelled material isolated from purified virus had the properties of DNA when banded in isopycnic CsCl gradients. This material was of two kinds: one banded in G + C rich density region; the other had less G + C, being similar in this respect to myeloblastic or chicken spleen DNA which has a G + C content of 44 mole per cent[11]. The presence of G + C rich DNA in the virions was more obvious in experiments with a longer labelling time (Fig. 2*a*) whereas the other type of viral DNA was detected when pulse labelling was used (Figs. 3 and 4).

Fig. 2*a* shows the relative buoyant density of chicken spleen DNA compared with DNA isolated from virus after a 7 h labelling period. In this case a large fraction of the DNA is rich in guanine and cytosine; there is a minor component that is rich in adenine and thymine. Fig. 2*b* shows that both fractions sediment in a sucrose density gradient at 7·5S as a uniform molecular species.

Fig. 3 shows the buoyant density of myeloblast cell DNA relative to that of DNA isolated from viruses produced by cells which were labelled for 60 min with ^{32}P in a phosphate free medium and then cultivated for 7 h with radioisotope in a complete medium that had been used for cultivation of leukaemic chicken myeloblasts[10]. In this case most of the DNA exhibited a lower G + C content while a little was situated in the density region of DNA rich in G + C. ^{32}P-labelled material was resistant to NaOH and sensitive to deoxyribonuclease. A core of deoxyribonuclease resistant material could be observed in the density region corresponding to a lower G + C content (Fig. 3). A total nucleic acid extraction from the same virus preparation, untreated with ribonucleases and analysed in glycerol density rate gradients, was composed of 65S RNA and the low molecular weight component which represented 70 per cent and 30 per cent respectively of the total radioactivity. A considerable part (about 30 per cent) of the low molecular weight material, which is considered to be a mixture of tRNA molecules and degradation products of 65S RNA[5,12–16], was resistant to alkali and sensitive to deoxyribonuclease. After alkali treatment there was a peak in the region of 7–8S (unpublished results of J. R.).

A similar characteristic was also observed after pulse labelling with thymidine (see legend to Fig. 4). Fig. 4

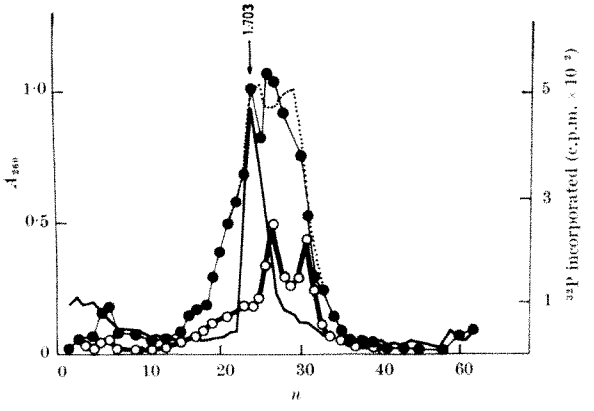

Fig. 3. Buoyant density profiles of ^{32}P-labelled material (●) remaining after ribonuclease treatment of the total viral nucleic acid extract, and its behaviour toward an alkaline and deoxyribonuclease treatment. Such ^{32}P-labelled virus material banded in an isopycnic CsCl density gradient, with myeloblast DNA (——) as an absorbance marker, was subjected in fractions to an alkaline or deoxyribonuclease I treatment. One third of each fraction was treated with 0·1 M NaOH at 22° C, for 30 min, or with deoxyribonuclease I (Worthington, ribonuclease free, 20 μg/ml.), 0·05 M Tris-HCl, 0·05 M (*p*H 8·5), and 0·005 M MgCl$_2$, at 22° C for 60 min. Then the radioactivity was determined in acid insoluble material of the untreated (●), alkali-treated (· · · ·) and deoxyribonuclease treated (○) samples. Virus labelling: in this case a myeloblast cell suspension (20 ml., 8·7 × 10^7 cells/ml.) was labelled for 60 min with 350 μCi/ml. of ^{32}P (carrier-free orthophosphate; Radiochemical Centre, Amersham; specific activity 78 Ci/mg P), in a phosphate-free medium. This medium was then replaced by a complete one[10] and the virus produced during a further 7 h of cultivation was concentrated and purified according to Bader and Steck[15].

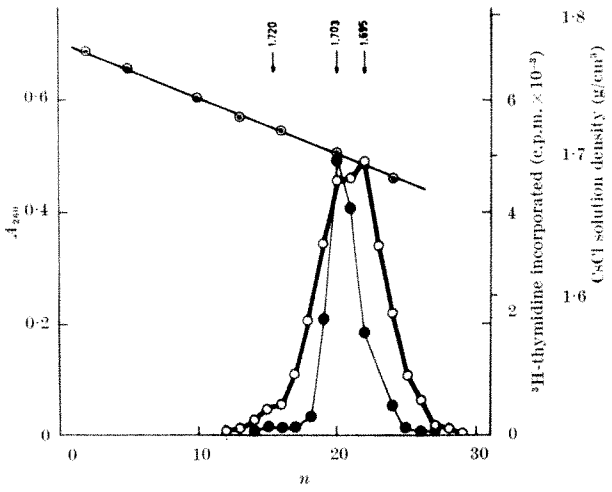

Fig. 4. Buoyant density profiles of 7·5S ^{3}H-thymidine labelled material (○) from AMV virions produced after pulse labelling of avian myeloblasts. Virus labelling: myeloblast cell suspension (10 ml., 7·2 × 10^7 cells/ml.) was labelled with 6-^{3}H-thymidine (UVVR, Praha), 350 μCi/ml. (specific activity 20 Ci/mmole) and with ^{14}C uridine (UVVR, Praha), 2·5 μCi/ml., (specific activity 286 mCi/mmole) in the presence of deoxycytidine (2·5 μg/ml.), deoxyadenosine (0·12 μg/ml.), deoxyguanosine (0·12 μg/ml.) and cytosine (2·5 μg/ml.) for 120 min. The medium was then replaced by an unlabelled medium[10] which was changed four times at 90 min intervals to obtain freshly produced virions unaltered by ageing[18] or not influenced by atypical cell incubation conditions like those represented by a phosphate-free medium. The virus was collected and purified[17] from the joined cell supernatant derived from each unlabelled medium exchange and viral nucleic acid was isolated according to Bader and Steck[15]. The isolated viral RNA was further analysed in a linear 40–10 per cent glycerol density gradient at 37,000 r.p.m., Spinco rotor 'SW 39', at 4° C for 140 min and the peak fraction of the 7·5S thymidine labelled material, selected on the basis of the radioactivity sedimentation profiles, was used for isopycnic CsCl density gradient centrifugation. Myeloblast DNA also served here as an absorbance marker (●). In this, as well as in all other cases, the density of CsCl solution (○) in individual fractions was determined according to Szybalski[8].

shows the buoyant density profiles of thymidine labelled 7·5S material extracted from the virions and selected after a glycerol density gradient rate centrifugation. In this case too, a large fraction of DNA exhibited a lower content of G + C while a small fraction was situated in the density region of DNA rich in G + C.

Our experiments demonstrate the presence of a DNA-dependent DNA polymerase in the virus enzyme preparation used for studying the endogenous activity of an RNA-dependent DNA polymerase in various oncogenic RNA viruses including AMV[3]. The primed reaction uses native and denatured DNA as templated with an outstanding preference for a DNA rich in guanine and cytosine. Such a template was chosen on the basis of similarities in base composition with one of the two kinds of DNAs detected in AMV. It remains to be seen whether such a preference exists for templates similar in their base composition to the second kind of DNA observed in the virions. In view of the high sensitivity of the endogenous virus enzyme to the omission of dATP, an A + T rich DNA might be the proper template for the virus enzyme endogenous reaction. This will be clarified by further definition of the viral enzymes using both types of virus DNA as templates. The function of the viral 7–8S DNA molecules remains to be elucidated. When double stranded, such molecules could carry a genetic message specifying one or two proteins of average size. That they are heterogenous as regards G + C content is evident from their relatively broad buoyant density profiles. This heterogeneity could be explained either by their association with some other component or by chemical changes which affect the buoyant density of a DNA[8]. Other possibilities such as association with very small fragments of RNA cannot be ruled out, even though these DNA types were free of ^{14}C-uridine (see legend to Fig. 2). The labelling kinetics of DNA extracted from virions revealed a synthesis independent of cellular

DNA (unpublished results of J. R.). Thus the origin of these molecules as well as the DNA-dependent DNA polymerase remains an open question.

G. S. B. is a visiting professor of the Czechoslovak Academy of Sciences, from Oregon State University, supported by the exchange programme between the Czechoslovak and the US Academy of Sciences, and recipient of a cancer development award.

Synthetic DNA–RNA Hybrids and RNA–RNA Duplexes as Templates for the Polymerases of the Oncogenic RNA Viruses

Six RNA viruses have now been shown to contain DNA polymerase activities directed by single-stranded RNA, double-stranded RNA and double-stranded DNA. It is further demonstrated that DNA–RNA hybrids, such as synthetic dC·rG, act as even more effective templates.

THE recent reports by Temin[1] and Baltimore[2] of an RNA-directed DNA polymerase in oncogenic RNA viruses have been confirmed and extended[3]. We established that the DNA synthesized is complementary to the viral RNA and that DNA–RNA hybrids appear as early intermediates of the reaction. Both features argue compellingly that viral RNA functions as a template in the synthesis of the DNA.

The RNA–DNA hybrids detected as presumptive intermediates are not likely to be integrated as such into the genome, an event necessary to explain the heritably stable state of the transformation induced by these oncogenic viruses. The required conversion of the RNA–DNA hybrid into a DNA–DNA duplex demands a DNA-directed DNA polymerase. We already had[3] suggestive evidence that DNA strands synthesized late in the reaction were identical rather than complementary to the viral RNA. We set out to find the DNA-directed DNA polymerase implied by these observations and detected[4] the relevant activity in all six oncogenic viruses examined. The DNA-directed polymerase activity thus revealed had a number of interesting properties. There was a clear preference for double-stranded DNA and, except for covalently linked circles, virtually any double-stranded DNA was accepted as a template. In each case, it could be shown by appropriate hybridizations that the DNA synthesized was complementary to the DNA used as the initiating template.

We were still left with the problem of identifying the polymerization reaction which converts the DNA–RNA hybrids into the DNA–DNA duplex. To synthesize natural DNA–RNA hybrids in amounts adequate for enzymatic test is still a formidable task. To avoid the logistic problems involved we decided to use synthetic polynucleotide duplexes. There is ample evidence[5–7] of their usefulness in studies of DNA and RNA synthesis, and the DNA polymerase of *E. coli* has been shown to use the synthetic ribopolymer rA·rU to synthesize the deoxyribopolymer dA·dT (ref. 8). We have found that certain of the synthetic duplexes are not only functional, but are superior to natural templates by almost two orders of magnitude in stimulating polymerization. This finding leads to an extraordinarily useful tool for detecting the enzyme activity. We summarize here the results of our investigations.

Comparison of Templates

The viruses used in the preparation of enzymes were avian myeloblastosis virus (AMV), feline leukaemia virus (FeLV), Moloney sarcoma virus (MSV), Rauscher leukaemia virus (RLV), mouse mammary tumour virus (MTV) and a rat mammary tumour virus (RMTV). Table 1 illustrates the responses of the six RNA oncogenic viral preparations to the resident RNA templates (column 1), exogenous DNA (column 2), and to the hybrid duplex (column 3) formed from polydeoxyadenylate and polyriboguanylate (dC·rG).

The stimulation observed with CEF–DNA is not maximal because for purposes of comparison it was held at the same level (4 μg/ml.), at which the reaction with the dC·rG is optimal. For all six viruses there is clear evidence of a hybrid directed DNA synthesis that is dramatically

superior to the reactions previously studied. The kinetics of DNA synthesis with the three templates (Fig. 1) emphasize the magnitude of the difference in template capabilities. When plotted on the same scale, the synthetic activities observed with the resident viral RNA and CEF–DNA are almost trivial compared with dC·rG.

We examined the template capabilities of as many synthetic polynucleotides as possible. Table 2 shows the response to single homopolymers. It should be noted that in this, as in the tables to be discussed, all measurements involved examinations over 20–30 min periods with samples taken every 5–7 min. The 5 min values are recorded to permit better comparison with those cases in which the kinetics diverge from linearity after 10 min. In all cases shown in this and subsequent tables, both complementary deoxyriboside triphosphates were included in the assay, one being identified by an α-^{32}P label, and the other by a ^{3}H label.

Table 2 demonstrates that of the ribohomopolymers, only rC possesses detectable template activity and here the synthesis lasts only for 5 min. In the case of the deoxyribopolymers, poly dC supports extensive and prolonged synthesis of poly dG, and some later incorporation of dC. Although much smaller, both poly dA and poly dI stimulate the incorporation of the corresponding complementary nucleotides.

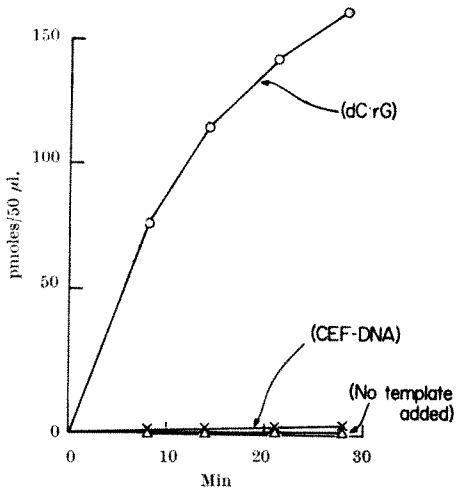

Fig. 1. Kinetics of incorporation of α-^{32}P-dGTP by RLV polymerase. A 0·25 ml. standard reaction mixture was used. The specific radioactivity of α-^{32}P-dGTP was 60 c.p.m./pmole. Methods of preparation of CEF-DNA and dC · rG are described in the legend to Table 1. At the indicated times, 50 µl. samples were withdrawn and the acid precipitable radioactivity was determined as described[3].

Table 1. RESPONSES OF ONCOGENIC VIRAL RNA POLYMERASES TO ADDED DNA AND A SYNTHETIC RNA–DNA HYBRID

Polymerase	pmoles nucleotide incorporated in 10 min/10 µg of viral protein		
	Template		
	None	CEF–DNA	dC·rG
AMV	2·8	5·3	140·0
FeLV	2·1	2·6	30·7
MSV	1·2	1·2	30·0
RLV	1·5	4·3	162·0
MTV	0·1	1·0	35·1
R-MTV	0·1	0·6	21·4

A standard incubation mixture of 0·25 ml. contains 12·5 µmoles Tris-HCl (*p*H 8·3); 3 µmoles $MgCl_2$; 10 µmoles KCl; 2·5 µmoles dithiothreitol; 0·04 µmoles of each of the deoxyribonucleoside triphosphates. To monitor the reaction, α-^{32}P-dGTP was used at a specific activity of 65 c.p.m./pmole. Reactions that were stimulated by added templates were carried out by including the template at a level of 1·0 µg per 0·25 ml. in the standard incubation mixture. The incorporations noted above represent those observed in 50 µl. aliquots corresponding to 10 µg of viral protein. Virus particles suspended in 0·01 M Tris (*p*H 8·3)—0·1 M NaCl—0·002 M EDTA (TNE) at a concentration of 2·3 mg of viral protein per ml. were preincubated for 10 min at 0° C in the presence of 0·2 per cent 'Nonidet P-40' and 0·1 M dithiothreitol. The incubated solution was then added to a standard incubation mixture at a level of 50 µg of viral protein per 0·25 ml. and incubated at 37° C. After incubation for 10 min, 50 µl. aliquots were withdrawn and processed for determining the acid precipitable radioactivity as described elsewhere[3]. The particles designated here as R-MTV were obtained from supernatant fluids of rat mammary tumour[9], R-35 grown *in vitro* at Charles Pfizer Co., Maywood, New Jersey. The source of the other viruses and their methods of purification have been described previously[3]; R-MTV was purified in the same way as the monkey mammary tumour virus. dC·rG was made by mixing equal amounts of poly dC and poly rG (100 µg per ml. in 0·01 M Tris, *p*H 7·4), making the solution 0·2 M with respect to NaCl and allowing the mixture to stand for 15 min at room temperature. The CEF DNA used was made from trypsinized cells from chick embryos according to the procedure of Gillespie and S.S.[10].

Table 2. RESPONSE OF AMV-POLYMERASE TO SINGLE-STRANDED HOMOPOLYMERS

Template	Incorporation (pmoles/5 min/10 µg viral protein)			
rA	dT	(<0·1)	dA	(<0·1)
rC	dG	(3·8)	dC	(<0·1)
rG	dC	(<0·1)	dG	(<0·1)
rI	dC	(<0·1)	dG	(<0·1)
rU	dA	(<0·1)	dT	(<0·1)
dA	dT	(1·2)	dA	(0·2)
dC	dG	(11·0)	dC	(0·8)
dG	dC	(<0·1)	dG	(<0·1)
dI	dC	(1·2)	dG	(<0·1)
dT	dA	(<0·1)	dT	(<0·1)

The composition of the reaction mixtures was as described for Table 1, except that in each experiment only the two deoxyriboside triphosphates were used which corresponded to the identity and the complement of the bases in the template. The template concentration was 1 µg/0·25 ml. of the incubation mixture. The labels used were: ^{3}H-dATP (115 c.p.m./pmole), ^{3}H-dCTP (125 c.p.m./pmole), ^{32}P-dGTP (60 c.p.m./pmole), and ^{32}P-dTTP (110 c.p.m./pmole). 50 µl. of the reaction mixture was withdrawn and acid precipitable radioactivity was determined as described[3] after 5 min of incubation at 37° C.

The abilities of various synthetic double-stranded DNA and RNA homopolymers to serve as templates are recorded in Table 3. Except for rC·rG, all stimulate some incorporation of one of the complementary nucleotide pairs. Of those tested, rI·rC is clearly the best, followed by dC·dG and dC·dI. It is interesting to note that, with the exception of rC·rG, the polyribopolymers are superior to the corresponding deoxypolymers as templates. Table 4 compares the template capabilities of a variety of synthetic DNA–RNA hybrid duplexes. Some of these are the best templates, notably dC·rG and dI·rC.

Table 3. RESPONSE OF AMV-POLYMERASE TO SYNTHETIC DOUBLE-STRANDED DNA AND RNA POLYMERS

Template	Incorporation (pmoles/5 min/10 µg viral protein)			
rA · rU	dT	(15·0)	dA	(0·4)
rC · rG	dG	(<0·1)	dC	(<0·1)
rI · rC	dG	(128·0)	dC	(2·1)
dA · dT	dT	(0·8)	dA	(1·4)
dC · dG	dG	(26·9)	dC	(0·4)
dC · dI	dG	(24·9)	dC	(2·0)

The reaction mixtures and conditions of reactions were as described for Table 1. The duplexes were prepared by using the appropriate polymer components, using the method described for dC·rG (see legend to Table 1). The specific activities of the deoxyriboside triphosphates used were the same as those for Table 2, and the appropriate complementary pair of ^{3}H and ^{32}P-labelled nucleoside triphosphates were present in each reaction.

Table 4. RESPONSE OF AMV-POLYMERASE TO SYNTHETIC HYBRIDS

Template	Incorporation (pmoles/5 min/10 µg viral protein)			
dA · rU	dT	(0·8)	dA	(<0·1)
dD · rG	dG	(141·0)	dC	(1·9)
dC · rI	dG	(44·5)	dC	(1·9)
dG · rC	dC	(<0·1)	dG	(<0·1)
dI · rC	dC	(1·3)	dG	(104·6)
dT · rA	dA	(0·9)	dT	(10·3)

The reaction mixtures and conditions of reactions were the same as described in the legend to Table 1. The hybrids were prepared using the method described for making dC · rG in the legend to Table 1. All other details are as described in the legends to Tables 2 and 3.

There is a striking preference for dGTP and rGTP as substrates. This recalls an analogous situation observed with the Qβ replicase[6] and the DNA-dependent RNA polymerase[7], both of which synthesize poly G if provided with poly C as a template. The preference for dG may

Table 5. TEST OF AMV POLYMERASE TO INCORPORATE RIBONUCLEOTIDES WITH SYNTHETIC POLYNUCLEOTIDE TEMPLATES

Template	Incorporation (pmoles/90 min/10 μg viral protein) Ribonucleotides				Deoxyribonucleotides	
rA · rU	rU	(< 0·1)	rA	(< 0·1)	dT	(73·6)
rI · rC	rC	(< 0·1)	rG	(< 0·2)	dG	(326·0)
dA · dT	rU	(< 0·1)	rA	(< 0·1)	dT	(9·0)
dC · dG	rG	(< 0·1)	rC	(< 0·1)	dG	(109·0)
dC · rG	rG	(< 0·1)	rC	(< 0·1)	dG	(322·0)
dT · rA	rA	(< 0·1)	rU	(< 0·1)	dT	(49·7)

The reaction mixtures and the conditions of experiments were as for Table 1. Here, however, riboside triphosphates were used together with their deoxy analogues. Reactions in the absence of deoxyriboside triphosphates gave the same results. α-^{32}P-labelled deoxyriboside triphosphates and ^{3}H-labelled riboside triphosphates were used to monitor the polyribonucleotide synthesis, and the specific activities for the rATP, rGTP, rCTP, and rUTP were all at 120 c.p.m./pmole. The α-^{32}P-dGTP and α-^{32}P-dTTP used to follow the DNA synthesis were at 60 c.p.m./pmole.

indicate that guanosine is the 5′ terminus and is therefore the first nucleotide inserted. This is in fact the case with the Qβ replicase.

Asymmetric Copying

Tables 3 and 4 show a marked asymmetry in the use of the substrates provided. In no case are the two complementary nucleoside triphosphates incorporated with equal facility. The asymmetry, however, is not absolute, even in the 5 min results recorded in Tables 3 and 4. We found that although there was an initial preference for the incorporation of ^{32}P-dT, ^{3}H-dA is polymerized. A very similar phenomenon is observed (Fig. 2) with ^{32}P-dG and ^{3}H-dC in polymerizations by dI·rC. In some cases, synthesis prolonged for 90 min or more leads to eventual equalization of the incorporation of the two substrates. It should be noted that the use of the preferred substrate (for example, dTTP by dT·rA or dGTP by dI·rC) is not strikingly influenced by the presence of the complementary nucleoside triphosphate in the reaction mixture. As expected, there is symmetrical use and a requirement for the presence of both complementary substrates when an alternating copolymer is used as a template (Fig. 3). Here both complementary nucleotides are incorporated from the very onset at almost equal rates and molarities. Further, unlike the homopolymeric duplexes, leaving out either one of the complementary substrates leads to the complete loss of synthetic activity.

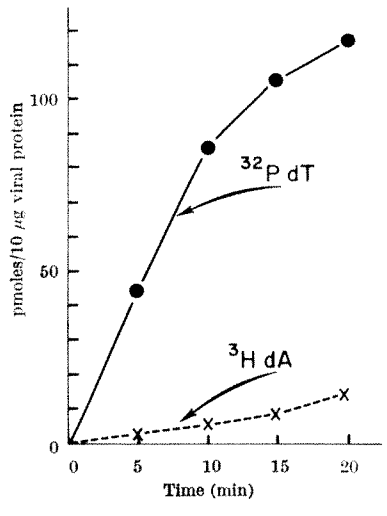

Fig. 2. Kinetics of incorporation of α-^{32}P-TTP and ^{3}H-dATP by AMV polymerase with dT · rA template. A 0·25 ml. standard reaction mixture was used. The specific radioactivities of α-^{32}P-TTP and ^{3}H-dATP were 110 c.p.m./pmole and 115 c.p.m./pmole, respectively. The method of preparation of the hybrid template is described in the legend to Table 1. At the indicated times, 50 μl. samples were withdrawn and the acid precipitable radioactivity was determined as described earlier[3].

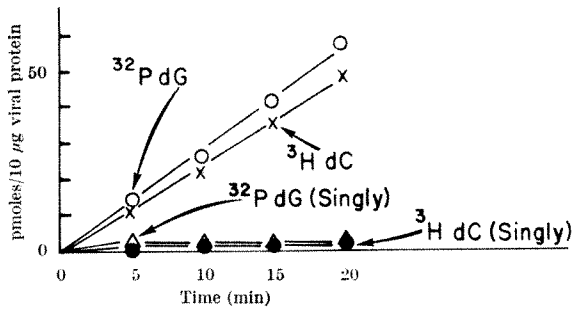

Fig. 3. Kinetics of incorporation of α-^{32}P-dGTP and ^{3}H-dCTP by AMV polymerase with d(I–C) as template. A 0·25 ml. standard reaction mixture was used. The specific radioactivities of α-^{32}P-dGTP and ^{3}H-dCTP were 60 c.p.m./pmole and 110 c.p.m./pmole respectively. At the indicated times, 50 μl. aliquots were withdrawn and the TCA precipitable radioactivity was determined as described earlier[3]. Results are expressed as pmoles of nucleotide incorporated/10 μg viral protein. ○ and × indicate the incorporation obtained when both deoxyribonucleoside triphosphates are present. △ and ● refer to the incorporation obtained when one nucleotide only is present.

Inability to Incorporate Ribonucleotides

It has already been noted[1–3] that the oncogenic polymerases do not synthesize ribopolymers using the viral RNA as a template. In view of the vastly superior template capabilities of some of the synthetic polymers, this question was re-examined and the results are recorded in Table 5. Even after 90 min, no signs of ribonucleotide incorporation could be detected with any of the templates during a period in which excellent polymerization (last column of Table 5) was occurring with the deoxyribonucleotides.

Uses for Synthetic Templates

A detailed examination of the intermediates in the reactions mediated by these synthetic duplexes should be very useful for the study of the chemistry of the polymerization and the factors which determine its asymmetry. Even a casual inspection of Table 1 and Fig. 1 reveals the obvious advantage of using templates such as dC·rG for detecting enzyme in cells or virus particles and following activity during purification procedures. We have now established that oncogenic viruses contain DNA polymerase activities directed by single-stranded RNA, double-stranded RNA, double-stranded DNA, and DNA–RNA hybrids. Further, all oncogenic RNA viruses examined contain all these activities. The number of different kinds of protein molecules required to handle this variety of templates remains to be determined.

We thank Drs F. Bollum, R. D. Wells and D. Brutlag for deoxyribonucleotide polymers; Dr J. W. Beard for a supply of AMV; Drs J. Moloney, F. Rauscher and T. O'Connor of the Special Virus Cancer Program (SVCP) of the National Cancer Institute for their assistance, and personnel of the laboratories associated with the SVCP for cooperation. The work was supported by a contract with the SVCP and a grant from the National Cancer Institute.

The RNA-dependent and DNA-dependent DNA polymerase activities of RNA tumour viruses can be distinguished by their responses to actinomycin D; only the latter is inhibited.

RNA tumour viruses contain an enzyme which can transcribe DNA from an RNA template[1,2]. We have already reported a number of the properties of the DNA polymerase activities associated with avian myeloblastosis virus and Rous sarcoma virus (RSV)[3]. Several of these data suggest that there are at least two enzymatic reactions; synthesis of DNA from an RNA template, with the formation of an RNA : DNA hybrid; and subsequent synthesis of double-stranded DNA. We now present further data which indicate that both enzymatic activities are distributed in a homogeneous fashion throughout the virion population. This confirms recent reports that RNA tumour viruses contain both RNA-dependent[1,2] and DNA-dependent[4] enzymatic activities, and demonstrates that only the latter is inhibited by actinomycin D.

Effect of Actinomycin D

High concentrations of actinomycin D cause a two to three-fold reduction in the rate of DNA synthesis by detergent-treated virus (Fig. 1). Pretreatment of the polymerase reaction mixture with ribonuclease results in a five to ten-fold inhibition of enzymatic activity[1-3,5]. The residual DNA synthesis is unaffected by actinomycin D (Table 1). We suggest that the failure of ribonuclease completely to inhibit DNA synthesis may be due to the capacity of the polymerase to use highly fragmented RNA as template rather than to small amounts of endogenous DNA serving as template[6]. This view assumes that actinomycin D would have no effect on an RNA-dependent reaction, but would inhibit DNA-dependent reactions.

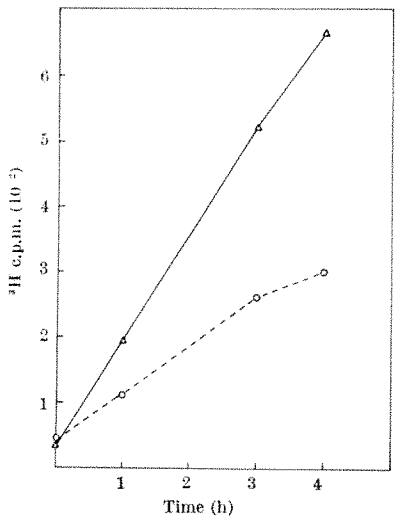

Fig. 1. Inhibition of viral DNA polymerase by actinomycin. Duplicate reaction mixtures were prepared, containing 23 μg of viral protein (purified RSV), 0·05 M Tris–HCl (pH 8·1), 0·01 M $MgCl_2$, 2×10^{-4} M dATP, dCTP and dGTP (Calbiochem), and 0·025 per cent 'Nonidet-P40' (Shell). One sample contained actinomycin D (50 μg/ml.), the other an appropriate volume of the solvent (50 per cent ethanol) used to dissolve the actinomycin. After incubation at 4° C for 15 min, ^{3}H-TTP (11 Ci/mmole, New England Nuclear) was added to 3×10^{-6} M, and incubation continued for 4 h at 37° C. Aliquots for precipitation with acid were taken at the indicated times after addition of ^{3}H-TTP (ref. 3). △—△, Control reaction; ○ - - - ○, actinomycin-treated reaction.

Table 1. INHIBITION OF THE POLYMERASE REACTION BY RIBONUCLEASE AND ACTINOMYCIN

	^{3}H c.p.m. incorporated	Per cent inhibition
(*a*) Control	2,100	—
(*b*) Ribonuclease	700	67
(*c*) Actinomycin	950	55
(*d*) Ribonuclease + actinomycin	720	66

Reaction mixtures similar to those described for Fig. 1 were prepared containing (*a*) an appropriate volume of the solvent (50 per cent ethanol) for actinomycin; (*b*) pancreatic ribonuclease (previously heated at 100° C for 15 min) at 1 mg/ml.; (*c*) actinomycin D, 50 μg/ml., and (*d*) ribonuclease and actinomycin at the foregoing concentrations. After incubation at 4° C for 15 min, ^{3}H-TTP was added and incubation continued at 37° C for 2 h. Samples were then precipitated with acid to determine radioactivity.

As previously reported[3-5,7], the product of the polymerase reaction contains at least two classes of DNA: (1) a complex between nascent DNA and viral RNA which has a heterogeneous, relatively heavy buoyant density in equilibrium density gradients of Cs_2SO_4; some of this material sediments rapidly during rate-zonal centrifugation (about 70S); and (2) DNA with a buoyant density approximately the same as that of the double-stranded DNA of lambda phage, but with a low sedimentation velocity (4–10S); we have shown (unpublished results) that this DNA is double-stranded by analysis on hydroxyapatite. We propose that these two species of nucleic acid represent the products of distinct enzymatic reactions, and that the synthesis of the second class of DNA should be preferentially inhibited by actinomycin D. Comparison of the DNA synthesized by the uninhibited reaction with that synthesized in the presence of actinomycin D has confirmed this hypothesis (Figs. 2 and 3). Synthesis of the rapidly sedimenting product is unaffected by the antibiotic, whereas that of the slowly sedimenting product is substantially reduced (Fig. 2; note the discontinuous scale in (*a*); the drawing is designed to illustrate the similar yields of rapidly sedimenting DNA in the two cases). Similarly, a normal amount of DNA with heterogeneous, relatively high buoyant densities is produced in the presence of actinomycin D (Fig. 3), whereas synthesis of the DNA which bands with phage lambda DNA is completely inhibited. Analysis of enzymatic product on hydroxyapatite demonstrates that the actinomycin-sensitive reaction is responsible for the synthesis of double-stranded DNA (Fig. 4). We conclude that actinomycin D preferentially inhibits the synthesis of one of the two or more classes of enzymatic product. The uninhibited portion of the reaction is responsible for the synthesis of a DNA : RNA hybrid, using viral RNA as template; the inhibited reaction

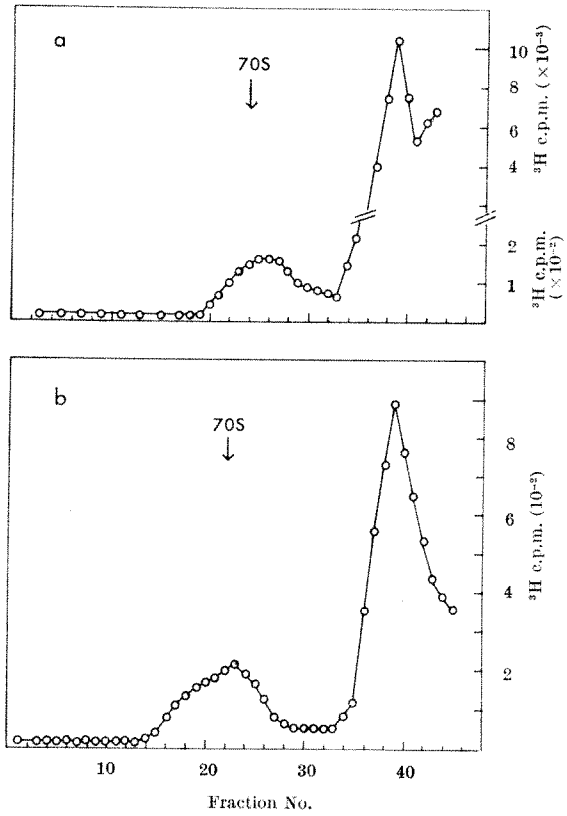

Fig. 2. Zone sedimentation analysis of enzymatic product. Reaction mixtures similar to those described for Fig. 1 were prepared with ten-fold more virus in ten-fold larger volumes. After incubation at 37° C for 4 h, the mixtures were treated with 0·5 per cent sodium dodecyl sulphate and pronase (500 μg/ml.) at 37° C for 45 min, followed by two phenol extractions at room temperature. Portions of the extracted nucleic acids were analysed by centrifugation through density gradients of 15–30 per cent sucrose in 0·1 M NaCl–0·001 M EDTA–0·02 M Tris–HCl (*p*H 7·4) ('SW 65' rotor, 60,000 r.p.m., 70 min, 4° C). The gradients were fractionated and precipitated with acid as described[3]. *a*, Control; *b*, actinomycin-treated reaction.

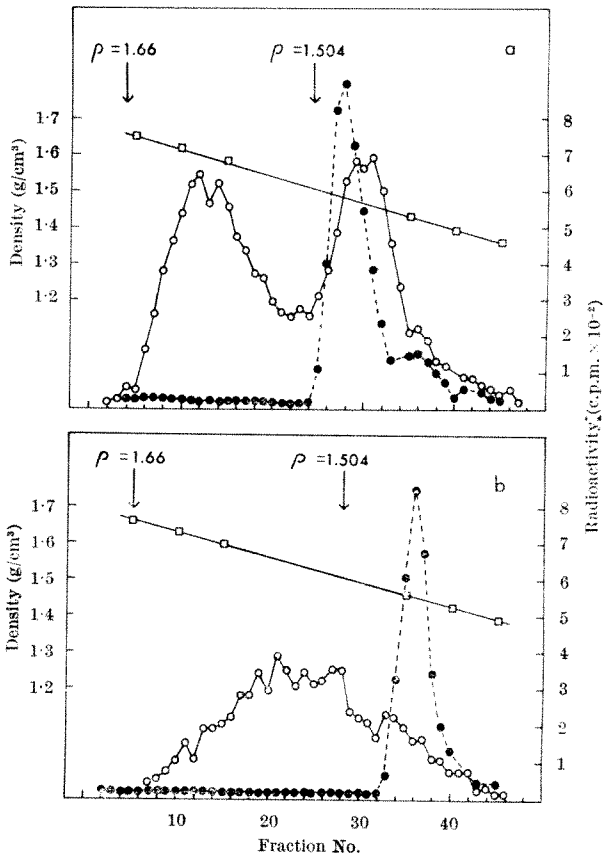

Fig. 3. Equilibrium centrifugation of enzymatic product. Nucleic acids were extracted from reaction mixtures as described for Fig. 2, then dialysed against 1,000 volumes of 0·05 M NaCl–0·002 M EDTA–0·02 M Tris–HCl (*p*H 7·4). Cs_2SO_4 (Gallard-Schlesinger, optical grade) was added to a final density of 1·52 g/cm³, and the solutions centrifuged in an 'SW 50' rotor, 33,000 r.p.m., 60 h, 4° C. Fractionation of the gradients, measurement of densities, and acid precipitation were carried out as described previously[3]. The arrows indicate the approximate expected densities for single-stranded RNA (ϱ=1·66) and hybrid molecules containing equal amounts of RNA and DNA (ϱ=1·504 (ref. 8)). *a*, Control. ³²P lambda phage DNA, denatured with alkali, was included as a density marker. *b*, Actinomycin-treated reaction. Native ³²P lambda phage DNA served as a density marker. ●, ³²P c.p.m.; ○, ³H c.p.m.; □, buoyant density (g/cm³).

synthesizes low molecular weight double-stranded DNA (Fig. 4).

Association of the Actinomycin-sensitive Reaction with Virions

To determine whether the actinomycin-sensitive reaction can be attributed to an integral component of the virion-associated polymerase, we have repeatedly examined the enzymatic activity of virions fractionated by isopycnic centrifugation in density gradients of sucrose (Fig. 5). In every instance, the actinomycin-resistant and actinomycin-sensitive components of the reaction were co-extensive through the virion population. These results suggest that the actinomycin-sensitive reaction is not an artefact from contamination with cellular DNA polymerase.

These findings suggest that synthesis of DNA by viral polymerase is at least a two step process. The putative second step, being sensitive to actinomycin, probably requires a DNA template. We have tested this further by determining the ability of the viral polymerase to respond to exogenous DNA. The initial, RNA-dependent reaction was inhibited by treatment with ribonuclease to reduce the production of intrinsic template for the second reaction. Addition of DNA (sheared, native calf thymus) then stimulated DNA synthesis so that incorporation of precursor exceeded that observed with a control reaction (Fig. 6). The same level of augmented incorporation was obtained by addition of DNA to a reaction which had not been treated with ribonuclease. Results similar to these were recently reported by Spiegelman *et al.*[4]. The effect of exogenous DNA is substantially

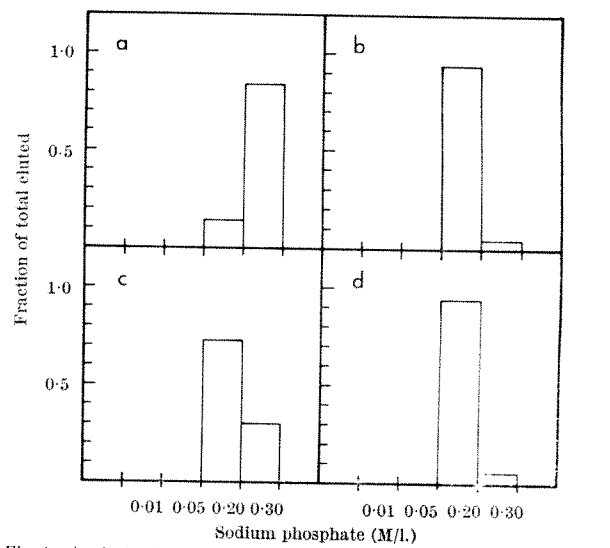

Fig. 4. Analysis of enzymatic product on hydroxyapatite. The products of control and actinomycin-treated reactions similar to those of Fig. 3 were analysed by step-wise elution from hydroxyapatite (our unpublished work). Double-stranded DNA, extracted from chick fibroblasts, and 70S DNA : RNA hybrid, purified by zonal centrifugation, were used as controls. The nucleic acids are treated with ribonuclease in 3 mM EDTA before adsorption to the hydroxyapatite. In these circumstances, hybrid DNA elutes in 0·20 M sodium phosphate; double-stranded DNA in 0·3 M sodium phosphate. *a*, Double-stranded DNA; *b*, purified 70S DNA : RNA hybrid; *c*, control reaction; *d*, actinomycin-treated reaction.

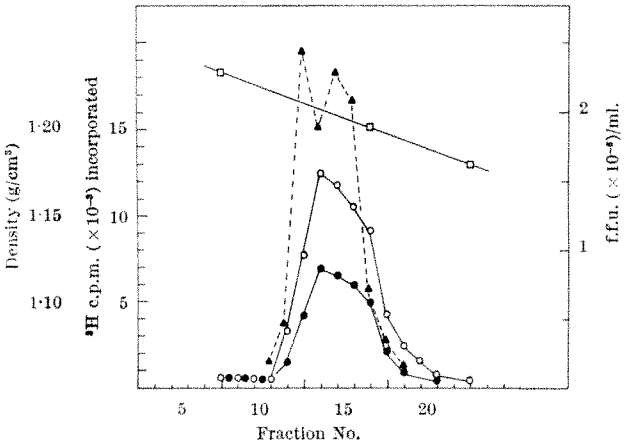

Fig. 5. Association of actinomycin-sensitive reaction with RSV virions. Purified RSV was layered over a preformed gradient of 25–55 per cent sucrose in 0·1 M NaCl–0·001 M EDTA–0·02 M Tris–HCl (*p*H 7·4). Centrifugation was carried out in an 'SW 25·3' rotor, 24,000 r.p.m., 4° C, for 16 h. Samples were taken from the gradient fractions for measurement of enzyme activity, focus-forming units (f.f.u.), and density. Total and actinomycin-resistant DNA polymerase activities were determined with reaction mixtures similar to those described for Fig. 1. ○, ³H c.p.m. incorporated (enzyme activity) in control reaction; ●, ³H c.p.m. incorporated in actinomycin-treated reaction; ▲, focus-forming units; □, density (g/cm³).

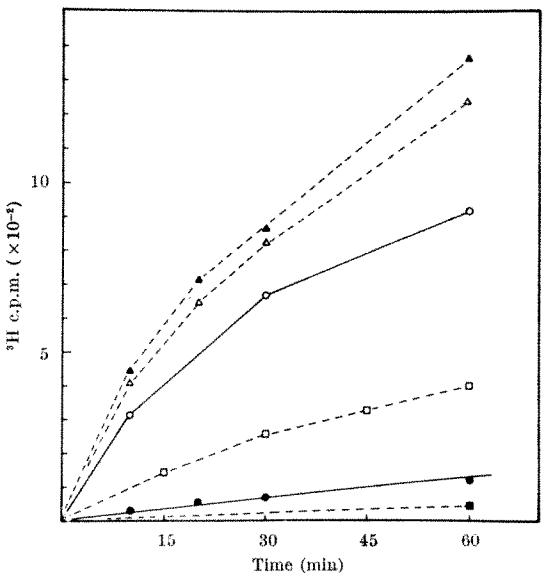

Fig. 6. Response of viral polymerase to heterologous DNA template. Replicate reaction mixtures were prepared and preincubated with actinomycin D and/or ribonuclease as described for Table 1. The reaction was then initiated by addition of ³H-TTP. At the same time, certain samples received 20 μg of native calf thymus DNA, sheared to a molecular weight of approximately 1×10^6–3×10^6. Control reactions contained appropriate amounts of the solvents for actinomycin, ribonuclease and DNA. ○—○, Control (no ribonuclease); ●—●, ribonuclease; △---△, control (no ribonuclease) plus DNA; ▲---▲, ribonuclease plus DNA; □---□, ribonuclease plus actinomycin D plus DNA; ■---■, control plus DNA, but incubated in the absence of detergent.

reduced by addition of actinomycin D to the reaction, and is therefore probably due to a template function of the DNA. No appreciable DNA-dependent activity could be elicited unless the virus preparations were first treated with detergent, an observation which again suggests that the enzymatic activity in question is an integral component of the virions.

Thus the DNA polymerase associated with RNA tumour viruses consists of two (or more) distinct enzymatic activities, one dependent on RNA template, the other on DNA template. The second, DNA-dependent reaction requires at least brief synthesis by the first, RNA-dependent reaction as a source of template[3]. The DNA products of both enzymatic reactions contain nucleotide sequences complementary to the 70S viral RNA[5,7]. The available data suggest a sequence of events in which a short segment (or segments) of the 70S viral RNA is transcribed into DNA, giving rise to an RNA : DNA hybrid with a long tail of single-stranded RNA[3,7]. The reaction then proceeds to the synthesis of double-stranded DNA. It is not yet clear whether this is accomplished directly from the hybrid structure, or whether another, intermediate stage intervenes. It is clear, however, that the final reaction can use double-stranded DNA as a template. This reaction can therefore continue independently of the first reaction, following either the synthesis of a small amount of hybrid or the addition of exogenous DNA.

We thank Dr L. Levintow for his support, advice and editorial assistance, and Drs D. Baltimore and H. Bauer for communication of their data before publication. This work was supported by grants from the National Institutes of Health, the California Division of the American Cancer Society, and the Cancer Research Coordinating Committee of the University of California.

EDWARD M. SCOLNICK
STUART A. AARONSON

National Cancer Institute,
Bethesda, Maryland 20014

DNA polymerase activity has been separated from intact virions and is found associated with the nucleoid. Antiserum to the viral proteins inhibits this activity.

An RNA-dependent polymerase activity associated with the avian and murine tumour viruses has been reported[1,2]. In sucrose gradients the purified virions, the DNA product and the enzyme activity cosediment as a ternary complex[3]. The enzyme can be demonstrated in the virions of C-type[4] leukaemia–sarcoma viruses of several species[3,5,6] and in

* Molecular Anatomy Program, US Atomic Energy Commission, Rockville, Maryland 20014.

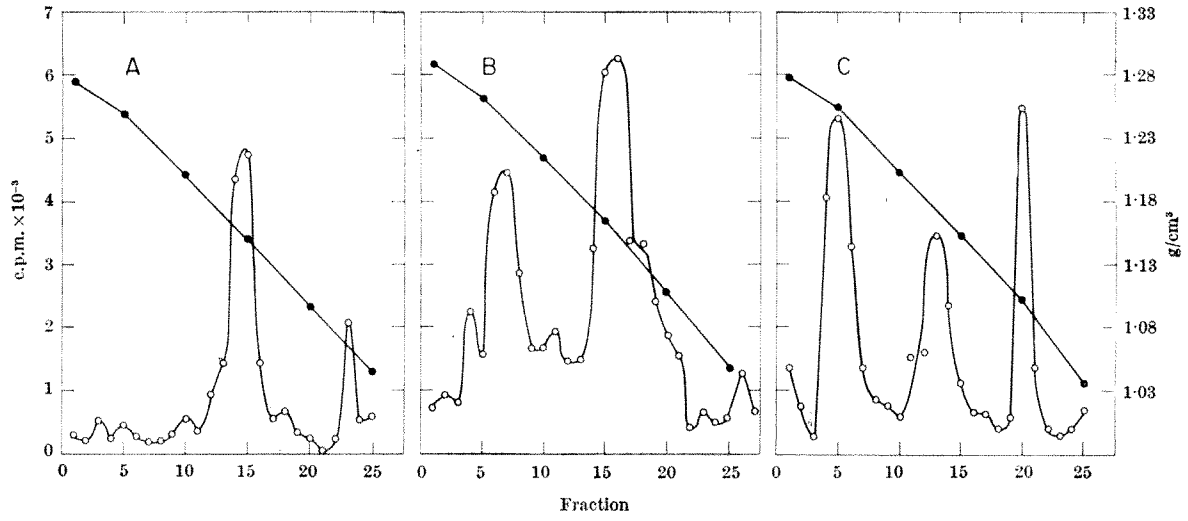

Fig. 1. The treatment of virus in *B* and *C* was as follows. A preparation of Rauscher virus[3] containing 10^7 plaque forming units per 0·10 ml. was incubated at 37° C for 20 min in a 0·20 ml. reaction mixture containing 0·05 M Tris-HCl (*p*H 8·3), 0·05 M NaCl, 0·005 M magnesium acetate, 0·02 per cent 'Triton X-100', 0·02 M DTT and 25×10^{-4} M dATP, dCTP, and dGTP. The 0·20 ml. reaction mixture was then incubated for an additional 90 min at 37° C after being diluted ten-fold in a solution in which the final concentration of each component was: 0·05 M Tris-HCl (*p*H 8·3), 0·07 M NaCl, 0·007 M magnesium acetate, 0·001 M dATP, dCTP and dGTP, 0·02 M DTT, and 0·002 per cent 'Triton X-100'. The mixture was then layered on a 15–60 per cent sucrose gradient containing 0·01 M Tris-HCl (*p*H 8·3), 0·08 M NaCl, 0·008 M magnesium acetate, and 0·006 M β-mercaptoethanol, and centrifuged in a Beckman 'SW-41' rotor at 40,000 r.p.m. at 4° C for 90 min (*B*) or for 15 h (*C*). Fractions of approximately 0·5 ml. were collected from below and assayed for polymerase activity as described by Scolnick *et al.*[3] without added 'Triton X-100'. The virus used in *A* was treated identically except that 'Triton X-100' and DTT were omitted from reaction mixtures before sucrose gradient sedimentation as described above. Each fraction was then assayed for polymerase activity in the presence of 0·012 per cent 'Triton X-100' and 0·02 M DTT.

the B-type mouse mammary tumour virus; the latter may play an aetiological part in carcinomas[7]. By contrast, non-oncogenic viruses, such as influenza and Sendai virus, that contain RNA and develop by budding from the cell membrane do not display this activity[3]. The above findings suggest that this enzyme may play a critical part in cell transformation and cancer development.

We describe here the separation of the enzyme activity from the intact murine leukaemia virion. Both a nucleoid and a light buoyant density fraction contain polymerase activity after detergent treatment and isopycnic banding in sucrose. Partial solubilization of the enzyme represents an initial step in the purification and characterization of this enzyme system.

Experiments with murine leukaemia viruses (Moloney and Rauscher strains) have disclosed a narrow range of optimal detergent concentration for expression of polymerase activity[3]. We assumed that higher detergent concentrations are inhibitory because they disrupt structures essential for enzymatic activity. Conditions were sought which would disrupt virus structure without interfering with active enzyme–substrate complexes. In the presence of 0·02 M dithiothreitol (DTT) and $2{\cdot}5 \times 10^{-4}$ M dGTP, dATP and dCTP, a 20 min treatment of the virion with 0·02 per cent 'Triton X-100' achieved this satisfactorily; virions treated with this concentration of detergent alone were inactive. After treatment the virus preparation was isopycnically banded in sucrose, and the polymerase activity of each gradient fraction was tested.

The results of isopycnic banding of untreated and treated virus are shown in Fig. 1. The activity (Fig. 1*A*) of an untreated virus sample after 15 h of centrifugation at 40,000 r.p.m. was almost entirely associated with intact virus; a low level of activity was found in the light region of the gradient. Fig. 1*B* corresponds to a treated virus sample which was centrifuged for 90 min. Considerable enzyme activity was now present in the region of the gradient (1·24–1·26 g/cm³) where the nucleoid[8] bands. The virus-associated polymerase peak was skewed toward the lighter region of the gradient, indicating the beginning of further separation of enzyme from whole virion. Fig. 1*C* shows a treated virus sample after a 15 h banding. Additional time in the centrifugal field allowed further separation of the activity into subviral components. Here, three distinct peaks of enzymatic activity were demonstrable, one in the nucleoid, one associated with whole virion and one in the lighter region of the gradient.

Electron Microscopy

Fractions showing high levels of polymerase activity were examined by electron microscopy with a Siemens 'Elmiskop 1A' at a base magnification of 30,000 using the negative staining method of Smith *et al.*[9]. Material from the region of the gradient at a buoyant density of 1·16 g/cm³ consisted of a relatively homogeneous population of intact particles (Figs. 2*A* and *B*). There was an occasional disrupted particle in which the intact inner membrane (the capsid of the nucleoprotein core)[10] was visible (Figs. 2*C* and *D*). Material in the high density region can be seen in Figs. 3*A–D* to contain disrupted viral cores. More than 95 per cent of the cores showed neither associated envelope material nor intact capsids. Fig. 3*A* illustrates a rare partially enveloped particle found in the 1·24 g/cm³ fraction. The light fractions in the gradient (1·08–1·10 g/cm³) contained primarily membranes and fragmented nucleoid material (Fig. 3*E*).

Inhibition by Antiserum to Murine Tumour Viruses

Enzymatic activity once freed from the virion should be more readily accessible to interact with added macro-

Virion (fraction 11)	155	1,381
Soluble (fractions 17–20)	275	1,190

* Protein was determined by the method of Lowry *et al.*[14].

molecules; these interactions cannot occur inside the intact virus. Table 1 shows that the polymerase activity which cosedimented with untreated virions was not inhibited by rat anti-MSV serum. By contrast, enzyme assays on the pretreated virus showed that the same antiserum almost completely inhibited polymerase in the nucleoid and soluble fractions and even partially inhibited enzyme activity associated with the virions. Normal rat serum tested at the same concentration showed no inhibitory effect on the nucleoid or virus peaks. Gamma globulins isolated from various anti-MSV sera inhibited the polymerase reaction while gamma globulins from control sera did not.

Table 2 shows that the nucleoid fraction in two separate experiments showed the highest specific activity (^{3}H-TTP incorporated/μg protein). This represents a three-fold increase in specific activity over that found in the intact virion fraction from the same gradient. These results along with those of electron microscopy of the most active gradient fractions lead us to conclude that DNA polymerase activity is located in the nucleoid.

Polymerase in Viral Fragments

The initial product of the reaction is an RNA–DNA hybrid[6,12]. Recent reports indicate that a later product is double-stranded DNA, suggesting that more than one enzyme activity is present within the virion[6,13]. The fragmentation of the virus as demonstrated here might make possible the experimental separation of the different activities.

Polymerase activity was markedly inhibited in both the nucleoid and more fragmented structures by antiserum directed against viral proteins. Thus disruption of the virion allows penetration of antibody to structures where polymerase activity is inhibited, either by specific or by non-specific binding. Further enzyme inhibition experiments using monospecific antisera directed against the various antigens associated with these viruses may permit identification of the polymerase with a particular group-specific antigen of the nucleoid. Experiments on improved stabilization and purification of the enzyme are in progress.

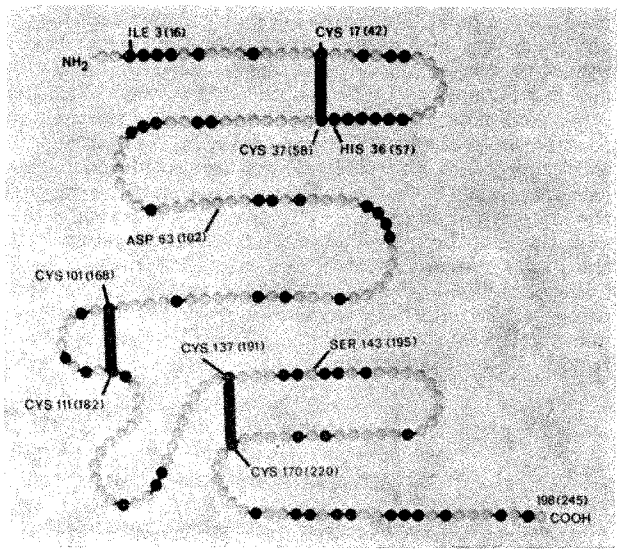
Comparison of the amino-acid sequence of the bacterial α-lytic protease with the mammalian pancreatic proteases shows homologies in the regions of the N-terminus, the single histidine, an aspartic acid residue, the active serine, and in the positions of the three disulphide bridges. The partial sequence of a trypsin-like enzyme from *Streptomyces griseus* provides further evidence for divergent evolution of this class of enzymes from a common ancestral gene.

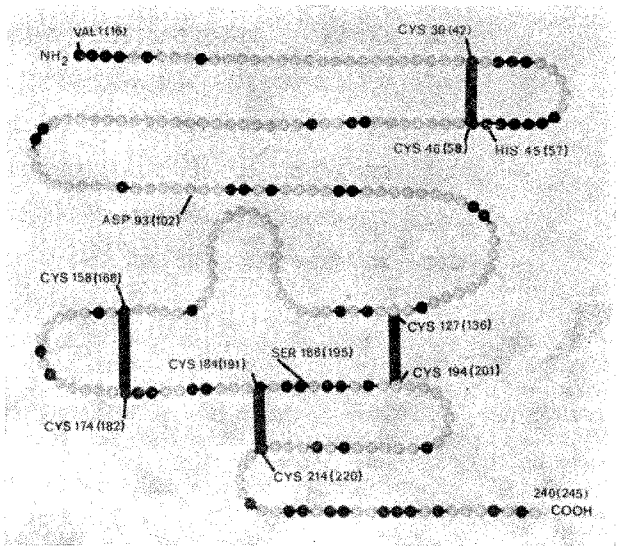
PRIMARY structures of several mammalian pancreatic serine proteases, including bovine chymotrypsins A and B[1–4], bovine trypsin[5–7] and porcine elastase[8], reveal extensive structural homologies in their amino-acid sequences and the positions of disulphide bridges. These similarities extend also to the tertiary structures in the case of chymotrypsin A, elastase and trypsin which X-ray diffraction[9,10] and comparative model building[7,9] have shown to have very similar peptide chain conformations. Serine proteases from other organisms, the spiny Pacific dogfish[11], the turtle[12] and the sea anemone, *Metridium senile*[13], possess some enzymatic and sequence similarities with the mammalian serine proteases as, for example, in the presence of the -Asp-Ser-Gly- sequence of the active serine residue.

But proteases from microbial sources seemed until recently to have no homology with the pancreatic serine enzymes. Thus subtilisin BPN′ from *Bacillus amyloliquo-*



faciens and subtilisin Carlsberg from *B. subtilis*, which are characterized by an active serine sequence Thr-Ser-Met, manifest no homology in amino-acid sequence[14] or in tertiary structure[15] with the mammalian enzymes. They do have a similar arrangement of one aspartic acid, a serine and a histidine residue at the active site, which has presumably developed by convergent evolution to produce enzymes with similar catalytic mechanisms.

The presence of a class of serine microbial proteases, homologous with the mammalian enzymes, has been suggested by the discovery of at least two serine proteases of the soil microorganisms, *Streptomyces griseus*[16–18] and *Myxobacter 495* (refs. 19–21), with many properties in common with the pancreatic serine proteases. The amino-acid sequences about the three disulphide bridges of a trypsin-like enzyme purified from the commercial preparation pronase have a remarkable homology with the corresponding cystine sequences of bovine trypsin[18]. These structures include both the -Asp-Ser-Gly-Gly- active serine sequence as well as the single histidine residue in a histidyl–cystine structure common to all the pancreatic serine proteases whose structures have been elucidated.



A number of proteases have been isolated from cultures of *Myxobacter 495* and shown to have bacteriolytic activity towards several other soil bacteria[19]. Of these, α-lytic protease has been most fully characterized and has many properties in common with porcine elastase and other pancreatic serine proteases. Like elastase, it hydrolyses casein, elastin and the A and B chains of insulin with a preferred specificity for peptide linkages involving the carbonyl groups of neutral, aliphatic amino-acids[20]. Both α-lytic protease and elastase have a common *p*H-activity profile[22,23], contain the Asp-Ser-Gly-Gly sequence[24,25] and depend for their activity on a single unprotonated imidazole group[23]. This group, which is contributed in α-lytic protease by its single histidine residue, is in an amino-acid sequence homologous with the histidine residue-57 sequence of the pancreatic serine protease family[26].

We report here the complete amino-acid sequence of α-lytic protease, which consists of a single polypeptide chain of 198 residues, with a molecular weight of 19,874. The structures of the three disulphide bridges were determined using the diagonal electrophoretic technique of Brown and Hartley[27], which also provided the sequence of the single histidine residue. Samples of the enzyme were then subjected to treatment with diisopropylfluorophosphate, reduced with mercaptoethanol, and either S-aminoethylated or S-carboxymethylated to form denatured derivatives. After digestion with trypsin or chymotrypsin, the peptides were isolated and subjected to amino-acid and sequential analyses by the dansyl-Edman method. Additional overlap peptides were obtained from peptic and α-lytic digests of the reduced and aminoethylated protein and from cyanogen bromide cleavage of the reduced and carboxymethylated material. Peptides were purified by gel filtration on 'Sephadex', chromatography on 'Dowex-50', and paper electrophoretic techniques.

Table 1 shows the amino-acid sequence of α-lytic protease. Table 2 compares this sequence with those for porcine elastase, bovine chymotrypsins A and B, bovine trypsin and the partial sequence of the trypsin-like enzyme from *Streptomyces griseus*. Here the numbering is based on that of chymotrypsinogen A. In arranging these sequences, appropriate deletions and insertions have been made to maximize homologies, particularly with respect to the positioning of the N-terminal sequence, histidine-57, aspartate-102, serine-195 and the positions of the disulphide bridges. In some cases, the exact assignment of deletions or insertions has been arbitrary; in others, for example residues 192A and 192B, it has been obvious. A schematic representation of the sequences of

a

b

Fig. 1. Bead models of (*a*) α-lytic protease and (*b*) porcine elastase. Numbering is from 1–198 for α-lytic protease (Table 1) and from 1–240 for elastase. Numbers in brackets are for the chymotrypsinogen A sequence as in Table 2. Black beads represent residues which are chemically similar or identical in the two enzymes as defined in Table 2. Disulphide bridges between half-cystines are shown as black bands.

α-lytic protease and elastase is also presented in Fig. 1.

Table 2 and Fig. 1 show immediately that several regions exist where the homology is striking. At the N-terminal end, there is the familiar -Ile-Val-Gly-Gly- sequence present in each of the other proteases with minor variations. Unlike the others, however, where isoleucine or valine is the N-terminal residue formed during the activation of the corresponding zymogen to its active form, α-lytic protease has an extra two residues, Ala-Asn-, at the N-terminal end. Recent X-ray diffraction studies[28] on bovine chymotrypsinogen A coupled with the previously reported tertiary structure of chymotrypsin-A[9] have demonstrated that on the tryptic scission of the arginine-15–isoleucine-16 peptide bond, there is a 180° rotation of the main chain in which the formerly exposed side chains of isoleucine-16 and valine-17 become buried, and the α-amino group of isoleucine-16 approaches the

buried side-chain carboxyl of aspartate-194 to form an internal ion pair. This same ion pair has also been demonstrated in the crystal structure of porcine elastase[29]. We cannot at present determine the relative importance of ion-pair formation, hydrophobic bond formation and the other conformational changes accompanying the zymogen to enzyme transition. But reports that the N-termini of α-lytic protease and elastase can be acetylated without loss of activity[22,30] indicate that, at least in these enzymes, the integrity of an ion pair between the N-terminal residue and the β-carboxyl of aspartic-194 is not essential for the maintenance of the active site conformation. The hydrophobic side chains of residues 16 and 17 which are preserved in all of the enzymes from mammalian and microbiological sources may be of more general importance to this class of enzymes.

90° rotation of its side chain during activation of chymotrypsinogen to provide the histidine-57–aspartic-102 region with limited access to the surrounding aqueous environment. In view of the evidence indicating a similar catalytic mechanism in α-lytic protease, we believe these residues will be shown to be involved in similar structural relationships with the histidine and serine of the active centre.

The next region of the sequence (positions 115 to 167) shows little homology with the pancreatic enzymes, and the assignment of residues and deletions (27 compared with elastase) is rather arbitrary. Clearly this is a region where the tertiary structure of α-lytic protease should differ appreciably from the other enzymes. This is followed by a disulphide loop structure between half-cystines 168 and 182 which in α-lytic protease is smaller (eleven

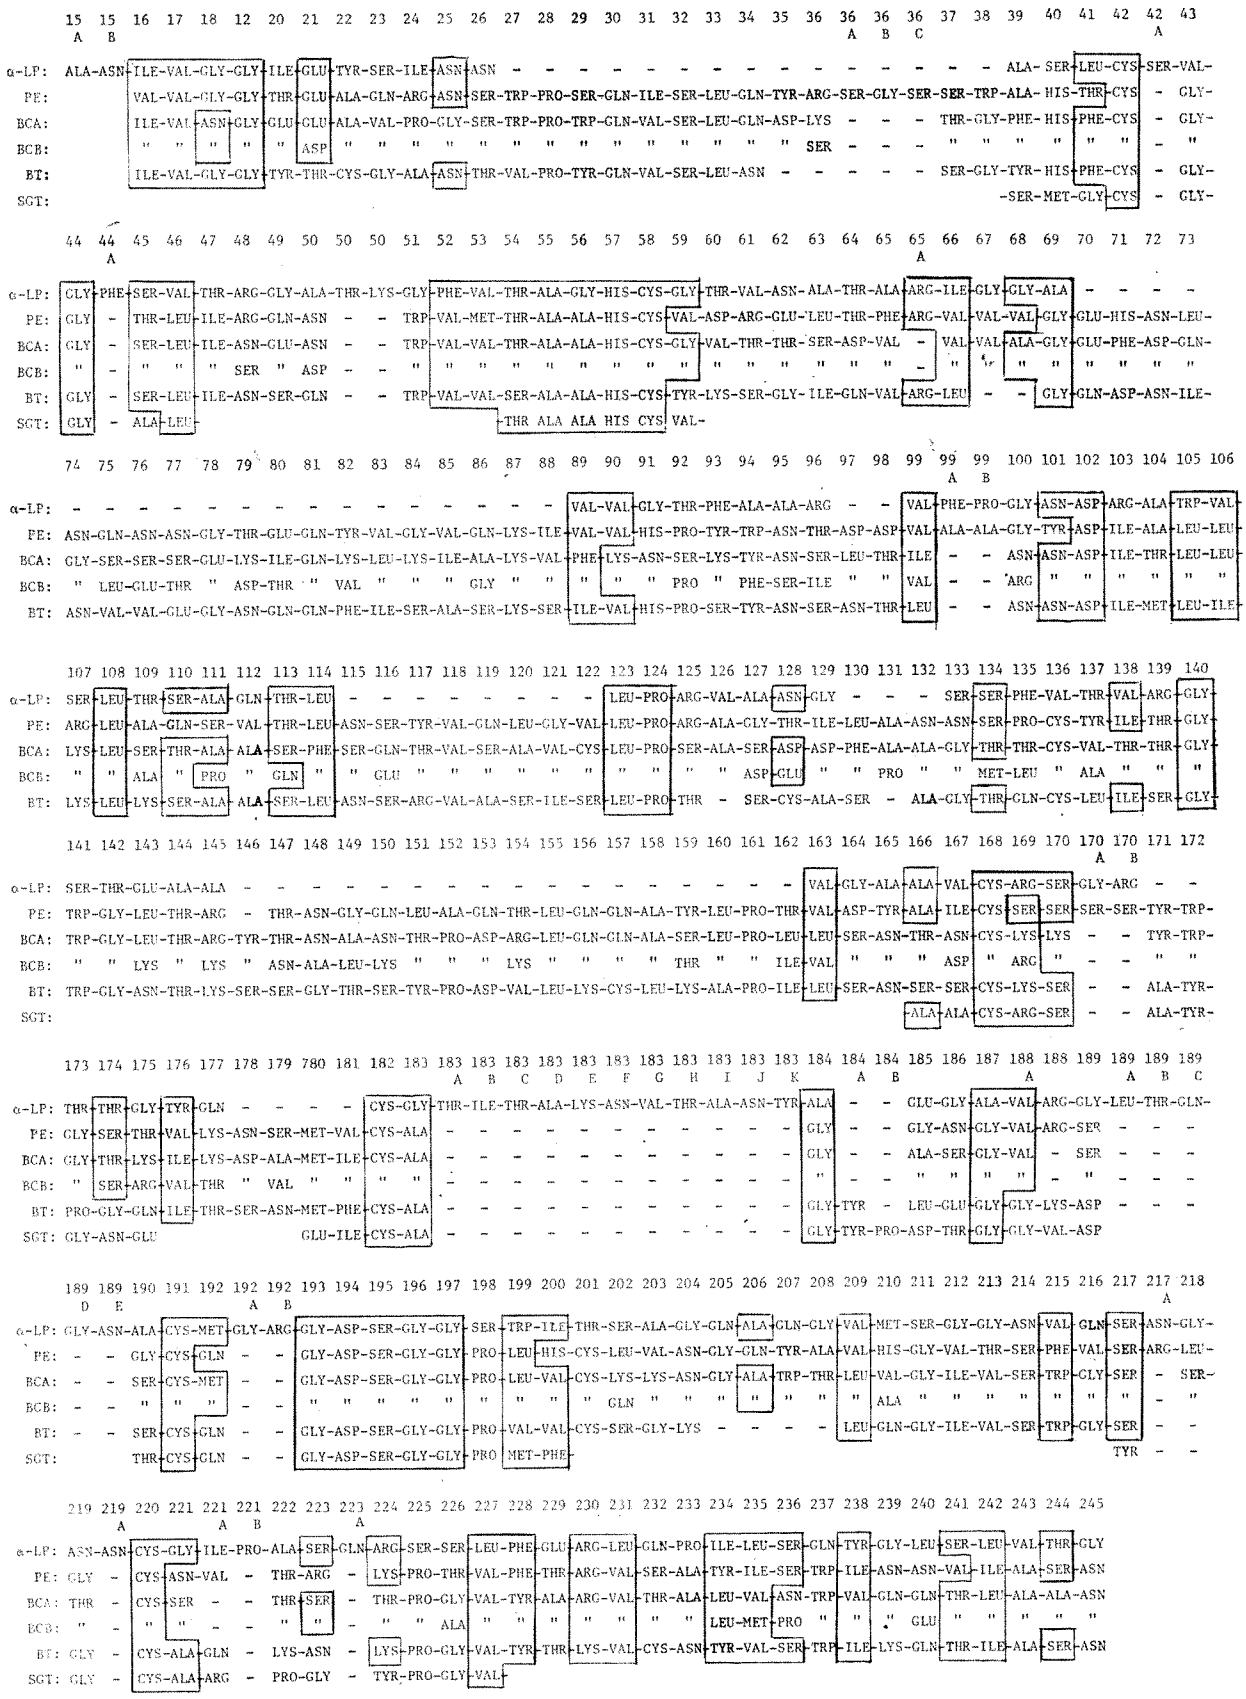
Disulphide bridges: 17–37, 101–111, 137–170

A large deletion of fifteen residues (positions 27–38 from the N-terminus) occurs in α-lytic protease as compared with elastase. Similar smaller deletions (three to five residues) also occur in this region with the chymotrypsins and trypsin. This deletion is followed immediately by the "histidine loop" formed by the disulphide bridging between half-cystine residues 42 and 58. The size of this loop (twenty-one residues) is somewhat larger in α-lytic protease than in the pancreatic proteases (seventeen residues) but there is considerable homology, particularly in the region from residues 52 to 58 which includes histidine-57 (part of the active site). Histidine-40 of the pancreatic proteases is replaced by a serine in an α-lytic protease. In the trypsin-like enzyme of *Streptomyces griseus*, this position is occupied by methionine[18]. It therefore seems unlikely that histidine-40 of the pancreatic proteases plays any functional part in the catalytic activity of these enzymes; this conclusion agrees with the position of this residue in the tertiary structures of chymotrypsin and elastase.

Following the "histidine loop" there is a further large deletion (residue 70–88) followed by a region of moderate homology including aspartic acid-102. X-ray diffraction studies have shown that this residue in chymotrypsin is in a "buried" position and seems to be hydrogen bonded to histidine-57 which in turn is hydrogen bonded to serine-195. Blow, Birktoft and Hartley[3] have suggested that the function of this buried aspartic is to increase the tendency to formation of negative charge on the active serine. Although the homology about this aspartic acid residue in α-lytic protease is not as striking as with the pancreatic proteases, it is the only negatively charged residue in the region of the sequence. Further, the hydrophobicity of residue-99 is preserved in α-lytic protease. This residue (isoleucine in chymotrypsin α) undergoes a



residues) than in the mammalian enzymes (fifteen residues in the chymotrypsins and trypsin and seventeen in elastase). This structure is followed by a sequence in which to maximize the homology of the half-cystine positions it has been necessary to insert a total of sixteen residues compared with the chymotrypsins and elastase. It is tempting to speculate that these insertions are necessary to compensate for the tertiary structural changes produced by the large deletions previously mentioned.

The active serine sequence from half-cystine-191 to residue 197 is identical to most of the chymotrypsins with the notable exception that a dipeptide -Gly-Arg- has been inserted between residues 192 and 193. The tertiary models of both elastase and chymotrypsin at Bristol and Cambridge suggest that this insertion can be accommodated on the exterior of the molecules without serious strain on the conformation of the active site. The remainder of the sequence to the C-terminal end contains approximately the same number of residues as the mammalian enzymes and shows periodic regions of homology, particularly in the region from 227 to 238. There seems to be no problem in accommodating this region of the sequence to the main chain conformation of the other enzymes.

The degree of homology between α-lytic protease and the pancreatic serine proteases described above, and best shown by Fig. 1, undoubtedly reflects a similarity in their tertiary structures, but because of the extensive regions of sequence which show little or no homology and because of the rather large deletions in the bacterial enzyme, we believe that this similarity is limited to only certain regions of the molecule. It will be particularly interesting to determine the structure of this enzyme by X-ray diffraction and we have started such studies[31].

Deductions concerning the evolutionary significance

Table 2. COMPARISON OF AMINO-ACID SEQUENCES OF α-LYTIC PROTEASE (α-LP), BOVINE CHYMOTRYPSINS A AND B (BCA AND BCB), BOVINE TRYPSIN (BT), AND *Streptomyces griseus* TRYPSIN-LIKE ENZYME (SGT)

The numbering is that of chymotrypsinogen A. Insertions in the sequences of other enzymes are numbered 36A, 36B and so on. Deletions are indicated by a dash. Only those residues of chymotrypsinogen-B which differ from chymotrypsinogen-A are indicated. Solid lines enclose residues in which chemically similar residues are present in α-lytic protease and at least two other enzymes. Chemically similar is defined in this paper as: Arg = Lys; Ala = Gly; Asp = Asn = Glu = Gln; Ser = Thr; Val = Trp = Ile = Leu = Tyr = Phe = Met. Disulphide bridges are as follows: αLP, PE, BCA, BCB, BT and SGT: 42–58, 168–182 and 191–220; PE, BCA, BCB and BT: 136–201; BT only: 22–157 and 128–232; BCA and BCB only 1–122.

of the observations described above on the sequence of α-lytic protease must be tempered with caution. It is not impossible that protein structures with some degree of homology could arise in these organisms by a process of convergent evolution. The case for divergent evolution has been considerably strengthened, however, by the isolation and characterization of a trypsin-like enzyme from pronase, a commercial preparation derived from culture filtrates of *Streptomyces griseus*[18]. This enzyme, which has a preferred specificity for peptide bonds of lysine and arginine, like α-lytic protease contains only one histidine residue and three disulphide bonds. Sequence analysis of the half-cystine peptides, however, shows a remarkable homology with bovine pancreatic trypsin. Homology based on identity of residues extends over more than 50 per cent of the sequences included in these disulphide structures. The *Streptomyces* enzyme therefore seems to be intermediate in structural features between those of bovine trypsin on the one hand and α-lytic protease on the other. The evidence is convincing, therefore, that this class of enzymes has evolved at a much earlier point than had previously been appreciated.

We thank Miss Christine Naylor, Mr M. Nattriss and Mr C. Roy for technical assistance, and Drs D. M. Shotton and H. C. Watson of the University of Bristol and Drs B. S. Hartley and D. M. Blow of the MRC Laboratory of Molecular Biology, Cambridge, for the opportunities to inspect the molecular models of elastase and chymotrypsin and to read manuscripts before publication. This work was supported by the Medical Research Council of Canada.

Gene Conversion in *Drosophila*: Non-Reciprocal Events at the Maroon-like Cistron

by
P. DENNIS SMITH*

A large scale half tetrad analysis in *Drosophila melanogaster* questions the reciprocality of intragenic recombination and demonstrates that all intragenic exchange events at the *ma-l* cistron occur by a conversion mechanism.

Although theories of recombination have usually been concerned with reciprocal exchange[1], experiments have demonstrated[2] that exchange events need not always lead to the production of reciprocal products. Such non-reciprocal events, termed "gene conversions", have been documented at a considerable number of loci in the fungi[3–5]. Investigations in *Neurospora*[2], demonstrating both reciprocal and non-reciprocal events within the same gene, may be contrasted with studies from *Ascobolus*[6] which show that all intragenic events may be non-reciprocal. These observations on the frequency of conversion indicate the importance of understanding this process for a clear insight into the mechanism of recombination in eukaryotic organisms.

In the absence of tetrad analysis, the demonstration of this phenomenon in other systems has been difficult. Suggestions that it may be occurring at the garnet locus of *Drosophila melanogaster* were first reported by Chovnick *et al.*[7], but convincing evidence for the occurrence of conversion in *Drosophila* had not been obtained.

We describe here a large scale half tetrad analysis using attached-*X* chromosomes to question the reciprocality of recombination events between separable site mutants of the maroon-like cistron, and demonstrate that (1) gene conversion does play a role in recombination events in *Drosophila melanogaster*, and (2) all intragenic recombination events at the maroon-like cistron seem to occur by way of a conversion mechanism.

The Maroon-like Cistron

The maroon-like cistron (*ma-l;* 1–64·8) is represented by a group of mutants which affect the eye colour phenotype and which are deficient for at least three enzyme activities: xanthine dehydrogenase (XDH), aldehyde oxidase (AO), and pyridoxal oxidase (PO)[8,9]. XDH converts hypoxanthine and xanthine to uric acid, and is

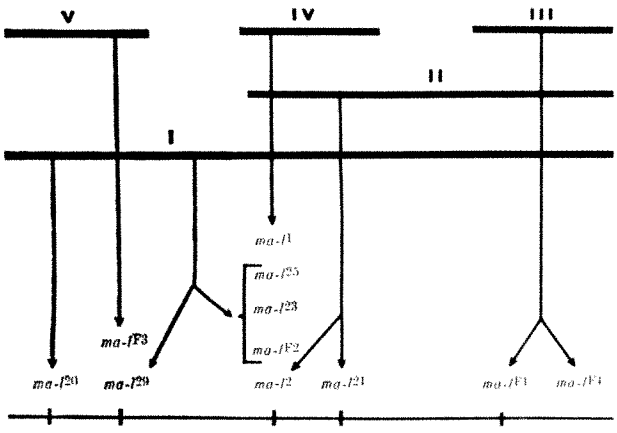

Fig. 1. Complementation and genetic maps of the *ma-l* cistron.

therefore involved in the excretion of purines[8]. Treatment of a developing *ma-l* culture with an aqueous purine solution can kill *ma-l* offspring[10], and this purine lethal effect has formed the basis of a recombination selection system. Recombinational[11] and biochemical[12] investigations indicate that this cistron consists of five complementation groups and a number of separable mutant sites (Fig. 1).

The Half Tetrad Technique

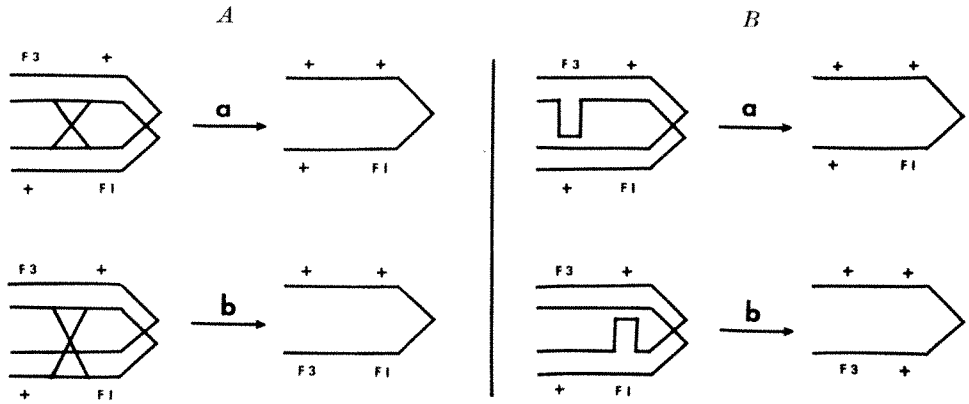
The attached-*X* or half tetrad system in *Drosophila* represents a compromise between tetrad analysis in fungi which enables one to examine each of the four products of a single meiotic event, and random analyses in other meiotic systems which allow the examination of only one of the products of a single meiosis. Attached-*X* females, which bear two *X* chromosomes attached to a single centromere, permit inspection of two of the four products of a single meiosis, for both chromosomes are passed to a single daughter. The *ma-l* half tetrad system provides an opportunity to question gene conversion in higher organisms for three reasons. First, the present system differs significantly from previous recombination studies with *Drosophila* because it does not rely on an examination of outside marker recombinations as indices of intragenic events. Rather, the analysis of *ma-l*$^+$ exceptional female progeny depends on the use of attached-*X* mothers which are heterozygous for two complementing *ma-l* alleles ($ma\text{-}l^{F3}/ma\text{-}l^{F1}$). Females of this complementing constitution possess low XDH activity and display an *ma-l*$^+$ eye phenotype. By allowing an unambiguous intragenic characterization of both strands of an exceptional half tetrad, this technique will permit a distinction between two models predicting the origin of *ma-l*$^+$ chromosomes. Second, because the analysis does not involve the use of outside marker genes, mass matings can be used. Third, the purine selector system can be adapted to kill the normal F1 progeny, which possess low XDH activity, while permitting larvae with higher XDH levels to survive. Thus selection for rare intragenic events leading to the production of *ma-l*$^+$ chromosomes can be performed on large samples of half tetrad bearing progeny from the attached-*X* females.

Origin of *ma-l*$^+$ Chromosomes

Previous recombinational studies[11] with normal (unattached) *X* chromosomes, heterozygous for two *ma-l* alleles, have yielded *ma-l*$^+$ progeny. Subsequent genetic and enzymatic examinations have shown there to be a recombinational mode of origin of the exceptional offspring in those experiments.

If wild type exceptional females arise by classical recombination, two types of *ma-l*$^+$ females can be predicted (Fig. 2*A*). An exchange event between the two alleles involving two strands attached to differing centromeres (*a*) will yield a female bearing an *ma-l*$^+$ chromosome attached to a singly mutant chromosome marked with the proximal $ma\text{-}l^{F1}$ allele. Equally likely, a recombinational event between the alleles involving two strands attached to the same centromere (*b*) will produce a female bearing an *ma-l*$^+$ chromosome attached to the doubly mutant chromosome, $ma\text{-}l^{F1}$ $ma\text{-}l^{F3}$. Conversely, if exceptional offspring result from non-reciprocal exchange, one may similarly predict the occurrence of two types of *ma-l*$^+$ females (Fig. 2*B*). If the distal $ma\text{-}l^{F3}$ allele is converted to wild type (*a*), the resulting female will contain a *ma-l*$^+$ chromosome and a singly mutant chromosome marked by the proximal $ma\text{-}l^{F1}$ allele. If, however, the proximal $ma\text{-}l^{F1}$ allele is converted to wild type (*b*), the exceptional offspring will carry an *ma-l*$^+$ chromosome attached to a singly mutant chromosome marked with the distal $ma\text{-}l^{F3}$ allele.

The salient features of the two models suggest contrasting predictions: with selection for a wild type chromosome, single conversions cannot produce an attached doubly mutant chromosome, $ma\text{-}l^{F1}$ $ma\text{-}l^{F3}$, while single exchanges cannot yield a singly mutant



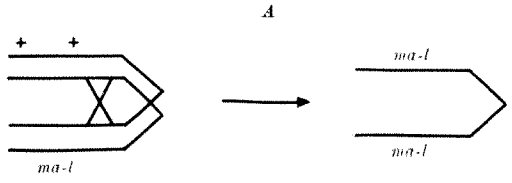


Fig. 2. Mechanisms of origin of *ma-l*$^+$ chromosomes: *A* depicts the origin of *ma-l*$^+$ chromosomes according to the classical recombination mechanism; *B* depicts the origin of *ma-l*$^+$ chromosomes according to a conversion mechanism (diagram does not imply adherence to any particular model). Reversion experiments sampling an estimated 2×10^6 normal *X* chromosomes from $ma\text{-}l^{F1}$ and $ma\text{-}l^{F3}$ homozygous stocks have failed to yield any *ma-l*$^+$ individuals.

chromosome marked by the distal *ma-l*^{F3} allele. Thus, evidence to demonstrate gene conversion may be derived from a consideration of the respective frequencies of the various mutant homologues accompanying an *ma-l*$^{+}$ chromosome.

The Experiment

A single *ma-l*^{F3}/*ma-l*^{F1} attached-*X* female was constructed by standard techniques[12] and fifteen of her daughters were used to initiate separately maintained sublines. A single female was selected from each of these subcultures, expanded two generations, and her virgin grand-daughters were collected to serve as the parental females in a given experiment. Among these collected females, occasional *ma-l* mutant daughters appeared. These represent single exchanges, occurring between the *ma-l* locus and the centromere and involving two chromatids attached to different centromeres. These exchanges render homozygous one or the other of the *ma-l* alleles, and provide a means of insuring that the data will not be biased by using large numbers of parental females containing a recessive lethal on one or the other of their *X* chromosomes (see legend to Fig. 3 for testing details).

The complementing *ma-l*$^{+}$ parental females were mated to non-complementing *ma-l* males. After two days of oviposition, the parents were transferred to fresh culture bottles and the developing cultures were treated with purine. After four successive transfers, the parents were discarded and, on days 12 and 18 of culture, each bottle was examined for the presence of exceptional females. A group of bottles in each experiment was left untreated and the number of emerging progeny provided an estimate of the total sample size.

Fig. 3. Analysis of the mutant homologue: *A*, proximal exchange event rendering the mutant chromosome homozygous for testing; *B*, complementation patterns expected from test crosses of the "*ma-l*" mutant half tetrads. For lethal testing, the *ma-l* mutant females appearing among the complementing parental females are mated to a male tester stock bearing a *Y* chromosome marked with the *ma-l*^{116} allele, a member of the *ma-l*^{F1} complementation group. If the female had been rendered homozygous for the *ma-l*^{F1} chromosome, her daughters would exhibit an *ma-l* mutant phenotype. Conversely, if the female had been rendered homozygous for the *ma-l*^{F3} chromosome, the resulting daughters would exhibit a complementing *ma-l*$^{+}$ phenotype. Five mutant appearing daughters from each of the sublines were tested and it was demonstrated that each of the initiator females for each experiment gave rise to both types of attached-*X* chromosomes and therefore possessed no recessive lethals closely linked to the *ma-l* cistron.

An estimated 5×10^6 progeny females were produced, of which thirty were *ma-l*$^{+}$ exceptional offspring. The method of analysis of these rare progeny is depicted in Fig. 3. By virtue of a single exchange between the *ma-l* cistron and the centromere (*A*), the wild type exceptional females will yield daughters homozygous for the mutant strand. The genotypic constitution of these mutant chromosomes may then be determined by matings to two kinds of tester males which bear differently marked *Y* chromosomes. One strain bears a *Y* chromosome marked by *ma-l*^{116}, a member of the *ma-l*^{F1} complementation group[12]. A similar strain, with the *Y* chromosome marked with *ma-l*^{F3}, constituted the second tester stock. *Ma-l* daughters derived from the exceptional *ma-l*$^{+}$ strains are mated to the two test stocks and the genotypic constitution of the *ma-l* chromosome accompanying the *ma-l*$^{+}$ chromosome can be distinguished by the pattern of complementation observed in the daughters (*B*).

Table 1 summarizes the genotypes of the mutant chromosomes of the twenty-nine exceptional females analysed in these experiments. Two points are immediately clear: (1) of the twenty-nine exceptional females, none carried the doubly mutant *X* chromosome predicted by the recombination model, and (2) approximately half of the mutant chromosomes were marked by the distal *ma-l*^{F3} allele, as predicted by the conversion model. The singly mutant homologue marked by the distal *ma-l*^{F3} allele could be produced by a classical recombinational mechanism if a second exchange between the *ma-l* cistron and the centromere accompanied a first exchange between the alleles (negative chromatid interference). But, because of the location of the *ma-l* locus approximately one map unit from the centromere (1·08 map units in our attached-*X* strain), this double exchange event can be ruled out on the basis of classical recombination studies from *Drosophila*[13,14] which demonstrate high chiasma interference. Interpretations based on high negative interference[15] would have to explain the high occurrence of double exchanges taking place simultaneously with a total absence of single exchanges between chromatids attached to the same centromere.

Table 1. GENOTYPIC CONSTITUTION OF THE MUTANT HOMOLOGUE

Class	Frequency
Distal convertant or single exchange *a*	14
Single exchange *b*	0
Proximal convertant	15
Total	29

Of the 30 exceptional females, 29 appeared as a rare single female, while one appeared as a "burst" of wild type females in all of the bottles involved in the four transfers of an original bottle. These "burst" females undoubtedly reflect the occurrence of an intragenic event in the stock in the previous generation to produce a wild type female who was subsequently used as a parent. This line was lost before completion of analysis of the mutant strand.

In conclusion, the present data provide ample support for the demonstration of gene conversion in higher eucaryotes and, in the case of the *ma-l* cistron, suggest that all intragenic recombination occurs by a conversion mechanism.

These studies were supported by the US Public Health Service through a research grant to A. C. and a post-doctoral fellowship to P. D. S.

Absolute Time-of-arrival Measurements of Optical Pulses from the Crab Pulsar

by
C. PAPALIOLIOS
N. P. CARLETON
Smithsonian Astrophysical Observatory
and Harvard University
P. HOROWITZ
Harvard University

An attempt is made to understand the characteristics of pulsar slowdown in terms of various possible emission mechanisms. Though magnetic-dipole radiation seems to be dominant, the deviations from a pure dipolar decay are large compared with errors in measurement and indicate the presence of more complicated braking mechanisms, small fluctuations, and major "jumps", or period discontinuities. Some rapid-relaxation effect is evident following the discontinuous jump in period in September 1969, but there is no evidence of the quasi-sinusoidal behaviour reported before the jump by Arecibo. An alternative interpretation of the Arecibo data is given.

Soon after the discovery[1] of the pulsating optical signal from NP 0531, the Crab Nebula pulsar, we began making measurements of the absolute times of arrival of optical pulses. With the 61 inch telescope at the Agassiz Station of Harvard College Observatory and the time-keeping facility of the Smithsonian Astrophysical Observatory, we can establish the phase of the pulses to an accuracy of ± 4 μs in absolute time (UTC), with an hour's observation. We made measurements on a few nights in March 1969, with the initial purpose of comparing the times of arrival of optical and radio pulses. The measurements were then begun again in September 1969, and continued at the rate of several per month until April 1970. The comparison of optical and radio arrival times will be reported in more detail elsewhere. The continued observations were made with the purpose of measuring the pulsar period as a function of time, and we shall discuss this behaviour here.

The manner in which the pulsar period changes with time is determined primarily by the torques exerted on it through various energy-loss mechanisms, and secondarily by changes in moment of inertia. By a careful measurement of the variation of period with time one might hope first to measure the secular behaviour and thus to determine, for example, whether magnetic-dipole or gravitational radiation could be identified as the chief source of energy loss. One might then subtract this time dependence and examine the residuals for evidence of other behaviour such as sudden jumps in the period (which have indeed been noted in this and in the Vela pulsar)[2-4], periodic variation that might result from orbital motion of the pulsar and any other short-term fluctuations that might yield information about the physical conditions at the pulsar.

To do all this one must know the position of the Earth relative to the solar system barycentre with an accuracy comparable with the precision of measurement, which is a few ms of the travel time of light. The cooperation of the planetary radar group at MIT has fortunately furnished us with one of the best available ephemerides of the Earth's motion. Uncertainties in some of the parameters of the solar system are still such that one might actually gain information about these if the behaviour of the pulsar were sufficiently predictable. Also, the differential gravitational redshift resulting from the eccentricity of the Earth's orbit[5,6] is large enough (800 μs peak amplitude) to be measured accurately, provided everything else is well behaved.

As we shall show, the non-secular behaviour of the pulsar period is sufficiently complicated to make it difficult to pursue the above objectives in a straightforward manner. One application of careful time-of-arrival measurements that remains essentially untroubled by this, however, is the use of the pulsar to synchronize clocks to a few μs at any two observatories having moderate size telescopes (say, 24 inch) that can observe NP 0531.

Description of Experiment

The telescope was offset from a visible star to the position of the pulsar and guided with an auxilliary eyepiece. Unfiltered light from NP 0531, along with some nebular background and sky light, passed through an aperture (usually 6 or 8 arc seconds in diameter) at the Cassegrain focus and was detected with a cooled 1P28 photomultiplier. This signal, amplified and discriminated with a single-channel analyser, was accumulated in a 1,024 channel signal averager swept at the pulsar rate, and subsequently dumped on half-inch digital tape for analysis.

In a separate operation, both before and after each signal accumulating run, absolute timing marks, generated by dividing down from a stable quartz or rubidium standard, were also fed into the cleared multichannel scaler in order to establish accurate reference of the averager sweep relative to national time standards. Loran-C from the Nantucket synchronized slave station was used to establish regular clock synchronization to better than 1 μs, and all pulse times of arrival (TOAs) are quoted in these units (UTC).

The complete data system is shown in Fig. 1. A 1 MHz signal from the standard source is divided by 32 and used as the channel-advance signal. The scan through the memory of the analyser takes $0{\cdot}032 \times 1{,}024 = 32{\cdot}768$ ms, which is slightly less than the pulsar period, of about 33·1 ms. The analyser then resets and waits for a start pulse, as described below. This system incorporated several important refinements of the usual methods[7,8] which make possible highly precise timing measurements.

(1) Because the averager has a 50 per cent dead time at these channel-advance rates, a one-bit buffer stores signal counts for injection during the live time. With a channel width of 32 μs, the average count per channel per sweep is about 0·01, so a one-bit memory suffices.

(2) A "leap-year machine"[9] generates pulses at the predicted pulsar rate, which start the sweep through the multi-channel analyser; these pulses also reset the channel advance divider to maintain the averager sweep precisely synchronous with the pulsar, for in general the channel-advance rate is incommensurate with the pulsar period. The leap-year machine is driven by the rubidium standard at 1 MHz, giving a peak phase error of ±1·5 μs. The apparent pulsar period changes by a few tenths of a nanosecond per minute, owing to its slowdown and to the Earth's spin and orbital doppler shifts; because a period error of 1 ns would give rise to a drift in the averaged pulsar signal of 20 μs in 10 min (a typical averaging interval) it was necessary to calculate the apparent period for each minute during the observing interval and alter the leap-year machine switch settings appropriately. No jump in synthesized phase results from this operation.

(3) The peak of the signal can be located to a few μs even though it has been quantized into 32 μs bins. It is therefore advantageous to know the phase of the timing markers relative to the bins in which they are found. To do this the store-and-dump buffer is also used to gate 1 MHz into a two-digit counter during the storage interval. This figure, which is the number of μs from receipt of the pulse to injection into the averager, is noted down, along with the UTC time of the pulse, when the calibration runs are made.

To verify that all parts of the timing system were working according to plan, a test was made as follows. The leap-year machine was set to a particular pulsar period and allowed to run without interruption. At arbitrary times during the next few hours timing pulses were fed into the averager, the scan of which was synchronized by the leap-year machine, and recorded on digital tape in the usual manner. From knowledge of the synthesized period and UTC time of each of these pulses it is possible to calculate the channel number, and phase within that 32 μs channel, of each of the pulses relative to the first. Indeed, all of these test pulses were found within 1 or 2 μs of their expected locations, demonstrating that the timing system behaves as expected.

The main peak of each 10 min run was located by cross-correlating a master template with the 1,024 numbers recorded from the digital averager (this is similar to the technique described in ref. 13). From the resulting discrete correlation function the maximum was found to a fraction of a bin by parabolic interpolation. The accuracy of the peak found by this technique is limited entirely by the available signal, a result verified both by "peak-finding" experiments on computer generated noisy signals and by explicit calculation (assuming counting statistics) of the scatter of the cross-correlated peak. The standard deviation of the correlated peak is a simple function of the baseline and height of the light curve on which this template matching technique has been applied, and so we have attached an estimated standard deviation to each measured arrival time. Using the time markers at both ends of the run, the average scanning rate was calculated and the location of the light-curve peak was converted to a site TOA for a pulse close to the median time of the run.

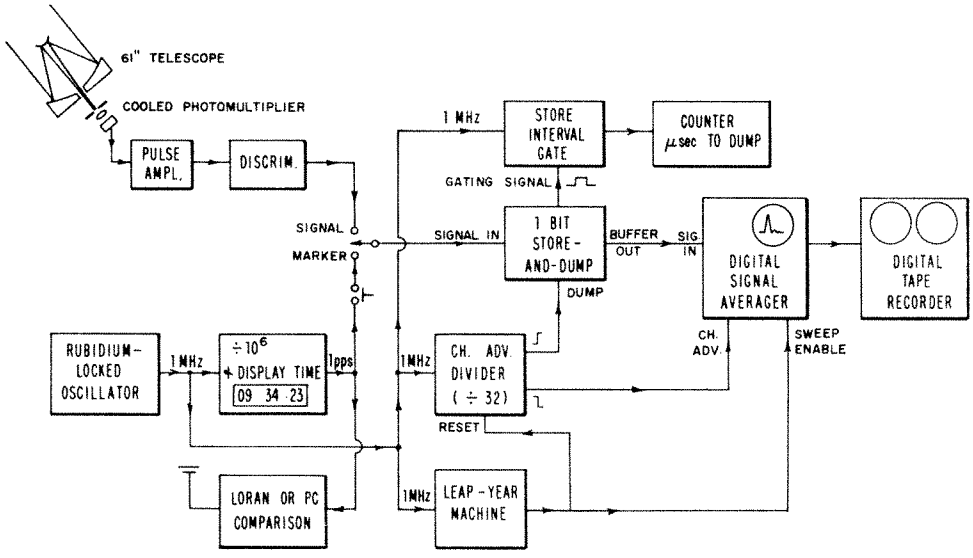

Fig. 1 Pulse time-of-arrival measuring system.

Another check was made to ensure that the timing system worked correctly. Any errors in the synthesized period supplied to the averager would result in an apparent drift of the light curve relative to the averager scan. Typically the peak was found to drift less than one 32 μs channel during 2 h of data-taking, consisting of five to ten independent runs. This gave confidence that the individual runs were accurately averaged modulo the apparent pulsar period. Taken with the test described earlier, this verified that both the pulsar light curve and the calibrating time markers were being recorded with an ultimate timing resolution limited only by the clock (1 μs) and the available signal.

A final check on the entire system consisted of reducing a set of 100 independent runs from a dozen different nights to solar system barycentric TOAs and then performing a cubic fit to phase against time. The resulting phase residuals within each night were compared with the weighted means, the deviations being expressed in units of predicted standard deviation for each timing measurement. Fig. 2 is a histogram of the result, with the curve for Gaussian fluctuations plotted for comparison. Except

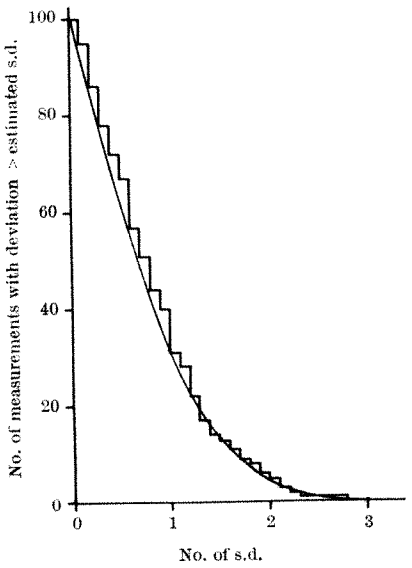

Fig. 2. Histogram of deviations of 100 individual residuals from nightly means, after a cubic fit to phase, in units of estimated standard deviations.

for possible errors of absolute clock synchronization, this result shows that pulse TOAs were being measured to the stated accuracy, and also, incidentally, that the pulsar has a greater stability (in other words predictability, for the secular slowdown has been subtracted) than can be measured in a few hours with TOA measurements of an accuracy of 10 μs.

All site TOAs were subsequently reduced to solar system barycentre TOAs by subtracting the light-time of the site-barycentre vector dotted with the unit vector in the direction of the pulsar, using the coordinates as given by Minkowski[10], and including a term for solar gravitational redshift and second-order doppler shift due to the eccentricity of the Earth's orbit. Because the scatter of measurements within each night was accounted for entirely by the limitations of available signal, a nightly representative TOA was computed and used for subsequent calculations. This was done by performing a cubic fit to phase of several months' data, then subtracting from the TOA of each night's median run the deviation of its phase residual from the weighted mean phase residual for the night. Table 1 lists the site and barycentric TOAs obtained in this way for each observing night.

Recognition of a Jump

The first calculation based on the barycentric TOA is to number each pulse. This is done by calculating the number of pulses ΔN that have elapsed from the last measured pulse by means of the formula

$$\Delta N = f_0\,\Delta t + \frac{\dot{f}_0}{2}(\Delta t)^2 + \frac{\ddot{f}_0}{6}(\Delta t)^3$$

where the parameters f_0, $\dot{f}_0$, $\ddot{f}_0$ have been obtained by a least-squares fit for all previous data, and Δt is the time difference between the present pulse and the previously measured one. The number of pulses ΔN separating these two times is rounded off to the nearest integer. Typically, even for an interval of several weeks ΔN is within 0·05 of an integer, indicating that the pulse numbering is unambiguous. The result is a set $\{(N,t_N)\}$, where t_N is the barycentric TOA of the Nth pulse. The problem is to find an analytic relationship between these two variables. If φ is a continuous variable approximating to the integer variable N, and φ is expanded as a power series in t (we have dropped the subscript N), then

$$\varphi = \varphi_0 + f_0 t + \frac{1}{2}\dot{f}_0 t^2 + \frac{1}{6}\ddot{f}_0 t^3 + \ldots \qquad (1)$$

If we truncate this series beyond the cubic term and define the residual r by $r = N - \varphi$, we can use the method of least squares to minimize these residuals, that is, find f_0, $\dot{f}_0$, $\ddot{f}_0$ such that Σr^2 is a minimum. In minimizing the residuals r we can weight each measurement by σ^{-2}, where σ is the standard deviation in the measured TOA. If, however, the calculated residuals are found to be much greater than the σ's (because of anomalous behaviour in

the pulsar, or errors in the ephemeris, for example) then the measurements should be equally weighted.

The first result of such a calculation was the recognition of a sudden decrease in period similar to that observed earlier in the Vela pulsar[2,3]. This jump, which has been reported by others[4], is apparent in Fig. 3, where the residuals are plotted from a weighted cubic fit to the pre-jump arrival times. Data for the summer months, when optical observation was impossible because the Crab was in the daytime sky, were kindly provided by the Arecibo Observatory group. The dispersion delay as calculated from radio measurements alone has been removed by the Arecibo group, and the radio/optical agreement in phase, which is apparent just before the jump, indicates approximate simultaneity of the pulse arrivals at these different frequencies. A sudden change of frequency alone would result in a straight-line deviation of points after the jump; the curvature here indicates that other parameters changed also. A fit to the post-jump points confirms this. The cubic parameters before the jump and their changes (final-initial) at the jump are

$f = 30{\cdot}209\ 297\ 624$ Hz $\qquad \Delta f = 9{\cdot}3 \pm 1 \times 10^{-8}$ Hz

$\dot{f} = -3{\cdot}857\ 212 \times 10^{-10}$ Hz/s $\qquad \Delta\dot{f} = -1{\cdot}8 \pm 0{\cdot}1 \times 10^{-14}$ Hz/s

$\ddot{f} = 1{\cdot}04 \times 10^{-20}$ Hz/s^2 $\qquad \Delta\ddot{f} = 5{\cdot}9 \pm 1 \times 10^{-21}$ Hz/s^2

t = JD 2440484·5 ± 4 = Sept. 20, 1969 ± 4 days.

What can we conclude from the jump? If we assume that the frequency f of the pulses is related to the angular-rotation rate of the pulsar by $\Omega = 2\pi f$, then the jump in frequency could be the result of a sudden decrease of the moment of inertia due to a reduction of the pulsar's equatorial radius. If the neutron-star radius is 10 km, the magnitude of the jump

$$\frac{\Delta f}{f} = \frac{\Delta\Omega}{\Omega} = -\frac{\Delta I}{I} \cong 3 \times 10^{-9}$$

implies a change in equatorial radius of about 15 μm. If this contraction is a starquake of a solid crust[13] caused by the change in equilibrium shape of the slowing star, then it can easily be shown that the mean time between quakes of this magnitude, for the present f and $\dot{f}$ of the Crab pulsar, is approximately 1 week (the equilibrium equatorial radius R_e changing as $\dot{R}_e = 5\Omega\dot{\Omega}R^4/6GM$, where R is the radius for $\Omega = 0$. That no further jumps of this sort have been observed in the seven months following the September event casts some doubt on the quake

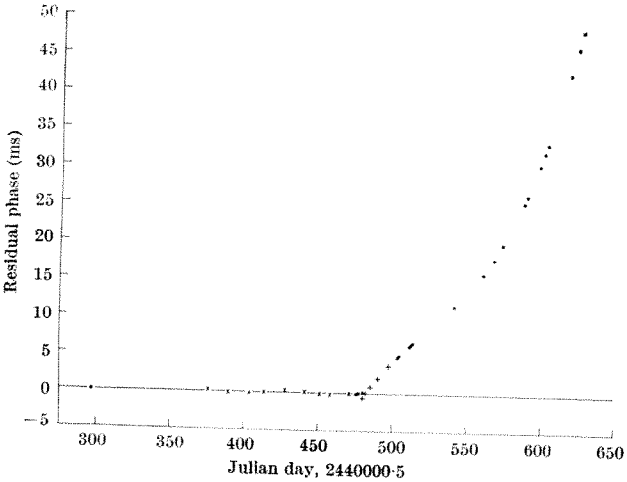

Fig. 3. Residuals against Julian day, after weighted arrival times prior to September 22, 1969 (JD 2440484·5) were fitted by the cubic form of equation (1). The phase residuals resulting from this calculation have been converted to units of time. ×, Arecibo (318 and 430 MHz); ●, SAO-Harvard (optical); +, extrapolated.

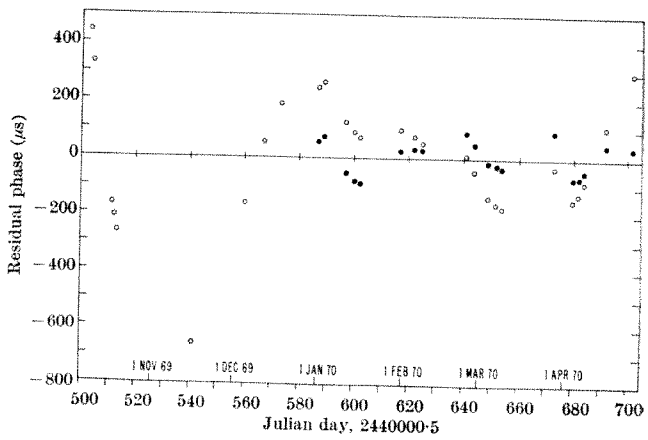

Fig. 4. Residuals against Julian day. ○, Residuals of a cubic fit from October 1, 1969, to April 26, 1970; ●, residuals of a cubic fit after January 1, 1970. The braking parameter n is 2·70 and 2·61, respectively, with an uncertainty of about 5 per cent due to possible errors of a second of arc in the alignment of solar system coordinates relative to NP 0531. The errors in measurement are too small to show in this figure but can be obtained from Table 1.

explanation, as does the observation[10] that major changes in the nearby nebula, following a period of relative quiet, coincide with the jump. The dimensionless parameter

$$Q \equiv \frac{(\Delta\dot{\Omega})^2}{\ddot{\Omega}\Delta\Omega} \quad (0 \leq Q \leq 1)$$

in the superfluid–core/rigid-shell model of Baym *et al.*[11] is approximately 0·34, implying, according to this model, that the moment of inertia of the crust is comparable with that of the core.

Fitting a cubic expression to unweighted data after the jump results in the residuals of Fig. 4. Some rapid post-jump behaviour is evident in the early points, and therefore smaller residuals result from fitting only the points beginning January 1, 1970 (solid circles); in both cases the residuals are far larger than the measurement errors, and lead us to inquire whether a more satisfactory equation relating t and φ can be obtained.

A useful general form of the slowdown law is

$$\ddot{f} = -af^n \qquad (2)$$

where n is related to the parameters in equation (1) by

$$n = f_0\ddot{f}_0/(\dot{f}_0)^2 \qquad (3)$$

If magnetic-dipole radiation is the dominant form of energy loss, $n = 3$; if gravitational quadrupole radiation dominates, $n = 5$. Because $n \approx 2{\cdot}61$ for the expression fitting the points after January 1, 1970 (Fig. 4), the dominant energy loss seems to be the result of magnetic-dipole radiation. The residuals, however, are still quite unsatisfactory because errors due to uncertainty in the Earth's position should not exceed 20 μs, and the measurement errors are only 4–10 μs. Adding one more adjustable parameter, by going to a quartic fit (truncating (1) beyond the quartic term), helps somewhat but not enough. The quartic term is also anomalously large if one compares its contribution to φ with that from the cubic term.

Perhaps a better approach would be to solve equation (2) exactly and then adjust the parameters of the solution

$$\varphi = \varphi_1 + \alpha(1 + t/L)^k \qquad (4)$$

where k is related to n by $k = (n-2)/(n-1)$, and L is a "lifetime" parameter. By expanding φ around approximately correct values for the parameters φ_1, α, L, k, equation (4) can be linearized in these parameters so that a least-squares fitting procedure can be used to minimize the residuals $\{r\}$. The set of residuals obtained by this

procedure is no better than that based on the cubic form of equation (1).

Another possibility is that the slowdown is the result of a combination of dipole and quadrupole radiation described by the equation

$$f = -Af^3 - Bf^5 \quad (5)$$

If the dipole term dominates ($A \gg Bf^2$), the solution to equation (5) is

$$\varphi = \varphi_1 + \alpha\{(t+L) + \beta[\ln(t+L) + 2]\}^{1/2} \quad (6)$$

If the quadrupole term dominates ($A \ll Bf^2$), the solution to equation (5) is

$$\varphi = \varphi_1 + \alpha(t+L)^{3/4} + \beta(t+L)^{5/4} \quad (7)$$

Each of the above solutions has four adjustable parameters and their best values result in a set of residuals identical to those obtained by using the cubic form of equation (1), which also has four adjustable parameters. The only criterion of importance in the quality of the fit seems to be the number of adjustable parameters, so that one should be very careful about the inferences drawn from the particular equation used. A good illustration of this point is the sinusoidal component introduced by the Arecibo group to minimize the residuals over the summer of 1969 (ref. 13). Their fit requires the simultaneous adjustment of seven parameters, four for the cubic part and three for the sinusoidal part of the equation relating t and φ. The cubic expression alone generates residuals as large as 300 μs, much larger than the 10 μs expected on the basis of the measurement process. It is not surprising that the addition of three more adjustable parameters allows one to reduce these residuals significantly. It is possible, however, to fit the same string of data as well with only five adjustable parameters, using an underlying theory that is even simpler than the planetary theory proposed by Richards *et al.* Fig. 5 indicates the residuals that are obtained from the data in their article by assuming a pure dipole braking law (three parameters), accompanied by a fractional increase in the dipole moment of 3·7 parts in 10^5 on JD 2440410·4 (two more parameters). A dipole fit without this jump results in residuals more than ten times as large.

We decided to analyse our data by the method of divided differences[14], because of the difficulty of deciding which function gives the smallest residuals, the desire to recognize discontinuities (jumps) quickly and the fact that none of the simple fitting functions adequately fits the data to our accuracy of measurement. Following the previous discussion, we can note that if $n = 3$, and if we expand t as a power series in φ (that is, make φ the independent variable), the cubic and higher powers of φ vanish identically

$$t = t_0 + P_0\varphi + \frac{1}{2}P_0'\varphi^2 \quad (8)$$

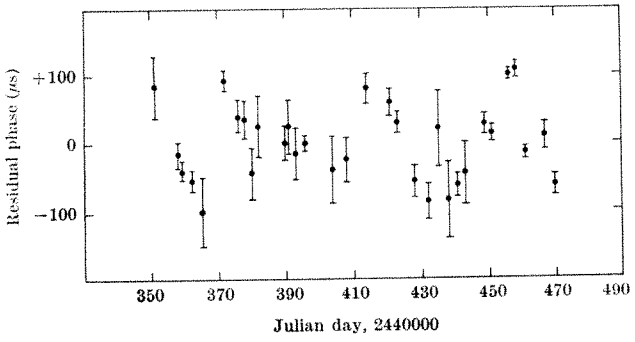

Fig. 5. Residuals against Julian day, after fitting a dipole braking law with a single jump in the dipole moment to the radiofrequency arrival times obtained during the summer of 1969 by the Arecibo group.

Because the period P is just $dt/d\varphi$, P is a linear function of φ (or N) for pure dipole braking. This simple relationship is exploited in the method of divided differences.

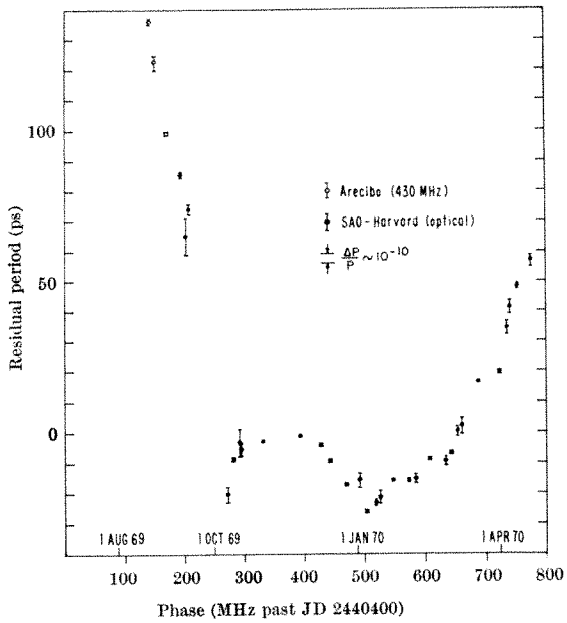

Fig. 6. Residual period against phase, calculated by divided differences, with a linear term subtracted. Error bars are omitted when less than 0·35 ps.

Method of Divided Differences

The analysis discussed before indicates that the parameter n, defined by equation (3), is close to 3. If $n = 3$, then t is a quadratic function of φ (or N) and the period P is a linear function of φ. If (t_1, N_1) and (t_2, N_2) lie on a parabola, then the slope of the parabola at $N_{12} = (N_1 + N_2)/2$ is given by

$$t_{12}' = P_{12} = (t_2 - t_1)/(N_2 - N_1)$$

By this method of calculation we can generate a new set of points $\{(P, N)\}$. Because P is expected to be a linear function of N (because $n \approx 3$), we can subtract out the best straight line (in the least-squares sense) and plot the residuals ΔP as a function of N. These residuals are shown in Fig. 6. The errors indicated are just

$$\pm \sqrt{\sigma_1^2 + \sigma_2^2}\,/(N_2 - N_1)$$

where σ_1 and σ_2 are the errors in measuring t_1 and t_2, respectively. The Ns, being integers, are considered exact. One can easily see from such a graph the discontinuous jump in P that occurred around September 20, 1969. Moreover, it is not possible to fit the data past the jump with a simple, low order polynomial. If the curvature were in one direction only, it would indicate that n was constant but that $n \neq 3$; the fact that the curvature goes both ways indicates either a varying n, an oscillatory component or the existence of long-period random fluctuations. Because the evidence for the first two is not very convincing, we prefer tentatively to accept the third conclusion, especially because a cubic fit (Fig. 4) shows similar unexplained fluctuations. In a rotating neutron star model, such "noise" could be produced by fluctuations in the braking torque (from changes in the radiating charge density, for example) of a part in 10^4, or by temporary mass redistributions that result in changes of equatorial radius of 0·1 μm. A possible cause of the latter comes from the hard-crust models. The previously mentioned failure to observe frequent large quakes suggests that the crust, if it exists, may be too weak to maintain a large distortion, and is consequently in a more or less continuous process of crumbling and fracturing to relieve the strain before it amounts to a departure of as much as 15 μm from the equilibrium shape. These effects are

extremely minute—only measurable at all because of the enormous accumulated phase (10^9 cycles per year) and the ability to measure arrival times to a small part of a cycle (10^{-4} cycles)—yet they preclude the possibility of measuring accurately the gravitational red shift of refining the Earth's ephemeris. The phase stability of the Crab pulsar, viewed as an oscillator, is described by a $Q \approx 10^{10}$.

An interesting consequence of the continuously crumbling model is that the braking parameter n, given by equation (3), is somewhat less than three even if the sole energy loss is through magnetic-dipole radiation. This results from the continuous adjustment of the equatorial radius, tending to maintain the angular velocity. The torque τ from dipole radiation is $\tau = -a\Omega^3$, and the moment of inertia about the axis of rotation of an oblate spheroid is given by $I = I_0(1 + 2\varepsilon)$, where $\varepsilon = 5R^3\Omega^2/(12GM)$, and R is the radius of the sphere when $\Omega = 0$. Setting

$$\tau = \frac{\mathrm{d}}{\mathrm{d}t}(I\Omega)$$

we find $n = 3\text{–}12\,\varepsilon$, that is

$$n = 3 - 5\frac{R^3\Omega^2}{GM} \qquad (9)$$

Using the measured value $n = 2{\cdot}61$ and setting $M = 1/2M_0$ gives $R = 50$ km. This is somewhat larger than the radius of typical neutron-star models, indicating that the deviation of the measured slowdown parameter n from the value for pure dipole braking ($n = 3$) is not the result solely of the effects of changing oblateness. In this calculation, however, we have assumed that the neutron-star material is homogeneous and incompressible and that the magnetic-dipole moment is constant.

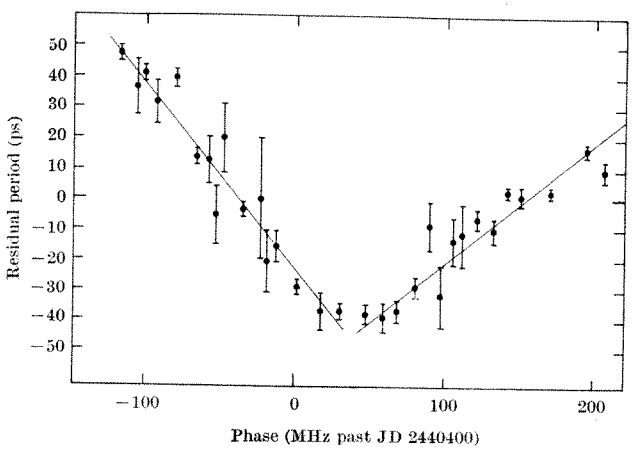

Fig. 7. Residual period against phase of the summer Arecibo data, with a linear term subtracted.

Applying the analysis of divided differences to Arecibo's summer data results in the residuals ΔP from a straight-line fit of P against N shown in Fig. 7. Richards *et al.*[13] accounted for these residuals by introducing a sinusoidal term, but two straight lines are also a possibility and permit the interpretation mentioned earlier of pure dipole radiation with a jump in the dipole moment.

Superposition of Light Curves

Because we determine the peak of each measured light curve to a typical accuracy of ~ 10 μs by cross-correlating with a template, we can easily superpose many such curves and maintain the 32 μs resolution. An example of such a superposed light curve is shown in Fig. 8, representing about 10 hours data taken throughout the previous year. It is interesting to note that the peak is still cusp-like even down to this 32 μs resolution. This implies that

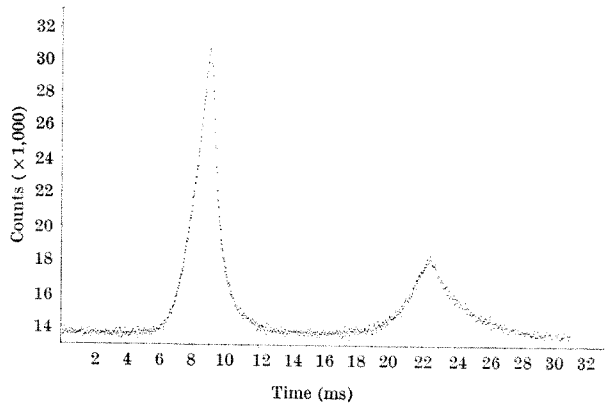

Fig. 8. Superposed light curve (32 μs per point) from ten nights of observing between October 1969 and March 1970. Total observing time is about 10 h.

the radiating region has significant detail on a scale of 32 μs of light-time, or 10 km.

The spacing between main and secondary peaks is 418 ± 1 bins, or $13{\cdot}376 \pm 0{\cdot}032$ ms. This is in excellent agreement with the spacing between the narrow spikes at 318 and 430 MHz found at Arecibo (personal communication from J. M. Rankin, J. M. Comella, H. D. Craft, jun., D. W. Richards, D. B. Campbell and C. C. Counselman, III), namely $13{\cdot}36 \pm 0{\cdot}03$ ms. The period is about 33·1 ms, so the secondary peak occurs 40 per cent through the cycle. This could not be produced by a pure dipole field configuration in a near-field model like that of Komesaroff[15], but would require a "bent dipole" with directions of peak field being no longer collinear. A curious fact about the light curve of Fig. 8 is that both main and secondary pulses are asymmetrical, but in opposite senses: the main pulse falls rapidly, but the secondary pulse rises rapidly. This is, however, just what one would expect from a bent dipolar field, for the gradients are larger on the closer facing sides of the two poles.

Details of all the computer programs, as well as additional comments on some aspects of this work, can be found in the thesis of P. H.[16].

We thank I. I. Shapiro and C. C. Counselman, III, of MIT, and F. D. Drake and D. W. Richards of Cornell University for their supply of information and for much discussion; our colleagues G. G. Fazio, L. Goldberg, D. Hearn, B. Kaplan, R. V. Pound and E. M. Purcell, and members of the Harvard Bubble Chamber Group; C. R. H. Tsiang, J. T. West and W. Wright of the Smithsonian Observatory for help in measurements of absolute time; and M. Mattei of Agassiz Station for assistance. P. H. is grateful to the Society of Fellows for support.

Observational Upper Limits to the Electromagnetic Energy radiated by Normal Galaxies

Low[1] has suggested that typical galaxies emit energies of the order of their present rest mass energies during their lifetime of $\sim 10^{10}$ yr. The observations[2] on which this theory is based indicate that the flux peaks sharply at an emitted wavelength of ~ 70 μm. In this report we indicate the constraints which can be put on such models from observations of the isotropic background radiation at these and longer wavelengths. It will be seen that the present upper limits on the flux still allow most of the energy emitted by galaxies to be in the infrared region of the spectrum.

In order to interpret the meaning of the background radiation measurements, we shall assume that the galactic emission is indeed confined to a narrow range of emitted wavelengths. Assuming a homogeneous and isotropic universe described by the Robertson–Walker metric, the galactic emission at λ_e leads to an observed intensity in the bandwidth λ_1 to λ_2 of

$$\Delta I = \frac{c}{4\pi} \int_{Z_1}^{Z_2} \frac{dZ}{(1+Z)^4} \left|\frac{dt}{dZ}\right| \int_0^\infty L\Phi(Z,L)dL = \frac{c}{4\pi} \frac{\Delta\varepsilon}{\langle 1+Z\rangle}$$

(see also ref. 3). Here $1+Z_1=\lambda_1/\lambda_e$, $1+Z_2=\lambda_2/\lambda_e$, and ΦdL is the number density of galaxies with luminosities (emitted near λ_e) between L and $L+dL$. Thus $\Delta\varepsilon$ is the energy radiated per unit comoving volume during the epoch corresponding to an average redshift $\langle Z\rangle$ of duration corresponding to Z_2-Z_1.

The best estimate of the present matter density in galaxies is $\rho_0=3\times10^{-31}$ g cm^{-3} (refs. 4 and 5) if the Hubble constant $H_0=75$ km s^{-1} Mpc^{-1} (ref. 6). The fraction of the present galactic mass which has been radiated electromagnetically during a given epoch is then given by

$$\Delta\varepsilon/\rho_0 c^2 = 1{\cdot}55\,\langle 1+Z\rangle\,\Delta I = 1{\cdot}55\,\langle\lambda/\lambda_e\rangle\,\Delta I$$

if ΔI is expressed in erg cm^{-2} s^{-1} sr^{-1}.

In discussing Low's model, we are interested in broad-band measurements of ΔI at wavelengths of 70–2,000 μm, corresponding to redshifts $Z=0$–30. It is unlikely that significant radiation occurs at higher redshifts, especially because the optical radiation from quasi-stellar objects seems to cut off beyond $Z\sim2$. Indeed, Low's model would indicate an effective infrared cutoff at $Z\lesssim10$, due to the short time available at large redshifts in which to radiate the maximum expected luminosity.

The observational upper limits on ΔI for various wavelength regions and the corresponding upper limits on the fractional rest mass radiated during various epochs are presented in Table 1. In computing ΔI (max), account has been taken of variation in detector response across the bandwidth. We now discuss the relevant observations, none of which are inconsistent with the expected large-scale isotropy.

Table 1. MAXIMUM ENERGIES RADIATED BY GALAXIES EMITTING NEAR 70 μm

*Ref. 7. †Refs 8 and 9. ‡Ref. 10.

The intensity in the band 70–120 μm was obtained from the data of Houck and Harwit[7]. Their detector response falls off rapidly at the limiting wavelengths, with the maximum response indicating an intensity of 0·01 erg cm^{-2} s^{-1} sr^{-1} if it were concentrated near 100 μm.

The maximum intensities at wavelengths 350–420 μm were computed from the data of Shivanandan *et al.*[8] and J. R. H. and M. O. H.[9], after a detector recalibration carried out with the help of Mrs J. Pipher. The basic detector response rises from 300 μm to 800 μm. At the shorter wavelengths the upper limits have to be corrected upwards. At longer wavelengths, around 900 μm, the corrected upper limits are consistent with results obtained from the data of Muehlner and Weiss[10] and correspond to a lower limit set by Shivanandan *et al.*[8] and J. R. H. and M. O. H.[9]. The Muehlner and Weiss data are presented in Table 1 for this spectral range. It is important to realize that the corresponding upper limits on $\Delta\varepsilon/\rho_0c^2$ are obtained under the assumption that all the energy falls within each segment of the bandwidth considered.

At wavelengths greater than 900 μm, the upper limits decrease because of the weaker signal detected by Muehlner and Weiss when long-wavelength filters were inserted. It is worth noting that if the signals observed by Muehlner and Weiss are assumed to be real rather than upper limits, they could all be due to a single feature near 870 μm plus the small contribution of a spectrum similar to a 2·7 K blackbody spectrum.

The results for $\Delta\varepsilon/\rho_0c^2$ listed in Table 1 indicate that galaxies could have released on the order of their rest mass energies in photons at redshifts $4\lesssim Z\lesssim12$. The lack of useful data between 120 and 350 μm allows even higher energy releases during the epoch $1\lesssim Z\lesssim4$. The present data do not allow such significant energy release at redshifts $Z\lesssim1$, however. These results are nevertheless still consistent with Low's model in strongly evolutionary cosmologies. Because $\Delta I \propto \langle 1+Z\rangle^{-5}\Delta Z$ in steady state cosmology, however, Low's proposal is ruled out in such a universe. The data can obviously be applied to any similar model if the effective emitted wavelength is known.

It is worth noting that the data inferred by Bortolot, Clauser and Thaddeus[11], on the basis of photographic interstellar absorption measurements, further restrict the amount of energy that could have been released at epochs around $Z=4$ and $Z=7$, corresponding to wavelengths of 359 μm and 559 μm. The upper limits placed on $\Delta\varepsilon/\rho_0c^2$, however, depend on the interval ΔZ over which emission occurred. If one takes $\Delta Z(Z+1)^{-1}\sim0{\cdot}1$, the limits on $\Delta\varepsilon/\rho_0c^2$ at these respective wavelengths become $\sim0{\cdot}04$ and 0·01. If $\Delta Z(Z+1)^{-1}\sim0{\cdot}5$, one obtains corresponding values of 0·2 and 0·07 for $\Delta\varepsilon/\rho_0c^2$ at 359

and 559 μm. In that case, there would be no region beyond $Z \sim 3$ where galaxies could have expended an amount of energy equal to their present rest mass energy.

Although the upper limits obtained are not very restrictive at present, more sensitive broad-band background measurements, especially at wavelengths around 200 μm, will help to clarify the situation.

On Pulsar Distances and Emission

IT has been suggested to us that it would be useful to extend the list of pulsar distances which two of us computed earlier[1,2] to include those pulsars which have been discovered since then. In Table VII of ref. 2 we listed distances of thirty-six pulsars. We now list the results for another eighteen, six of which were mentioned previously[2] in a note added in proof. The results are given in Table 1. Because a plot of pulsar distribution against height z above the galactic plane shows a sharp distinction between those objects for which a precise distance was found and those for which we use equation 44 of ref. 2, we have adopted $l = 200\ |\sin b|^{-1}$ pc as a lower bound distance estimate for pulsars with $n_0(\infty) \gtrsim 0{\cdot}05$ cm^{-3} whose line of sight does not intersect an HII region. For the Jodrell pulsars we have used the data of Davies, Large and Pickwick[3,4].

We want to make the following remarks concerning the data in Table 1.

(i) *MP* 0254, *MP* 1911 and *AP* 2303 seem to lie beyond the galactic electron layer, and *MP* 1857 at its edge.

(ii) As our list of HII regions does not extend beyond 1 kpc, we can only put an upper bound on the distances to *MP* 1154, *JP* 1845 and *JP* 1858.

(iii) The line of sight to *MP* 1604 just strikes the N = 2 HII region of ζ Oph at 170 pc. If this HII region is completely disregarded, we find $l \sim 300$ pc. A mean was taken in Table 1.

(iv) 70 cm^{-3} pc of the dispersion to *JP* 1946 is attributable to WR star 97 in Smith's list[5], and of the dispersion to *JP* 2003, 170 cm^{-3} pc is attributable to the same star.

(v) The line of sight to *JP* 2111 hits the HII region of 68 A Cyg.

(vi) The line of sight to *JP* 2319 hits the HII region of III Cep.

Table 1. PULSAR DISTANCES

Pulsar	l^{II}	b^{II}	$\int n_e\, dl$ (cm^{-3} pc)	$10^2\, n_0(\infty)$ (cm^{-3})	l (pc)
MP 0254	271	−55	10	5·1	> 250

JP 2111	89	−1	140	1·4	1,400
AP 2303	98	−27	50	13·5	> 400
JP 2319	112	−1	140	1·4	800

Recently, Tsytovich and two of us[6] have suggested that one might perhaps find optical or infrared pulsed emission at those frequencies where the brightness temperature would become of the order of the effective temperature of the relativistic particles which produce the magneto-brems radiation. To find the frequency ν_0 at which this emission would take place, we assumed a bandwidth of about 10 ν_0 and a total emitted radiation at these frequencies of the order of the total loss of rotational energy. When writing our earlier note we had data about the rate of change of only nine pulsars. At the Jodrell Bank Crab Nebula Symposium, data were presented for seven more pulsars, and we felt that it might be of interest to repeat our calculations for those pulsars. In Table 2 we give the values of ν_0 calculated in the same way as in ref. 6, the value of the rate of change of the period (ref. 7 and unpublished data of G. C. Hunt, and ref. 8), the possible total flux in the band near ν_0 (assuming about 10 per cent of the loss of rotational energy to be converted, as seems reasonable from *NP* 0532 data). From the data in Table 2 and elsewhere[5] it seems that the most likely candidates to show pulsations in the infrared would be *CP* 0950 at about 1 μm and *PSR* 1642 and *PSR* 1929 at about 2 μm.

Table 2. POSSIBLE PULSAR INFRARED EMISSION

Pulsar	$\dot{P}$ (10^{15})	ν_0 (10^{14} Hz)	Power (10^{31} erg s^{-1})	l (pc)
AP 0823	1·66	3	0·3	> 900
PSR 1642	6·2	5	3	160
PSR 1749	8·23	4	1	1,000
PSR 1929	1·16	5	3	150
JP 1933	6·0	6	4	~3,000
AP 2015	0·13	1	0·02	300
PSR 2045	11·15	1	0·05	400

We thank Dr M. I. Large and Dr A. G. Lyne for putting Jodrell Bank data at our disposal before publication.

Plate Tectonics of the Red Sea and East Africa

I WOULD like to comment on some of the assumptions and results of a recent letter by McKenzie *et al.*[1]. They reconstruct the pre-movement position of Arabia and Africa by fitting the two coast lines of the Red Sea, assuming that the entire space between the coasts is occupied by newly formed oceanic crust. This assumption ignores the existence of the Danakil horst, which consists of continental crust (Pre-Cambrian, Jurassic) and which is some 80 km wide, in between these two coast lines in the southern Red Sea depression. It seems impossible to close the gap of the Red Sea without leaving the space required for this continental block.

This reconstruction on a pole of rotation at 36·5° N, 18°, off western Greece leads (ref. 1, Fig. 4) to a considerable extensional component along the Dead Sea rift. This does not correspond to the nature of the movement along this fault line, where the strike slip movement is dominant, with minor extension alternating along it with large shortening in Lebanon[2]. This reconstruction leads finally to a crustal separation of 60–90 km across the Gulf of Suez. This is difficult to reconcile with the fact that the total width of the Gulf of Suez depression does not exceed 50 km in the north and 65 km in the south. Furthermore, there are blocks of continental material within the depression, that of Gebel Kabiliat in the west and of Gebel Zeit in the east. The extension across the Gulf of Suez cannot therefore exceed 25–30 km, according to the assumption of McKenzie *et al.* that the crust has thinned by half beneath the Gulf. This leaves a 40–60 km excess discrepancy with their results. Thus the two coast lines of the Red Sea could not be said to be matching. Instead, they may reflect the marginal faults of a rift which formed at the early stages of the opening of the Red Sea. Judging from the East African rifts, the marginal faults are usually nearly parallel, and the width of such a rift is about 60 km.

The reconstruction should therefore be carried out not by fitting the two coast lines, but by fitting two lines which are about 20–30 km seawards from each coast. This might be the place where the 2,000 m depth contour (which is the most reliable outline of the continents[3]) could be expected in such a fresh crustal separation, were it not concealed by the thick sedimentary cover.

It is true that such a suggestion leaves a wide margin of inaccuracy if a precise reconstruction of the positions of the African and Arabian plates is attempted. The pole of rotation found manually, according to the assumption that there was originally a rift 60 km wide along the Red Sea, occurs at about 32° N, 22° E, north-west of Egypt.

Magnesium, Organic Matter and Soil Structure

SURFACE soils with good structure consist of aggregates that do not disintegrate on sudden wetting with water to form a crust when re-dried. Crusting is most severe when disintegration proceeds down to the level of clay sized particles. The beneficial effect of soil organic matter in reducing the break-up of initially dry soil aggregates when wetted with water is well known. Equally well known is the deleterious effect of exchangeable sodium in causing spontaneous dispersion of clay from aggregates if the external electrolyte concentration is reduced when the soil is wetted. Spontaneous dispersion does not occur if the exchange complex of a soil is effectively saturated with Ca ions or if sufficient organic matter is present[1]. If external work is performed on such soils when they are wet, however, then spontaneous dispersion may occur[2]. Thus a surface soil can apparently have a good structure as measured by the slaking (break-up) of dry aggregates in water and yet after shearing, as in tillage, it may still crust badly[3].

The present work was undertaken to determine, first, whether there is a difference in the ease of dispersion of a sheared surface soil when saturated with Mg rather than Ca ions; second, to show directly, by the addition of organic compounds to the oxidized clay fraction extracted from the surface soil and the corresponding untreated subsoil, that dispersion can be enhanced by organic matter.

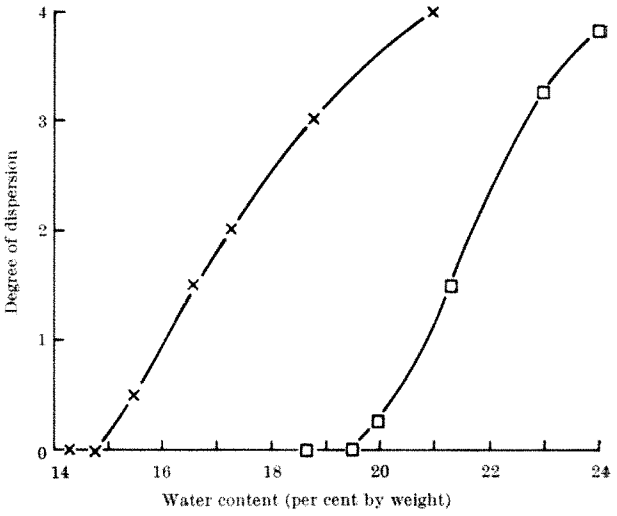

Fig. 1. The visual dispersion in water of surface aggregates of a red earth remoulded at various water contents. ×, Washed $MgCl_2$; □, washed $CaCl_2$.

The degree of dispersion in water of remoulded surface aggregates of a kaolinitic red earth[3] (C content 1·3 per cent) washed with either $CaCl_2$ or $MgCl_2$ is shown in Fig. 1 as a function of the initial water content of the aggregates. Dispersion was assessed visually using the scale 0 to 4, where 4 means apparently complete dispersion into primary particles. This simple technique is adequate for detecting the first appearance of dispersed clay. The Mg-washed soil showed signs of dispersion when remoulded at a water content of 15 per cent by weight whereas the Ca soil started to disperse at 20 per cent. The difference is significant because the field capacity of this soil is about 20 per cent by weight.

Various commonly used organic dispersants such as Na-carboxymethyl cellulose and Na-citrate were added to the peroxidized clay fraction ($< 2\ \mu$) of the surface soil and the untreated subsoil. After washing the mixtures

with $CaCl_2$ and drying, all failed to cause dispersion after remoulding wet. It was known that acid suspensions of kaolinite can be dispersed by extracts of some trees[4]. Leaves from various eucalypt spp. were slowly dried at 55° C and then extracted with water. Without added leaf extract, the water contents for dispersion of the washed clay or subsoil were greater than 200 per cent by weight. By adding the extract, not only was the water content for dispersion reduced to 30–40 per cent by weight, but the Ca-washed clay was now less easily dispersed than the Mg-washed clay (Fig. 2). Further, the respective water contents for dispersion were close to those of the natural surface soil washed with the two cations (compare Fig. 1) when multiplied by the ratio of their clay contents[2] (100/48). The subsoil plus leaf extract gave similar curves to those shown in Fig. 2 but displaced to slightly lower values according to the clay content.

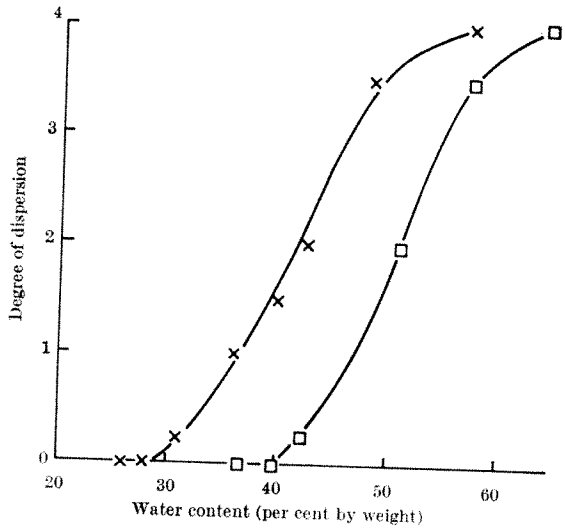

Fig. 2. The visual dispersion in water of the oxidized clay fraction of the surface soil remoulded at various water contents, after the absorption of 0·4 per cent C from an aqueous extract of *E. melliodora* leaves. ×, Washed $MgCl_2$; □, washed $CaCl_2$.

Using electro-osmosis[5], it has been shown that Al ions in the natural surface soil of the red earth are coordinated with the soil organic matter, whereas Al ions in the subsoil are free to react with added oxalate. It is suggested that the added leaf extract coordinates Al ions on the surface of the oxidized clay and on the natural subsoil, so reducing the attractive forces between the clay particles. The enhanced dispersion after Mg-washing compared with the Ca-washing is probably due to the relative solubility of the Ca and Mg salts of the added organic matter.

Until now laboratory experiments have shown little or no differential effect of Mg and Ca ions on structure, although there have been reports in the literature for a long time that the structure in the field of surface soils with a dominant percentage of exchangeable Mg ions is worse than that of similar soils where Ca is dominant[6,7]. The permeability of beds of unsheared surface soil aggregates has been measured[8,9] and experiments have been carried out with clays free from organic matter[2,10]. Where exchangeable sodium is present as well in an Mg dominant soil, the water content for dispersion can be reduced to very low values compared with field capacity.

Tree Ring, Varve and Carbon-14 Chronologies

Carbon-14 dating has become of great importance and it is therefore necessary to determine the possible deviations between radiocarbon and actual ages. A radiocarbon age, given in radiocarbon years elapsed since the origin of the sample, is based on ^{14}C decay and is calculated from the ratio of the present ^{14}C activity of the sample to the ^{14}C activity of the standard (95 per cent of the ^{14}C activity of NBS oxalic acid). The standard ^{14}C activity is assumed to be identical to the atmospheric ^{14}C activity over the whole time interval over which ^{14}C dating is used. Thus the conventional radiocarbon age does not allow for deviations in atmospheric ^{14}C content during the past. As a result, radiocarbon years need not always be equal to solar years.

Variations in atmospheric ^{14}C have been studied in many ways, using tree rings, historically dated samples, varves, lake sedimentation rates and chronological frequency distributions[1]. Dendrochronologically dated tree rings are the most suitable for precise determinations of atmospheric ^{14}C variations during the past[2]. Each ring is formed during one year only, and ceases to accumulate or exchange carbon thereafter. By measuring the present concentration of ^{14}C in wood samples the ages of which are dendrochronologically determined it is possible to calculate the initial ^{14}C concentration in the sample at the time of formation.

There seem to be both long and short-term variations in the ^{14}C concentration of wood samples. The short-term oscillations of about one to two hundred years have been shown to correlate significantly with the solar cycle modulation of the cosmic ray flux[3–7]. The most recent figures for long-term variation in atmospheric ^{14}C obtained from tree ring data by Suess[8] are given in Fig. 1. This curve agrees in its basic features with the results obtained by Damon[9] and Michael and Ralph[10]. The time span of the tree ring chronology, at present 7,400 years, is unlikely to be extended more than a few thousand years because of the lack of suitable specimens, but varve series seem a suitable alternative for the extension of the study of ^{14}C variations.

The results of ^{14}C measurements of two extended varve series are available at present, one series being the classic Swedish varve chronology of de Geer. Although the Swedish varves contain insufficient authigenic organic material for precise ^{14}C measurements, it is possible to correlate ^{14}C dated climatic episodes of northern Europe with varve dated rates of recession and geomorphological features in southern Sweden. In addition, pollen-zone boundaries, varve dated in the Ångerman series by Fromm[11], can be correlated with ^{14}C dated pollen-zone boundaries in nearby peat bogs[12]. Using both techniques, Tauber[13] calculated the ^{14}C deviations resulting from the differences in ^{14}C age and the corrected Swedish varve age (Fig. 1).

The second varve series, from the Lake of the Clouds, Minnesota, was discovered a few years ago by H. E.

Wright and E. J. Cushing of the University of Minnesota. Parts of the ^{14}C analyses for this lake have been reported previously (for a detailed core description, see refs. 1 and 14).

Alan Craig, at the University of Minnesota, counted about 9,500 varves through the entire core, with the exception of the lowermost 40 cm where a continuous sequence was lacking. His counts are used here. All ^{14}C ages are based on the 5,730 year half-life and have been corrected for isotopic fractionation. A deduction of 340 years was made to correct for the ^{14}C deficiency of the lake water.

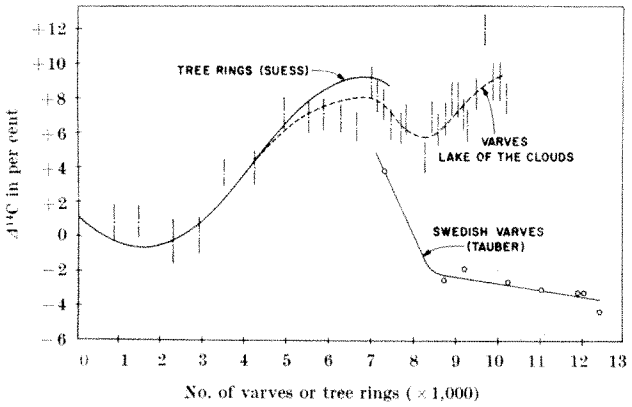

Fig. 1. $\Delta^{14}C$, in per cent of atmospheric content, plotted against Lake of the Cloud varve years (dotted line and experimental points), varve years of the Swedish varve chronology (solid line at bottom) and number of tree rings (solid line at left). Lines drawn are approximate only.

A comparison of the Lake of the Clouds varve ages with ^{14}C ages results in the calculated atmospheric ^{14}C deviations given in Fig. 1. All experimental points in this drawing are derived from Lake of the Clouds samples. The agreement between tree ring and Lake of the Clouds varve series is excellent over a 7,400 year interval. Agreement is lacking, however, between both varve chronologies before 7,000 years BP. The discrepancy may have been caused by errors in either the Swedish or North American chronology, or both.

According to the Swedish varve series, the level of atmospheric ^{14}C was about 2 to 4 per cent below the AD 1950 standard level for the 8,500 to 12,500 varve year interval. Because the tree ring chronology indicates a level of +9 per cent around 7,500 years BP, atmospheric ^{14}C activity should have increased about 11 per cent between 8,500 and 7,500 years BP (from −2 per cent at 8,500 years to +9 per cent at 7,500 years). Such a large change in atmospheric ^{14}C conflicts with the constancy in atmospheric ^{14}C indicated by a floating tree ring chronology between 7,050 and 7,350 ^{14}C BP[15], and is also not supported by lake sedimentation measurements[14,16].

If the Swedish chronology is assumed to be correct, the Lake of the Clouds varve chronology has to be in error by about 800 years. Shortening of the 7,500–9,300 varve interval to 7,500–8,500 years brings the North American chronology in agreement with the Swedish one. Such a large error seems unlikely because the agreement with the tree ring results proves that the errors in varve counting of the Lake of the Clouds series is only 2 per cent over the preceding 7,400 years. It should be noted also that such a small error has not yet been proven for the Swedish chronology. Other interpretations of the Swedish varve chronology, different from the one from which the curve in Fig. 1 was derived, are possible[17,18]. They would generally tend to increase atmospheric ^{14}C between 9,000 and 12,000 varve years above the baseline in Fig. 1.

The differences between both varve chronologies should be solved with the extension of the tree ring chronology by an additional 1,000 years. If the Lake of the Clouds chronology is shown to be correct, the following picture seems indicated. (1) Atmospheric ^{14}C concentration over the past 2,500 years was within a few per cent of the nineteenth century level; (2) between 5,500 and 2,500 years BP atmospheric ^{14}C content was reduced from about +9 per cent to the present base line; (3) for the entire 5,500 to 10,000 year BP interval atmospheric ^{14}C level was about 7 to 10 per cent higher than at present. Such a long-term trend in ^{14}C content may have resulted from a combination of: (*a*) changes in Earth magnetic dipole moment; and (*b*) changes in exchange rate between atmosphere and the oceans caused by a lower mean ocean temperature, lower sea level, and increasing ice cover.

For the Lake of the Clouds varve chronology, the change in exchange rate may explain the gradual reduction in atmospheric ^{14}C content from about +10 per cent 10,000 years ago to the present level. Changes in Earth magnetic field intensity would add a ^{14}C oscillation with an amplitude of about 4 per cent and with a period of about 7,000 years on this general trend.

The only basic assumption inherent to the calculation of the deviation of atmospheric ^{14}C from the base line is the assumption that both varves and tree rings are annual. The agreement between the Lake of the Clouds varve series and the tree rings leaves little doubt that this basic assumption is justified for the past 7,400 years. It is difficult to envisage a process that influences annuality of tree rings in Arizona and lake varves in northern Minnesota in the same manner.

In general, ^{14}C dates corresponding with 5,000 to 7,400 solar years will be 600 to 800 years too young. If the Lake of the Clouds varve chronology is accepted, a similar error is also indicated for the 7,400 to 10,000 varve year interval. On the other hand, the Swedish varve chronology indicates little deviation between ^{14}C and varve ages between 8,000 and 12,000 years. Both varve sequences show that ^{14}C ages (based on the 5,730 year half-life) are expected to deviate less than 800 years from the true age over the past 10,000 years.

Dielectric Relaxation Studies by Time Domain Spectroscopy

DIELECTRIC relaxation has long been recognized as a powerful method of studying the physical state of a system containing polar molecules or groups. At the same time a number of inevitably time-consuming frequency domain techniques are usually required to cover a reasonably wide range of frequency, each demanding the highest degree of experimental expertise. We report here the application of one variant of time domain spectroscopy (TDS) to the study of dielectric relaxation processes in the frequency range 10 MHz–15 GHz, to illustrate the enormous potential of this method, by virtue of its simplicity of operation, for the relatively rapid estimation of the parameters usually associated with a dielectric relaxation process.

TDS may be subdivided into a number of categories (whose individual applicability to dielectric relaxation measurements will be described elsewhere) one of which is time domain reflectometry (TDR). The use of TDR for the measurement of dielectric properties was first reported by Fellner-Feldegg[1]. This method involves the generation of a step pulse containing a broad range of frequencies in a coaxial system, and monitoring the change in pulse shape after reflexion from the surface of a dielectric sample enclosed in a coaxial cell. The measured parameter is the reflexion coefficient (ρ) which is related to the complex permittivity (ε^*) by the expression

$$\varepsilon^* = \left(\frac{1-\rho}{1+\rho}\right)^2 \qquad (1)$$

Fellner-Feldegg[1] analysed his experimental data in terms of the time dependence of ρ and calculated relaxation times for a series of aliphatic alcohols.

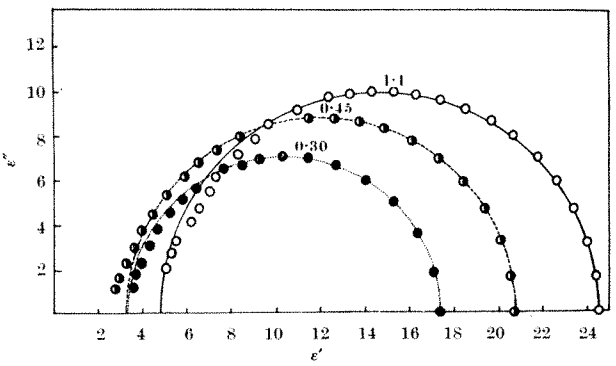

Fig. 1. Permittivity–loss data for ethanol, *n*-propanol, and *n*-butanol at 25° C displayed on the complex plane diagram. ○—○, Ethanol; ◑- - -◑, *n*-propanol; ●···●, *n*-butanol. Indicated frequencies are in GHz.

TDR has been used for several years for the qualitative analysis of transmission line systems. The paper of Fellner-Feldegg[1] is therefore of importance in that it showed for the first time the quantitative possibilities of the technique. On the other hand, the rather poor agreement between many of his estimated relaxation times and other values in the literature might be taken to indicate that TDR is too imprecise to be of much value for the study of dielectric relaxation processes. We take the view that the erroneous results of Fellner-Feldegg are largely a consequence of his method of analysing the experimental data, and do not represent the true precision of TDR. This view has been supported recently by Whittingham[2] who discussed the major limitation of the Fellner-Feldegg method.

We report here the results of an alternative approach to the analysis of TDR data. The reflected pulse and the incident pulse (in practice, the pulse after reflexion from a precision short circuit) are Fourier transformed into the frequency domain by making use of the following modification of the Shannon sampling theorem[3] due to Samulon[4]

$$F(\omega) = \frac{e^{i\omega\tau/2}}{2i \sin \omega\tau/2} \sum_{n=-\infty}^{n=+\infty} \{f(n\tau) - f(n\tau - \tau)\}\, e^{-in\omega\tau}$$

provided that $F(\omega) = 0$ for $\omega > \pi/\tau$ where ω = angular frequency in radians s^{-1} and $i = \sqrt{-1}$. The pulses to be compared are displayed on an X–Y recorder and individually sampled (n samples) at some regular time interval, τ such that the pulse under analysis has no effective frequency contribution above a cut-off frequency of $1/2\tau$. This condition can usually be met without much difficulty in practice, although for some systems it is convenient to split the waveform into two parts so that the region of most rapid change can be more densely sampled than the region of relatively slow change. The resulting Fourier analysis yields the reflexion coefficient (ρ) expressed as $re^{i\theta}$. Information about the amplitude (r) and phase (θ) may then be converted by means of the first equation to ε' and ε'', where $\varepsilon^* = \varepsilon' - i\varepsilon''$.

Experiments were performed using Time Domain equipment manufactured by Hewlett Packard Ltd. The major modification to the earlier experimental arrangement[1] is the introduction of a time marker system so that the pulses to be compared may be referred accurately to a standard point in time. This is an essential requirement of the method of analysis described here.

Table 1. COMPARISON OF RESULTS OBTAINED BY DIFFERENT TECHNIQUES FOR THE MAJOR DIELECTRIC RELAXATION PROCESS OF ETHANOL, *n*-PROPANOL, AND *n*-BUTANOL AT 25° C

Parameter	This work	TDR Fellner-Feldegg[1]	Frequency domain methods*
τ (Ethanol)	140 ps	130	150 (ref. 5), 125 (ref. 8)
τ (*n*-Propanol)	330 ps	220	385 (ref. 6), 350†
τ (*n*-Butanol)	480 ps	330	575 (ref. 6), 540†
ε_0 (Ethanol)	24·5	24·3	24·4 (ref. 5)
ε_0 (*n*-Propanol)	20·6	20·5	20·5 (ref. 6)
ε_0 (*n*-Butanol)	17·3	16·8	17·0 (ref. 6), 17·6 (ref. 7)
$\varepsilon\infty$ (Ethanol)	4·8	8·3	4·4 (ref. 5)
$\varepsilon\infty$ (*n*-Propanol)	3·0	7·2	3·3 (ref. 6)
$\varepsilon\infty$ (*n*-Butanol)	3·3	4·2	3·2 (ref. 7)

* Corrected to 25° C where necessary.

† Reference 6, recalculated from low frequency data.

A range of dielectric samples have been subjected to analysis by TDR in order to (*a*) assess the general applicability of TDR for the study of dielectric relaxation processes, and (*b*) make comparisons where possible between the results from TDR and those from the traditional frequency domain methods. We report here results for three aliphatic alcohols which have been studied fairly extensively by frequency domain methods and which were also examined by Fellner-Feldegg using TDR[1]. Fig. 1 shows permittivity data obtained by TDR for ethanol, *n*-propanol and *n*-butanol at 25° C plotted on the complex plane diagram, and clearly demonstrates the broad band nature of the technique. In Table 1 a comparison is made between the dielectric parameters obtained for the major relaxation process of the alcohols, and other values in the literature. A reasonably good agreement between the results obtained from TDR and those from frequency domain methods is thus indicated. Furthermore, it is apparent from an inspection of original experimental data that the TDR results are much more consistent with a semicircular Cole–Cole plot than the results from the different frequency domain techniques required to cover the same frequency range. The differences in Table 1 between the relaxation times derived from time domain and frequency domain methods should not therefore necessarily be ascribed to errors in the former.

A more detailed account of the experimental and analytical problems associated with time domain dielectric measurements will be discussed elsewhere, but it is pertinent in conclusion to assess briefly the major advantages and limitations of TDR at the present time. The large saving in experimental equipment (because of the broad frequency range covered) and the large saving in experimental time are, as pointed out previously[1], perhaps the most striking advantages of TDR over the traditional methods. At the same time one must set against this the lower degree of precision of TDR information, particularly for high permittivity samples, and the necessity for Fourier analysis of the data.

Taken together, these points indicate that TDR is an extremely acceptable method if information is required at other than a small number of frequencies in a limited band, provided that accurate measurements of small dielectric losses or great precision of measurement are not required. Even there, TDR offers an excellent guide to the frequencies at which the precise frequency domain measurements should be made.

BIOLOGICAL SCIENCES

Trimodal Response of *Escherichia coli* and *Proteus mirabilis* to Penicillins

It has been generally believed that penicillins act on Gram-negative bacilli by interfering with cell wall synthesis leading to the release of spheroplasts which then succumb to osmotic damage. Such damage is usually fatal although in conditions of suitably high osmolarity the spheroplast phenomenon is known to be reversible[1]. Using turbidimetric methods supported by morphological studies in the scanning electron microscope, we have recently demonstrated that *Escherichia coli* and *Proteus mirabilis* show a variety of responses to penicillins which cannot be satisfactorily explained on the basis simply of the emergence and subsequent osmotic destruction of spheroplasts[2,3]. With the high bacterial population densities used, large numbers of "persisters" (organisms which survive exposure to bactericidal concentrations of penicillin although their progeny remain fully sensitive[4]) could be recovered after prolonged exposure to penicillins, and it seemed that this survival resulted from yet another response to the agents. In this investigation we have extended our studies and have attempted to elucidate the persister phenomenon.

A strain of *E. coli* and one of a typical swarming *P. mirabilis* previously studied[2] were used throughout. Continuous records of the opacity changes of growing cultures were obtained by means of a simple photometer[5]. Minimum inhibitory concentrations (m.i.c.) of the agents for the strains used were determined by a conventional doubling dilution tube titration method. Enough penicillin was added to the growing cultures in the mid-to-late-logarithmic phase to produce a concentration 15 times the m.i.c. To study the phase of recovery from exposure to penicillin, excess penicillinase (Neutrapen*, Riker) was added at various times. In a further set of experiments, the spheroplast fraction of the population surviving exposure to penicillin was inactivated by the addition of erythromycin (1/5 m.i.c. for intact cells[6,7]). An experiment was designed to test the penicillin sensitivity of the surviving population. The minimum amount of penicillinase which allowed growth on overnight incubation from penicillin-treated cultures was determined by preliminary titrations. In the definitive experiment, this amount of penicillinase was added to cultures which had been exposed to ampicillin overnight. When growth had again reached the point at which the original addition of ampicillin had been made, a second identical dose of antibiotic was added.

Minimum inhibitory concentrations of the agents used were: ampicillin 4 μg/ml.; erythromycin 50 μg/ml., for *E. coli*; and benzylpenicillin 4 μg/ml.; erythromycin 250 μg/ml., for *P. mirabilis*.

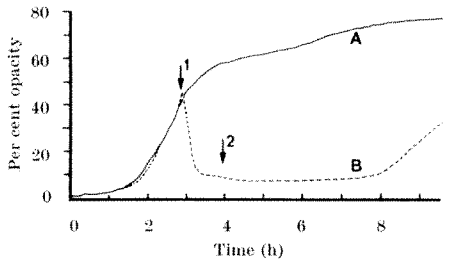

Fig. 1. *E. coli*: *A*, normal growth curve; *B*, 66 μg/ml. ampicillin added at 1; excess penicillinase added at 2.

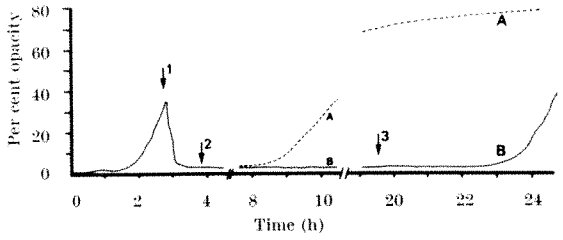

Fig. 2. *E. coli*: Two experiments with 66 μg/ml. ampicillin added at 1; *A*, excess penicillinase and 10 μg/ml. erythromycin added at 2; *B*, excess penicillinase added at 3.

The normal growth curve of the *E. coli* strain in our system is shown in Fig. 1*A*. On addition of 66 μg/ml. (15 m.i.c.) ampicillin there was a very short lag of 2–3 min before precipitate "lysis" occurred and continued over a 20 min period. During this time a hundred-fold drop in the viable count was demonstrated. Penicillinase added 1 h after the ampicillin brought about a recovery of growth which showed on the opacity trace after about 4 h. The machine will not record bacterial concentrations below about 10^6/ml. (Fig. 1*B*). This recovery was unaffected by adding erythromycin at the same time as penicillinase (Fig. 2*A*) and was observed even when the penicillinase was withheld for up to 21 h (Fig. 2*B* and 3). When an amount of penicillinase was added which just neutralized the ampicillin present, the subsequent culture showed a reaction to the addition of more ampicillin similar to that of the original one (Fig. 3), the dose of ampicillin

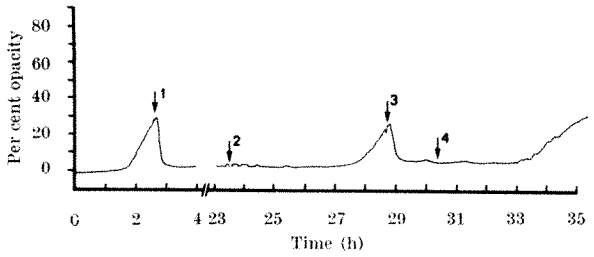

Fig. 3. *E. coli*: 66 μg/ml. ampicillin added at 1. One neutralizing dose penicillinase added at 2. A further 66 μg/ml. ampicillin added at 3. Excess penicillinase added at 4.

apparently being sufficient to induce lysis before neutralization by residual penicillinase.

The normal growth curve of *P. mirabilis* was similar to that of *E. coli*, but the response, in this case to benzylpenicillin, was different. There was only a transient lytic phase: most of the population underwent metamorphosis into spheroplasts, which accounts for the increase in opacity which followed the lytic phase (Fig. 4*A*). When penicillinase was added, fresh progressive increase in opacity was apparent after about 3 h (Fig. 4*A*). By contrast, if one-fifth m.i.c. erythromycin was added with the penicillinase, progressive increase in opacity did not take place for about 12 h (Fig. 4*B*).

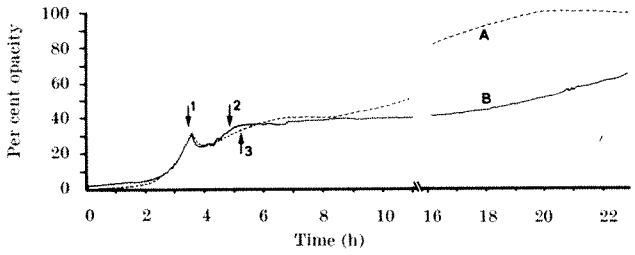

Fig. 4. *P. mirabilis*: 66 μg/ml. benzylpenicillin added at 1; *A*, excess penicillinase added at 3; *B*, excess penicillinase and 50 μg/ml. erythromycin added at 2.

Inhibition of spheroplasts by erythromycin was also directly demonstrated by microscopical examination of penicillin-treated cultures to which both penicillinase and erythromycin had been added. Unreverted spheroplasts were present and there was no sign of the bizarre morphological forms which abound during the early stage of spheroplast reversion.

Previous studies had already indicated that the traditional view of penicillin action on Gram-negative bacilli was inadequate[2,3]. Apart from transformation to spheroplasts, a proportion of the bacterial population of cultures of *E. coli* and *P. mirabilis* appeared to be rapidly "lysed", and in addition cells apparently unaffected by the antibiotic could be seen in the scanning electron microscope.

It has been shown by Taubeneck[6] that stable L-forms of *P. mirabilis* are more than 1,000 times more sensitive to erythromycin than the parent strain. In the present experiments exposure of *P. mirabilis* spheroplasts to erythromycin greatly delayed but did not abolish growth of the culture on addition of penicillinase. With *E. coli*, where spheroplast formation is typical of only a small minority of the bacterial population, recovery on addition of penicillinase was indistinguishable in the presence and absence of erythromycin. Furthermore, subsequent recovery, detectable on the opacity trace after about 4 h, was independent of the time the penicillinase was added. The surviving cells, which must retain sufficient external structure to make them insusceptible to erythromycin, are evidently inhibited by the ampicillin yet yield, on neutralization of the penicillin, progeny exhibiting the same mixed response as the parent strain. It is tempting to identify such cataleptic cells with the apparently morphologically normal survivors seen in the scanning electron microscope.

These findings are entirely analogous with those of Gunnison *et al.*[8], who concluded that staphylococcal persisters survived because at the time of first contact with penicillin they were in a state unfavourable to division. The simplest version of such a hypothesis is that penicillin exerts a bacteriostatic effect on some cells which resume growth on its removal.

So it seems that *E. coli* and *P. mirabilis* react to the presence of penicillins in three ways: rapid lysis, predominant in the case of *E. coli*; transformation to spheroplasts, predominant in the case of *P. mirabilis*; and bacteriostasis, manifest in a small proportion of both species.

Guze and Kalmanson[7] and others have demonstrated the importance of spheroplasts in the persistence of infection, where osmotic conditions are favourable. The dormancy of intact bacterial cells in the presence of high concentrations of antibiotics may offer an even more efficient survival mechanism, for it is totally independent of the osmotic ambience. Such cells might also prove to be important in being resistant to other factors, such as the bactericidal action of serum, to which spheroplasts are highly susceptible[9].

Rapid Detection of Penicillin Sensitivity in *Staphylococcus aureus*

Conventional antibiotic sensitivity tests require many hours for accurate interpretation. We have now discovered a means of detecting the effects of the antibiotic penicillin on viable bacteria within minutes, by observing changes in the differential light scattered from bacterial suspensions. Sensitivity to penicillin in *Staphylococcus aureus* is detectable in as little as 3 min after the addition of the antibiotic.

The effect of penicillin and its derivatives on the integrity of the cell wall of sensitive bacterial strains is well known. Indeed, recent[1] scanning electron micrographs of ampicillin-treated sensitive strains have vividly shown the resulting deterioration. Differential light scattering patterns of bacterial suspensions are extremely sensitive to any changes in shape, size, structure or size distribution[2], and would therefore be expected to provide an excellent means for rapidly observing the effects of antibiotics on cells. Differential light scattering has been applied to measuring species differences in bacteria[3] and morphological characteristics of living cells[4]. The principle of the differential light scattering method depends on the unique scattering characteristics of a dilute suspension of cells of fairly uniform size.

The penicillin sensitive (pen^s) and penicillin resistant (pen^r) strains of *S. aureus* used in our studies were obtained from clinical material. They exhibited the typical haemolytic, coagulase, and mannitol fermentation characteristics of virulent strains. In addition, we confirmed by conventional means that the pen^s strain was sensitive to less than 10 units of penicillin per ml. of fluid medium, while the pen^r strain was apparently unaffected when grown in the presence of 40,000 units per ml. Light scattering measurements were made with a Science Spectrum 'Differential I' light scattering photometer equipped with a vertically polarized helium–neon laser (632·8 nm) as the light source. The relative intensity of scattered light was recorded as a function of angle with respect to the forward direction defined by the incident laser beam. For the light scattering measurements, cells were diluted in water to a concentration of about 5×10^5 cells per ml. Fig. 1 shows the differential light scattering curves obtained for the pen^s culture growing exponentially at 37° C in brain heart infusion (BHI) both (*a*) before and (*b*) after treatment with 400 units of penicillin for 10 min. The dramatic changes induced by penicillin treatment included the total disappearance of the two scattering peaks shown in (*a*) and a large increase in the scattering noise. We interpret the former change as resulting from a significant broadening of the cell size distribution[4]. In addition, the increased noise of the scattering curves such as shown in Fig. 1*b* is manifest when suspensions contain significant amounts of cellular debris. So a variety of subtle changes in morphology as well as changes in cell dispersion and fragility were detectable within minutes after antibiotic treatment.

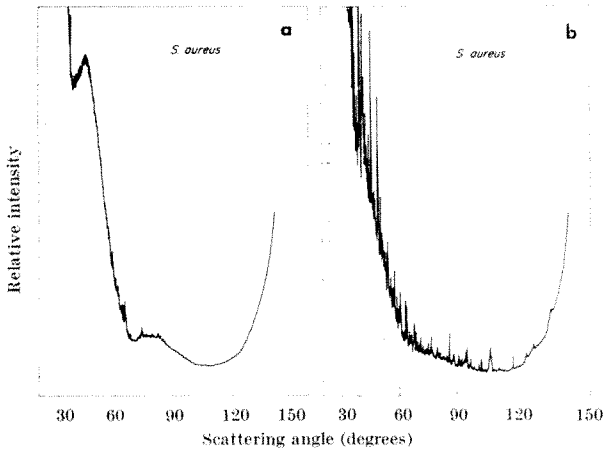

Fig. 1. Differential scattered intensity of 632·8 nm vertically polarized light from *S. aureus* (pen^s) during rapid growth in the presence of penicillin. After growth on BHI agar overnight, the culture was transferred to BHI broth and incubated for 20 min at 37° C. Light scattering measurements were made (*a*) at this time and (*b*) after another 10 min in the presence of 400 units of penicillin per ml.

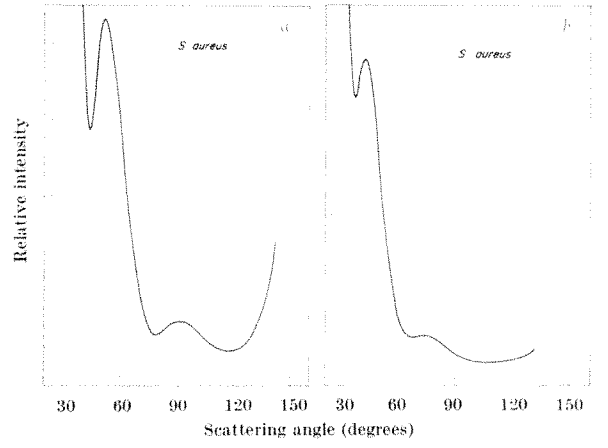

Fig. 2. Differential scattered intensity of 632·8 nm vertically polarized light from *S. aureus* (pen^s). Before the measurements, the cells were grown (*a*) in 2 per cent BHI at 37° C for 8 h, and (*b*) resuspended in fresh BHI broth for 20 min at 37° C.

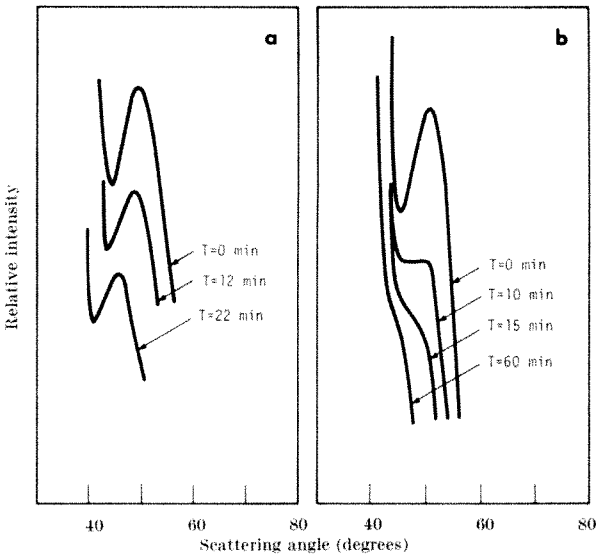

Fig. 3. Scattered intensity of 632·8 nm vertically polarized light from *S. aureus* (pen^s) in the region of the primary peak. Following a period of starvation, the culture was grown in fresh broth for 20 min at 37° C. At this time ($T = 0$), differential light scattering was measured on (*a*) a control lacking penicillin, and (*b*) a culture containing 400 units of penicillin per ml. The scattering intensities were measured at subsequent time periods as indicated.

To study in greater detail the changes in light scattering induced by penicillin, we performed experiments on pre-starved bacteria which are more uniform in size than growing cells. Strains of *S. aureus* grown overnight on BHI agar were transferred to a starvation medium which consisted merely of BHI diluted 1/50 with distilled water (2 per cent BHI). After incubation for several hours in 2 per cent BHI and in the absence of the antibiotic, the cells, which were growing slowly if at all, were transferred to normal BHI broth and incubated for 20 min at 37° C.

The differential light scattering characteristics of *S. aureus* after starvation and nutrient supplementation are shown in Fig. 2. Curve *a*, recorded at the end of the starvation period, is characterized by two well defined peaks located at angles typical of cells of approximately 500 nm average radius, and having a narrow size distribution[4]. Curve *b* shows the changes we observed in differential light scattering after the additional 20 min period in BHI broth undiluted. The marked shift in the light scattering peaks to lower angles and the decrease in the relative depths of the minima correspond, respectively, to an increase in average cell size and a broadening of the size distribution[4]. Such changes clearly indicate an acceleration in growth rate. During this period of accelerated growth the sample was divided and to one aliquot 400 units of penicillin were added ($T = 0$). The subsequent changes in differential light scattering in the region of the primary peaks are shown in Fig. 3. In the control culture (*a*), the changes which occurred during the next few minutes were small. The consisted of a decrease in the depth of the primary minimum and a displacement of the peak to lower scattering angles, effects caused by further increases both in cell size and in size distribution[4]. During the same growth period, however, light scattering characteristics of penicillin treated cells (*b*) were clearly altered after 10 min, and we observed a continued degradation of the peak for about 1 h. In Fig. 3, we have smoothed out the characteristic noise so that these changes can be seen more clearly. The interpretation of the results shown is similar to that of the earlier experiment, although for the slower growing populations the time scale obviously has been widened.

When a pen^r strain of *S. aureus* was used in identical experiments no difference could be observed between light scattering curves in the presence or absence of the antibiotic.

We specificially chose penicillin for this initial study because of its potent inhibition of cell wall synthesis, an effect which leads to gross morphological changes in growing populations. But the extreme sensitivity of differential light scattering to small physical changes suggests that it will be useful for other drug studies as well.

Radiation Stimulated Incorporation of ^{3}H-Thymidine into Diplotene Oocytes of the Guinea-pig

UNSCHEDULED synthesis of DNA has been observed in the nuclei of HeLa cells at some stage of the cell cycle other than the S-phase when cells are exposed *in vitro* to ultraviolet light or X-ray irradiation[1]. It has since been confirmed for several other cell types[2–5]. Part of the synthesis defined in terms of the uptake of ^{3}H-thymidine —which was detected in HeLa cells as the result of large doses of ultraviolet irradiation—was non-semiconservative (repair replication), corresponding to the insertion of DNA precursors into extant parental DNA strands. Here I present evidence that X-irradiation of a 1 day old female guinea-pig with 5,000 rad is followed by a small but autoradiographically detectable incorporation of ^{3}H-thymidine into the DNA of diplotene oocytes. In the guinea-pig, the mouse and most other mammals the premeiotic DNA synthesis occurs during embryonic life[6]. After birth the oocytes have all entered prophase of meiosis during which no DNA synthesis is normally observed.

Three 1 day old female guinea-pigs received 5,000 rad of X-rays (6 meV, dose rate 385 rad/min). The animals were injected intraperitoneally immediately before irradiation with 50 μCi/g of ^{3}H-thymidine (5·0 Ci/mmole, Radiochemical Centre, Amersham) and with the same amount of precursor 15 min later in order to be sure that ^{3}H-thymidine was available during and shortly after the irradiation. Three animals served as controls and received ^{3}H-thymidine only. The animals were killed 1 h after the last injection. The histological sections of the ovaries from the experimental group and the control group were stained by the Feulgen technique, coated with Ilford 'K2' liquid emulsion, exposed for 8 or 12 weeks and developed together.

In the autoradiographs a few grains were observed over the oocyte nuclei from the irradiated as well as from the control animals. The number of grains over each oocyte nucleus was counted and the number of grains over an area of exactly the same size just beside the nucleus (representing the background labelling) was subtracted.

The grain counting over areas of equal size was performed by placing a glass slide with an engraved circle the size of an average oocyte nucleus in the ocular of the microscope. The specimens were coded before counting so that the observer was unaware of whether the specimens originated from irradiated or control animals.

Table 1. MEAN GRAIN COUNTS OVER OOCYTE NUCLEI CORRECTED FOR BACKGROUND LABELLING

	Experiment 1		Experiment 2	
	5,000 rad	Control	5,000 rad	Controls
Number of animals	1	1	2	2
Number of oocytes	241	203	197	185
Mean grain count (oocyte/background)	2·92 ± 0·20 (s.e.)	−0·21 ± 0·14 (s.e.)	1·87 ± 0·16 (s.e.)	0·09 ± 0·05 (s.e.)

In both experiments the mean grain count over the oocyte nucleus in irradiated animals is significantly higher than the background count (Table 1). In the control animals there is no significant difference. These results indicate that there is a small but significant incorporation of ^{3}H-thymidine into DNA of diplotene guinea-pig oocytes after irradiation with 5,000 rad of X-rays. By comparing the number of grains over the oocyte nuclei with the number of grains over the follicle cells that were in normal S-phase at the time of ^{3}H-thymidine injection, the radiation stimulated incorporation of ^{3}H-thymidine was roughly estimated as being less than 10 per cent of the amount incorporated during normal replication of DNA. This result is of the same order of magnitude as was observed in the radiation stimulated incorporation of DNA precursor in human blood lymphocytes *in vitro*[4].

Whether some of the ^{3}H-thymidine incorporated into guinea-pig oocytes after irradiation is the result of repair replication is not yet clear. Painter and Cleaver[5], however, have examined several kinds of cultured mammalian cells after exposure to ultraviolet light. They found that all kinds of cells in which unscheduled DNA synthesis was observed also exhibited repair replication, and there seemed to be a rough correlation of the extent of the two phenomena suggesting that they both are manifestations of the same process. The guinea-pig oocytes seem to be much more resistant to irradiation than oocytes of mice and rats[7]. The question therefore arises whether the unscheduled DNA synthesis observed after irradiation can be correlated with the higher resistance to irradiation of guinea-pig oocytes compared with oocytes of rats and mice. In a few experiments the incorporation of ^{3}H-thymidine into mouse oocytes was investigated after irradiation with 200 rad of X-rays, which kill almost all oocytes in less than 24 h. There was no autoradiographically detectable incorporation of ^{3}H-thymidine into mouse oocytes, which is in accordance with the suggestion of a correlation between the extent of unscheduled DNA synthesis and repair synthesis, and the survival of the oocytes after irradiation.

Sarcoma Blockade *in vivo*: Rabies–Rous System in Chickens

A RECENT review[1] describes the systems involved in inhibition of viral oncogenesis by non-oncogenic viruses and emphasizes the possible use of attenuated viruses as anti-neoplastic agents. This communication describes the total *in vivo* blockade of the tumour produced by

Rous sarcoma virus (RSV), an avian subgroup A leucovirus[2,3], by a vaccine strain of rabies virus (RV), a rhabdovirus[2].

The Paris strain of live, fixed RV (Semple vaccine), prepared in rabbit brain[4] and giving a titre of $10^{6.5}$ to $10^{7.2}$ adult mouse LD_{50}/0·03 ml. (Reed–Muench), was used. Controls were a 10 per cent homogenate of normal rabbit brain (NRB) in 0·05 M sodium citrate buffer (*p*H 6·7) and ultraviolet-irradiated rabies virus (UVRV), the non-infectiousness of which was confirmed in adult white mice intracerebrally. RSV was the Bryan Master standard (strain 559). This material was injected into the wing webs of White Leghorn chickens (3–5 days old) in 0·05 ml. amounts. On days 7–10, 10 per cent tumour homogenates were prepared in citrate buffer and titrated on the chorioallantoic membranes (CAM) of 11 day chick embryos, the titres ranging between $10^{6.9}$ and $10^{7.0}$ pock forming units p.f.u./0·1 ml. Chickens were highly susceptible to the RSV, only 2·0 per cent being resistant. Daily tumour progress was recorded for at least 21 days following RSV inoculation. The criteria of total sarcoma blockade were (*a*) absence of tumour for 21 days, (*b*) absence of plasma anti-RSV neutralizing antibody.

Fig. 1 (pooled data from four experiments, each in duplicate) presents the time–effect relationship of the blockade. The maximal effect seen (44·4 per cent) was with RV at 48 h. Mean latent periods (arithmetic), although not depicted in Fig. 1, were significantly longer in RV and UVRV groups at 0, 24 and 48 h. No blockade was seen at −24 h, indicating absence of oncolysis. The possibility of its later occurrence, however, cannot be ruled out: as pointed out by Takehara *et al.*[5], it is difficult to distinguish between oncolysis and interference in such systems. Stewart and Sulkin[6] were unable to demonstrate interferon in hamsters for 24 h after rabies virus inoculation: the appearance of blockade at zero time in our system is therefore unusual. Further, the reduction in the blockade at 24 h as compared with that at 0 h leads one to wonder whether there is more than one interference mechanism.

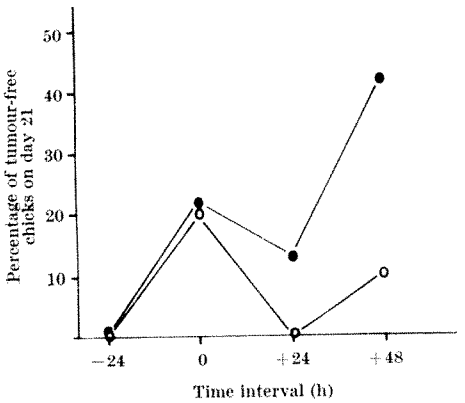

Fig. 1. Time–effect relationship. 6–8 day chicks inoculated with RV (●) or UVRV (○) or NRB* (0·05 ml. amounts per web bilaterally) and challenged with 0·05 ml. RSV at varying time intervals: RSV 24 h before RV, UVRV or NRB (each group containing 18, 8 and 5 chicks, respectively); RSV with RV or UVRV or NRB as single inocula (25, 10, 5); RSV 24 and 48 h after RV, UVRV or NRB (18, 8, 5). The RSV concentration was $10^{3.9}$ chick CAM p.f.u./0·1 ml. and RV concentration $10^{4.8}$ adult mouse LD_{50}/0·1 ml. NRB was used at the 10^{-2} dilution.

* Because all NRB controls became tumour-positive by day 7, they are omitted from the graph.

The next set of experiments investigated the RSV dose–response relationship of the blockade. Fig. 2 summarizes this relationship when the birds were treated with RV, UVRV or NRB 48 h before RSV inoculation. A graded increase in the percentage of tumour-free chicks was clearly demonstrable with increasing RSV dilution. RV and UVRV pretreatment shifted the dose–response curves in the direction of higher RSV concentration.

That the blockade was transient in nature became apparent when 33 tumour-blocked chicks, rechallenged with RSV, became tumour-positive by day 7. Here the time-interval range between the initial RSV inoculum and the rechallenge was 30–49 days. The transient nature of the blockade suggested that interferon-like substances might be the mediators. Preliminary experiments at 48 h—RV or UVRV inoculation followed by contralateral RSV challenge—indicate that the effect can be produced at a distant site. Further, the blockade seems to be reversible by hydrocortisone[7] and by actinomycin D[8]. So although at 48 h this evidence supports the hypothesis that the effect is mediated by interferon-like substances, the possibility that more than one mechanism is involved cannot be excluded for the reasons stated.

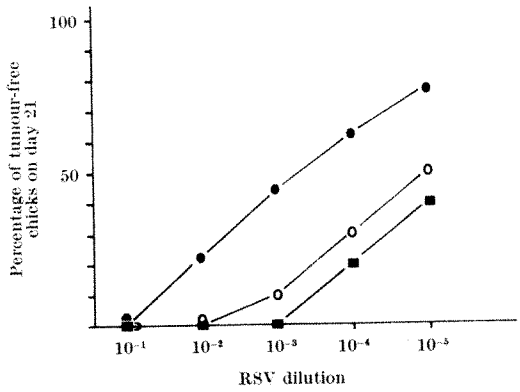

Fig. 2. Dose–response relationship. 3–7 day old chicks treated with RV (●) or UVRV (○) or NRB (■) in 0·05 ml. amounts/web in groups of 18, 10 and 5, respectively, challenged with serial ten-fold dilutions of RSV 48 h later. The 10^{-1} dilution of RSV corresponded to $10^{6.9}$ chick CAM p.f.u./0·1 ml. The concentration of RV used throughout was $10^{4.8}$ adult mouse LD_{50}/0·1 ml./chick. The NRB used was identical to that already described.

Absence of anti-RSV neutralizing antibody in tumour-blocked chicks suggests that Rous associated viruses RAV-4 and RAV-5[2] have also been totally suppressed. This seems to be unusual in a single *in vivo* system[9]. If this system is interferon mediated, and in the light of Wheelock and Sibley's work with the 17-D strain of yellow fever virus[10], it seems possible that interferonogenic, attenuated, avianized strains of rabies could be used to confer longer protection against RSV and RAV-4,5.

I thank Dr N. K. Dutta, Haffkine Institute, Bombay, for laboratory facilities, Drs S. S. Rao, A. N. D. Nanavati, M. V. Shirodkar and Mr P. B. Sehgal for help, and Mr R. V. Ghatikar for technical assistance.

Gerbich Blood Group System: a Useful Genetic Marker in Certain Melanesians of Papua and New Guinea

THE red cell antigen Gerbich (Ge^a), thought to be among the most widely distributed of blood group antigens, was first noted in 1960 when three women who lacked the antigen made anti-Ge^a in response to pregnancy[1]. Subsequently a further fourteen Ge(a−) subjects were discovered through the presence of anti-Ge^a in their serum, the antibody selecting them out of perhaps millions. The seventeen propositi were from ten different countries and were of European, Mexican, South American Indian and Negro extraction. Some of the sibs of these propositi were also Ge(a−), but outside their families no Ge(a−) subject was found in testing nearly 40,000 random people, chiefly Europeans but including more than 1,000 Negroes and more than 100 Asiatics[1,2]. The antigen was shown to be a dominant character and its locus to be genetically independent of those responsible for most of the established blood group systems[2].

A native of New Guinea, Mrs Imp., previously transfused after a post-partum haemorrhage, needed a transfusion after the birth of her second child and was found to have a strong immune IgG type antibody, which reacted with the cells of all of 700 samples from white people in Port Moresby and Brisbane: it did not react with the cells of thirteen of 371 random natives from widely spread places in Papua and New Guinea. In London, Mrs Imp. was, surprisingly, found to be Ge(a−) and her antibody to be anti-Ge^a. (Mrs Imp. does not belong to the very rare subtype[2] of Ge(a−) known as "Yus".)

Gene frequencies calculated from the 371 random Melanesian people would be misleading, for it is noteworthy that eleven of the thirteen Ge(a−) people live on the north-east coast line between Lae and Samarai. These eleven Ge(a−) coastal natives belong to at least six well recognized ethnic groups, from whom only fifty-two samples have so far been tested. Tentative gene frequencies along this strip of coast are therefore Ge^a 0·54 and *Ge* 0·46, a startling divergence from the Ge^a 1·00 and *Ge* 0·00 of the rest of the tested world.

Mrs Imp.'s husband, mother-in-law and child are also Ge(a−): she and her husband's family come from a village about 100 miles from Lae up the Markham Valley, and have no known coastal affinities. The Markham Valley is sparsely populated, however, and movement along it from the coast would have presented no problems.

We hope that this brief report may encourage those involved in surveying blood groups of remote people to include tests for antigens, such as Ge^a, known in a different part of the world to be possessed by virtually everyone and therefore thought incapable of providing any useful genetical information. Extensive testing of Melanesians is now planned, but the relatively small investigation recorded here was sufficient to bring to light a most dramatic difference in the frequencies of the Gerbich blood group genes.

We thank Dr N. Muirden and Mrs C. Brady of the Department of Public Health, Mount Hagen Hospital, New Guinea, for referring the original sample from the patient.

Lymphocyte Stimulation by Bovine β-Lactoglobulin

In vitro stimulation of lymphocytes, by either specific or non-specific mitogens, is accompanied by increased DNA synthesis[1]. During a study of milk sensitivity in ten patients with gastrointestinal disease (including seven with coeliac disease) it was observed that β-lactoglobulin had a mitogenic activity of the same order as phytohaemagglutinin (PHA) both in patients and in five healthy controls.

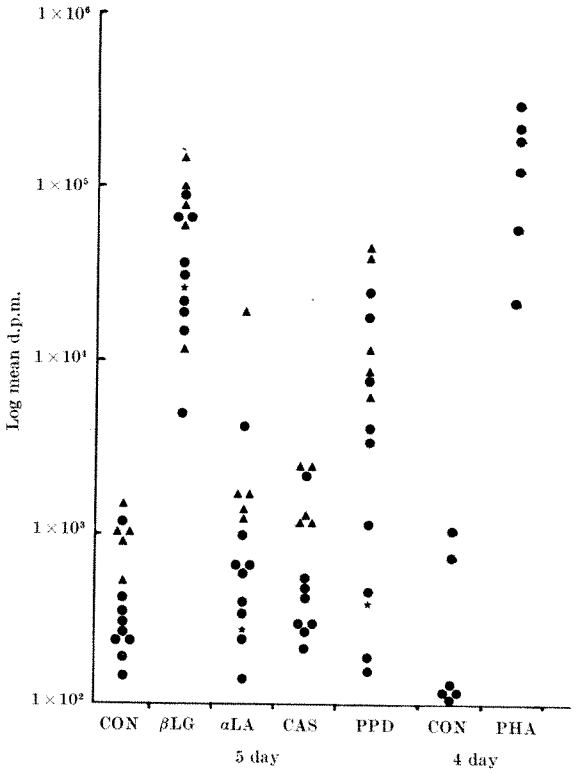

Fig. 1. DNA synthesis expressed as log mean disintegrations per min (log mean d.p.m.) for healthy controls (▲) and patients (●) with gastrointestinal disease. Control cultures (CON) containing no stimulant are compared with cultures containing 2 mg KL β-lactoglobulin (βLG), 2 mg KL α-lactalbumin (αLA), 2 mg BDH casein (CAS), 10 μg PPD or 0·033 ml. phytohaemagglutinin (PHA). The cultures of 1 patient ★ were all harvested on the fourth day.

Bovine β-lactoglobulin AB[2] and α-lactalbumin were purchased from Koch–Light (KL) Laboratories and β-lactoglobulin AB and casein hydrolysate were purchased from BDH. Bovine β-lactoglobulin AB, A and B, α-lactalbumin, casein and whole-whey protein were provided by Dr R. G. J. Lyster of the National Institute for Research in Dairying, Shinfield, Reading. Bovine β-lactoglobulin AB was prepared by Dr G. Pardoe of this department using pooled unpasteurized cow's milk within 24 h of collection. The milk was defatted by centrifugation at 4° C. PHA was purchased from Burroughs Wellcome. The contents of each ampoule were dissolved in 5 ml. of phosphate-buffered saline; 0·033 ml. was added per culture. Tuberculin purified protein derivative (PPD) was provided by the Ministry of Agriculture, Fisheries and

Food, Weybridge; 10 μg was added per culture. Staphylococcal filtrate was kindly prepared by Dr N. R. Ling in this department; 0·1 ml. was added per culture.

Peripheral blood lymphocytes were obtained from defibrinated blood by sedimentation with gelatin. The cells were spun down and re-suspended in Eagle's medium, supplemented with 15 per cent normal human serum, to give a final concentration of $1{\cdot}5 \times 10^6$ cells/ml. The serum used throughout was from two healthy individuals. Triplicate 2 ml. cultures (3×10^6 cells) were set up in 5 ml. snap topped phials containing either no stimulant, PHA, PPD, 0·1 ml. staphylococcal filtrate or 2 mg of the appropriate milk protein (the milk protein was dissolved in phosphate-buffered saline and sterilized by filtration). The cultures were incubated for 4 days in the case of PHA and 5 days for the other substances unless otherwise stated. Sixteen hours before the end of the culture period 1 μCi of ^{3}H-thymidine (150 mCi/mmole, Radiochemical Centre, Amersham) was added. When subsequently harvested two of each set of three were processed for DNA synthesis as described by Ling and Holt[3]. The radioactivity was counted in a Packard Tri-Carb scintillation counter, corrected to 100 per cent efficiency by the channel ratio method and DNA synthesis expressed as mean disintegrations per min (d.p.m.) for the two cultures. A Jenner–Giemsa stained smear was made from the third culture of each set.

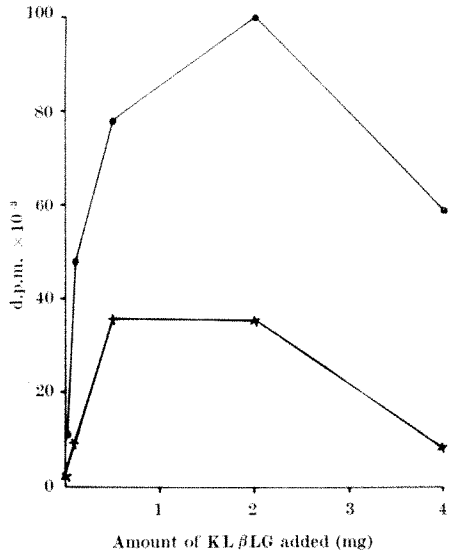

Fig. 2. DNA synthesis (d.p.m. $\times 10^{-3}$) in 5 day cultures of lymphocytes from two healthy individuals A and B produced by adding either 10 μg, 100 μg, 500 μg, 2 mg or 4 mg of KL β-lactoglobulin (KL βLG) to each culture. ×, Control A; ●, control B.

DNA synthesis in control cultures and test cultures for patients and healthy controls is shown in Fig. 1. In all cases there was marked stimulation of peripheral blood lymphocytes by 2 mg of KL β-lactoglobulin often of a similar order to that produced by PHA. By contrast, 2 mg of KL α-lactalbumin produced only moderate stimulation in one healthy individual and one patient, and either no, or minimal, stimulation in the rest, and this latter observation was also true for casein. Five healthy individuals and six patients responded to PPD to variable degrees; they were all Mantoux positive. Lymph node lymphocytes from three of the patients, obtained during diagnostic biopsy, were also tested with the same substances; the results were similar to those for peripheral blood lymphocytes.

DNA synthesis produced by different quantities of KL β-lactoglobulin AB in 5 day cultures of lymphocytes from two healthy controls A and B is shown in Fig. 2. A significant response was produced by the smallest dose used—10 μg per culture—and a maximum response by approximately 1–2 mg, beyond which increasing amounts of KL β-lactoglobulin AB seemed to be toxic.

The effect of harvesting the cultures on different days, from day 3 to day 9 inclusive, for staphylococcal filtrate, PPD and KL β-lactoglobulin AB is shown in Fig. 3. Staphylococcal filtrate produced a peak response between days 5–6, KL β-lactoglobulin AB at day 7 and PPD between days 6–8. A previous experiment with PHA showed a maximum response occurring between days 3–4.

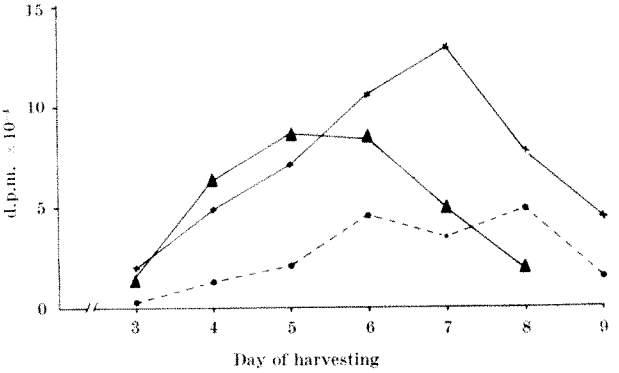

Fig. 3. The effect of harvesting cultures of lymphocytes from one healthy individual on different days. The lymphocytes were cultured in the presence of either 2 mg of KL β-lactoglobulin AB (×—×), 0·1 ml. of staphylococcal filtrate (▲—▲) or 10 μg of PPD (● - - - ●). DNA synthesis (d.p.m. $\times 10^{-3}$) on different days is shown for each substance.

In other experiments peripheral blood lymphocytes from the same five healthy controls were cultured in the presence of equal quantities of milk protein from various sources, and the results compared. The BDH β-lactoglobulin AB preparation produced very marked stimulation (mean degree of stimulation, 155× = ratio of mean radioactivities of the two test cultures to the mean radioactivities of the two control cultures). Shinfield β-lactoglobulin A, β-lactoglobulin B and β-lactoglobulin AB and our own preparation of β-lactoglobulin AB, however, produced either minimal or no stimulation (mean 9·4×, 1·9×, 1·3× and 1·0× respectively). Shinfield α-lactalbumin produced some stimulation (7× and 2×) in two individuals who also reacted to KL α-lactalbumin (66× and 8× respectively). Whole whey protein and defatted milk (sterilized by filtration), the latter in amounts varying from 0·033 ml. to 0·33 ml. (equivalent to approximately 100 μg and 1,000 μg of β-lactoglobulin), produced no stimulation. After dialysis for 24 h KL β-lactoglobulin AB retained its stimulatory capacity, while heating (100° for 10 min) reduced the degree of stimulation from 45× to 3×.

Intradermal skin tests using 100 μg of KL β-lactoglobulin AB produced a Mantoux-like reaction, maximal at 24 h in the 5 healthy controls with an area of induration ranging in size from 1·0 to 1·5 cm in diameter. There was no reaction to 100 μg of Shinfield β-lactoglobulin AB.

Cellulose acetate and polyacrylamide gel electrophoresis of the active and inactive preparations of β-lactoglobulin AB showed similar appearances and analytical ultracentrifugation produced a single peak.

Whatever the nature of the active substance it has a potency and range comparable with the strongest plant mitogens, such as PHA. The presence of such powerful mitogenic activity in two samples of demonstrably highly purified β-lactoglobulin (ascertained to be from different primary sources) and its absence from other purified or crude preparations suggest at least four possible explanations. (*a*) It may be a genuine property of β-lactoglobulin molecule lost (or gained in the case of active materials) in some processes of purification, or neutralized by inhibi-

tor substances in the inactive preparations; (*b*) it may be a mitogenic non-β-lactoglobulin bovine product in trace (< 1 per cent) amounts, which may or may not happen to be present in milk or milk preparations; (*c*) it may be a dietary constituent, such as a phytomitogen, which enters the milk only when the cows are fed on certain sorts of pasture or prepared feeds, or at certain seasons of the year; (*d*) it may be a contaminating bacterial mitogen (such as that derived from staphylococci) though it is unlikely to be a purely chance contaminant because two independent preparations contained it in much the same amount. If it is any sort of non-β-lactoglobulin contaminant (as in (*b*), (*c*) or (*d*)), it must fractionate preferentially with β-lactoglobulin and be active as a mitogen down to a concentration of approximately 0·1 μg, for KL β-lactoglobulin is at least 99 per cent pure, and 10 μg of this preparation shows appreciable activity; it is also apparently non-dialysable and thermolabile.

We thank Professor P. G. H. Gell for advice, Miss M. Smith, Miss C. Turner, Mr R. Shaw and Mr T. S. Dee for assistance and Dr D. R. Stanworth for the analytical ultracentrifugation. P. A. is supported by a grant from the Medical Research Council.

Prevention of Hypercholesterolaemia in Thyroidectomized Rats by Growth Hormone

The importance of the thyroid gland in the metabolism of cholesterol is illustrated by our finding[1-3] that the rate of conversion of cholesterol into bile acids is decreased in the absence of circulating thyroid hormone and its rate of synthesis in the liver is diminished. Conversely, an excess of thyroid hormone leads to increased conversion of cholesterol into cholate, enhanced hepatic synthesis, and less cholesterol in the plasma.

Recent observations indicate that other endocrine glands are concerned in cholesterol metabolism. We have demonstrated[4] that pituitary growth hormone is important in normal cholesterol metabolism in the rat. Because the secretion of growth hormone soon ceases in the absence of circulating thyroid hormone[5,6], we wondered to what extent the hypercholesterolaemia apparently arising from a deficit of thyroid hormone was in fact a result of a secondary deficit of growth hormone. We now present results suggesting that the hypercholesterolaemia resulting after thyroidectomy is largely the result of a lack of circulating growth hormone.

Thyroid extract and bovine growth hormone were administered in various combinations to groups of both hypophysectomized and thyroidectomized male rats (Long Evans strain). Untreated hypophysectomized, thyroidectomized and normal rats served as controls. Hypophysectomized rats and their controls were each given daily 55 ml. of an egg white, milk and oil diet containing 40 mg of cholesterol/100 ml. The thyroidectomized rats and their controls were given the same volume of a previously described[7] high cholesterol diet (273 mg/100 ml.). All rats completely consumed their daily allotment of food.

Blood samples were obtained weekly and analysed for their serum cholesterol content according to the method of Martinek[8]. In addition, all blood samples obtained from the hypophysectomized animals one week after surgery were analysed in a commercial laboratory (Bay Area Pathologists' Central Laboratory, San Francisco) for their serum thyroxine content according to the method of Pileggi and Kessler[9].

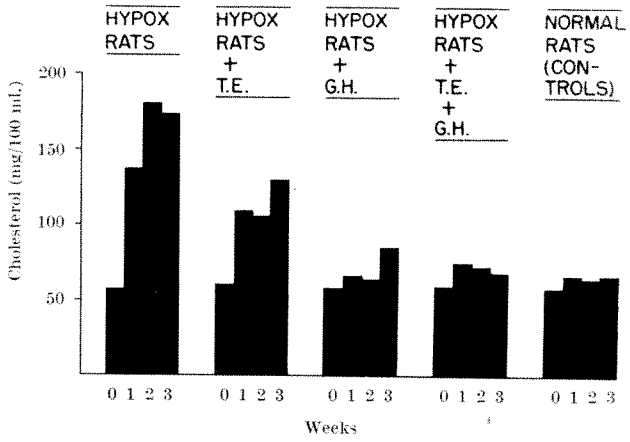

Fig. 1. Average serum cholesterol of untreated hypophysectomized (Hypox) rats (15), hypophysectomized rats (15) injected subcutaneously with 2 mg of thyroid extract daily, hypophysectomized rats (10) injected intraperitoneally with 300 μg of bovine growth hormone three times a day, hypophysectomized rats (8) injected with both thyroid extract and growth hormone, and normal control rats (10), following hypophysectomy in the first four groups.

As Fig. 1 illustrates, the average serum cholesterol of the untreated hypophysectomized rats rose significantly ($P < 0.001$) 1 and 2 weeks respectively after operation. Administration of thyroid extract to the group of hypophysectomized rats, while it did not prevent the hypercholesterolaemia entirely (see Fig. 1), did lessen it by comparison with that observed in the untreated hypophysectomized rats. The average serum thyroxine of these thyroid extract treated hypophysectomized rats 1 week after surgery was 1·9 μg/100 ml., a value not significantly different from that (2·1 μg/100 ml.) found in the normal control rats.

Administration of growth hormone to hypophysectomized rats essentially prevented the appearance of any hypercholesterolaemia during the 3 weeks of its administration, nor did injection of thyroid extract in addition to growth hormone increase the cholesterol-lowering efficacy of the growth hormone. The average serum thyroxine in these rats 1 week after surgery was normal (2·1 μg/100 ml.).

Untreated thyroidectomized rats exhibited a moderate rise in their serum cholesterol 1 week after surgery, and a much more marked rise at the end of the second and third weeks (see Fig. 2). We believe the greater rise in the serum cholesterol of these thyroidectomized rats (compared with hypophysectomized rats) was a consequence of their cholesterol-rich diet. Administration of thyroid extract to thyroidectomized rats prevented the otherwise expected hypercholesterolaemia; but when it was discontinued at the end of the third week, a marked hypercholesterolaemia ensued (see Fig. 2). Administration of growth hormone alone to thyroidectomized rats was essentially as effective as thyroid extract in preventing the occurrence of hypercholesterolaemia. Again, as with the thyroidectomized rats given thyroid extract, stopping growth hormone administration led in 1 week to a marked rise in the serum cholesterol of these previously growth hormone-treated rats (see Fig. 2).

In a previous study[4] we observed that the hypercholesterolaemia of the hypophysectomized rat could be minimized by administration of 300 μg of growth hormone per day. We now find that the hypercholesterolaemia of the hypophysectomized rat can be prevented completely by a larger dose of growth hormone (900 μg/day).

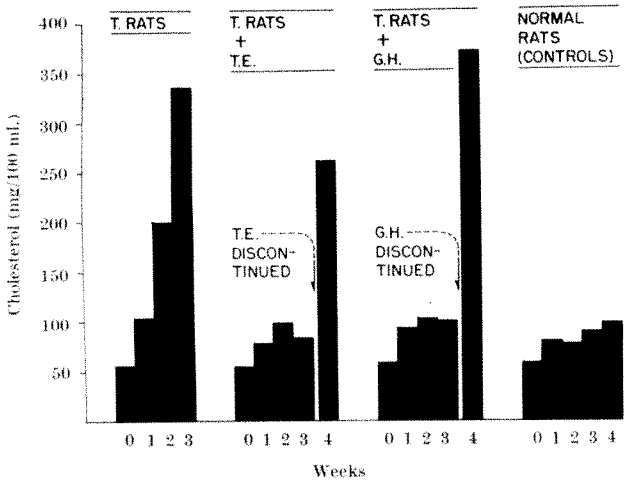

Fig. 2. Average serum cholesterol of untreated thyroidectomized (T) rats (10) thyroidectomized rats (10) injected with 2 mg of thyroid extract daily, thyroidectomized rats (15) injected with 300 μg of bovine growth hormone 3 times a day, and normal control rats (10), following thyroidectomy in the first three groups. Three weeks after thyroidectomy, the administration of both thyroid extract and growth hormone was discontinued in the two groups receiving these hormones.

These results also indicate that even in the thyroidectomized rat, growth hormone is as efficacious as thyroid hormone in preventing hypercholesterolaemia. When this fact is considered together with the observation[5,6] that secretion of growth hormone markedly diminishes after thyroidectomy, it seems possible that the chief cause of the hypercholesterolaemia following thyroidectomy may be the latter's effect on the secretion of growth hormone. Thyroxine, however, undoubtedly plays some part in the control of serum cholesterol level because its administration to the hypophysectomized rat, which is not secreting growth hormone, does mitigate[4] the animal's hypercholesterolaemia.

We thank Dr C. H. Li, Hormone Research Laboratory, University of California Medical Center, San Francisco, for the bovine growth hormone. This work was supported by grants from the US National Institutes of Health, National Heart Institute, the Tarrant County Heart Association and the Burroughs Wellcome Fund.

Quantitative Tissue of Human Malnutrition using Scalp Hair Roots

THERE is at present no adequate way of detecting or quantifying slight degrees of protein or protein/calorie deficiency. Yet such deficiencies may affect health: malnutrition is known to increase susceptibility to infection and interferes with normal development in children. We therefore set out to find a measure of protein deficiency which would be simple to use on humans in the field and more sensitive than measurement of hair shaft thickness[1,2] or root diameter[3] or serum protein concentrations[4], which are subject to such influences as haemodilution. At best serum proteins provide an indirect measure of tissue protein metabolism. A more direct assay can be obtained from scalp hair roots which are easily accessible and are sensitive to systemic influences including drug toxicity[5,6], poisoning[7] and malnutrition[8]. Bradfield[3,8,9] has demonstrated the potential value of morphological examination of hair roots in the evaluation of protein or protein/calorie deficiencies, but experienced observers are needed for this technique, which is subjective and only semi-quantitative. These studies were performed to evaluate a method which can provide accurate quantitative objective data which reflect both hair root size and partial tissue loss in a single numerical value.

Hair roots were epilated manually by means of 'Tygon'-sheathed surgical needle-holding forceps from the parieto-occipital area. The hairs were placed immediately in physiological saline and examined with a dissecting microscope. Resting (telogen) hairs were removed. (In separate experiments resting hairs were shown not to contribute protein or DNA to the measurements used.) Total 1 M NH_4OH soluble protein/hair root was determined with groups of 10–40 hairs by the Lowry method[10]. Total DNA extracted in the NH_4OH was measured by modification of the method of Kissane and Robins[11]. (Neither DNA nor protein is extracted in significant amounts from fully formed hair shafts, so the length of shaft left attached to the root does not affect the results.) For special comparisons, individual hair root volume was measured by optical estimation of linear displacement of water in a calibrated micropipette capillary tube under a dissecting microscope, and volume/hair root values were converted from the known dimensions of the capillary tube. As with protein or DNA measurements inclusion of variable amounts of shaft does not significantly change the results. Serum albumin was determined by densitometric scanning of paper electrophoretic separations and calculation of percentage of total protein. Serum transferrin was estimated by 'Partigen' quantitative immunodiffusion plates[12].

Control protein/hair root values averaged $18{\cdot}02 \pm 5{\cdot}25$ μg (mean $\pm \sigma$) in 191 observations made on fifty-three individuals. The values were normally distributed and all fell within two standard deviations of the mean. There was no difference with age or sex between 18 and 90 years; racial differences have not yet been ruled out. Protein/hair root in several chronic mental patients, selected for their clinically evident malnutrition and histories of inadequate protein–calorie intake, ranged from 1·5 to 7·5 μg, all clearly below the control range. Similarly, hair shipped from Africa (courtesy of Dr Stewart Weegan, Communicable Disease Centre, Atlanta, Georgia) from both children and adults with severe kwashiorkor or marasmus showed very low values; hairs from well fed individuals shipped simultaneously had normal amounts of protein.

Concomitant measurement of serum albumin, transferrin and protein/hair root in a large series of hospital and clinic patients with known or suspected protein/calorie malnutrition proved that hair root protein was often more sensitive than either serum protein. Many patients showed low hair root protein with normal serum albumin or transferrin. Feeding several patients resulted in increases in hair root protein concomitantly with gain

of weight (Fig. 1). Moreover, in several instances this increase in both protein/hair root and body weight occurred with no discernible change in serum albumin and transferrin, which were already normal.

Comparison of the hair root protein with the DNA content and measurement of volume of the same hairs over the range of protein values (Fig. 2) demonstrated that all these values are directly and quantitatively related. The response of the hair root to protein/calorie malnutrition in addition to decrease of soluble protein content is therefore one of reduction in size and cell number, a phenomenon which has been noted experimentally in other tissues such as intestinal mucosa[13].

Similar suggestions were made by Short *et al.*[14] who painstakingly examined hair (wool) follicles from a single sheep during an extended period of low food intake compared with a period of high food (protein supplemented) intake. The hair roots showed a decrease in mitotic rate, follicle size and number of cells during the low intake period.

Hair root protein thus reflects hair root volume, and so can be used as a measure of the size reduction and of the loss of specific tissue elements found in malnutrition[8,9]. Morphological evaluation is therefore unnecessary except for separation of growing (anagen) from resting (telogen) hairs, a procedure which may be useful in any case for distinguishing between protein deficiency, which is said to reduce diameter of hairs, and calorie deficiency, which appears to increase the proportion of resting hairs[9]. Histological evidence of atrophied "hair papillae" in pigs on a high calorie–low protein diet[15] agrees with this interpretation.

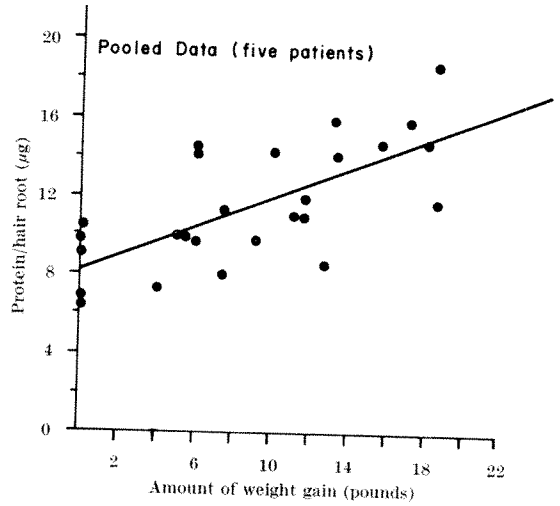

Fig. 1. Hair root protein increases significantly with refeeding of five malnourished individuals. Three of the patients had initial hair values in the "low normal" range and normal serum proteins. $n=26$; $r=0{\cdot}7040$; $0{\cdot}001<P<0{\cdot}01$.

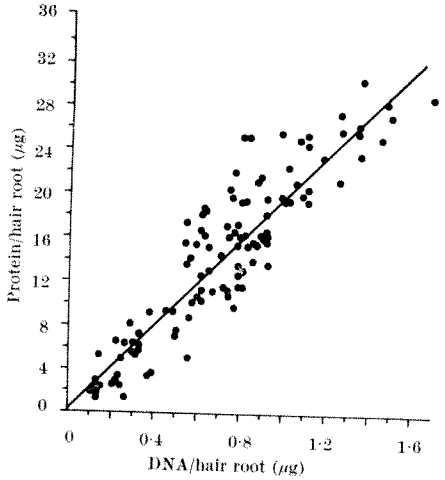

Fig. 2. The amount of DNA/hair root in plucked hairs correlates directly and highly significantly with the protein content. $n=112$; $r=0{\cdot}9176$; $P\ll0{\cdot}001$.

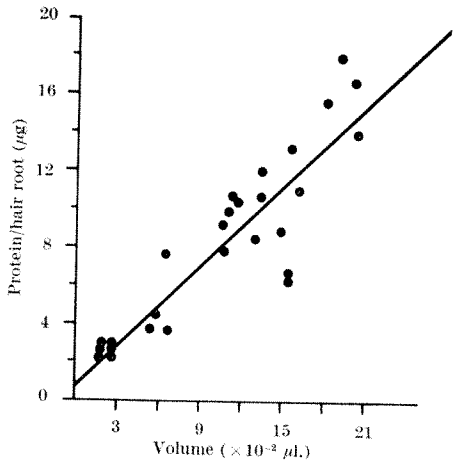

Fig. 3. Individual hair root volume and protein content are directly proportional. Because total DNA is similarly related to protein (Fig. 2) the plucked hairs from malnourished individuals are both smaller and contain fewer cells. So any of the three techniques quantify size diminution and/or completeness of hair root tissue[7,8]. $n=27$; $r=0{\cdot}9033$; $P\ll0{\cdot}001$.

Effects of Glutaraldehyde on the Protein Loss and Photochemical Properties of Kale Chloroplasts: Preliminary Studies on Food Conversion

Ruminant animals are adapted to survival in adverse nutritional conditions. The alimentary tract has an expanded portion, the rumen or fore-stomach, where extensive microbial fermentation makes available the energy of bulky foods and fibrous materials before the food passes into the rest of the digestive tract. Extensive degradation of dietary protein, however, occurs in the rumen to give large amounts of ammonia and fatty acids.

Some of the ammonia is synthesized into microbial protein. Microorganisms are eventually digested after passing from the rumen. Large amounts of ammonia, however, pass through the rumen epithelium into the blood system and are eliminated chiefly in the urine after conversion to urea in the liver. From this point of view the ruminant is inefficient with regard to protein conversion, especially when high grade protein diets are given.

Chloroplasts are a very important source of dietary protein for herbivores. When the outer membrane of the chloroplast is ruptured the soluble stroma proteins are released, although the lamellar system is retained together with the capacity for photochemical electron transport and photophosphorylation. The degradation of soluble protein which occurs in the rumen results in a lowered nitrogen and energy retention[1,2]. Reis and Schinckel[3] and Reis[4] showed that abomasal administration of casein increased wool growth, and other work has shown[5,6] that casein treated with formaldehyde was not degraded in the rumen and increased wool growth and nitrogen retention. Zelter *et al.*[7] have prevented deamination by rumen fluid *in vitro* by treatment with tannins or aldehydes. Mangan and Pryor[8] showed that intact chloroplasts were ingested by entodiniomorphid protozoa in the rumen and degraded without producing large quantities of ammonia. During mastication of herbage, however, large amounts of soluble protein and chloroplast material may be released into the food bolus[9], revealing extensive damage to chloroplast membranes.

West and Packer[10] studied the effects of glutaraldehyde on the light-induced reactions and osmotic properties of pea chloroplasts. We wish to describe an investigation of the effects of similar glutaraldehyde treatment on the protein lost from chloroplasts after osmotic shock, and of their digestibility *in vitro*. Osmotic shock was chosen as the simplest way to rupture the chloroplast membranes and release the soluble stroma proteins which would normally be released during mastication. Measurements of the ferricyanide Hill reaction were made to establish the photochemical state of the original chloroplast preparations and to indicate the extent of glutaraldehyde fixation.

Marrowstem kale (*Brassica oleracea* L. variety *Acephala* D.C. (marrowstem)), available during the winter, gave good chloroplast preparations when ethylenediamine tetraacetic acid (EDTA) was incorporated into the grinding medium: there seems to be an excess of calcium over oxalate in this plant (personal communication from R. Hill). Walker's rapid homogenizing technique was used[11], and the chloroplasts were kept at 0° C unless otherwise stated. Leaves (80 g) freed from large veins were homogenized for 3·5 s in 500 ml. of a part frozen slurry of 0·4 M sucrose, 0·04 M sodium phosphate, *p*H 7·4, 0·01 M EDTA and 0·01 M sodium iso-ascorbate using an 'Ultra-Turrax T 45' (Janke and Kunkel, Staufen, Germany) with a 4·5 cm head (TP 45G). The homogenate was squeezed through eight layers of muslin and filtered through twelve layers. After centrifugation at 1,000*g* for 5 min the pellets were combined in 20 ml. 0·4 M sucrose. The chloroplasts which sedimented after 2 min at 3,500*g* were suspended in 0·4 M sucrose to give a chlorophyll concentration[12] of about 2 mg/ml. and used as the stock chloroplast preparation. Each 80 g kale preparation gave 10–14 mg of chlorophyll with 50–80 per cent of the chloroplasts intact. Preparations with low proportions of whole chloroplasts were always obtained after severe weather.

Oxygen production (Table 1,*a*) and protein content of the original chloroplast preparations were measured. Four equal volumes of the chloroplast stock containing 3–13 mg of chlorophyll were incubated with 0, 60, 120 and 240 mM glutaraldehyde (Polysciences Inc., Warrington, Pennsylvania) in 2–10 ml. of 0·5 M sucrose for 7 min. The glutaraldehyde was removed by diluting with 10–30 volumes of 0·4 M sucrose and sedimenting the chloroplasts at 10,000*g* for 15 min.

The treated chloroplasts were shocked osmotically to release stroma proteins by suspending them in 3–8 ml. of distilled water for 20 min. These chloroplast suspensions complete with soluble nitrogen compounds were sampled for nitrogen and chlorophyll content and digestibility. They are referred to as osmotically shocked complete preparations (Table 1,*b*).

Table 1. EFFECT OF GLUTARALDEHYDE ON PROTEIN LOSSES, DIGESTIBILITY AND THE OXYGEN PRODUCTION OF KALE CHLOROPLASTS

Experiment			Original preparation	Treated chloroplasts: mM glutaraldehyde 0	60	120	240
1	Chloroplasts about 50 per cent intact before GADH		—				
	Oxygen (μmoles/mg of chlorophyll/h)		*a*	*d*	*d*	*d*	*d*

		10 h	—	100	91	62	31

This table summarizes the results of 3 sets of experiments. Details of the methods used are given in the text but the types of chloroplast preparation used and the general treatment are as given here.

Experiments 1 and 3

(*a*) The original chloroplast preparations had about 50 per cent of the chloroplasts intact. The chlorophyll and protein content and rates of photochemical oxygen production were measured.

(*b*) The four types of chloroplast produced after treatment with 0, 60, 120 and 240 mM glutaraldehyde (GADH) for 7 min, and its subsequent removal, were each suspended in an excess of water to give an osmotic shock. Samples of each were removed for measurements of chlorophyll and protein content. In experiment 3 the digestibility of the four types of chloroplast was also measured. The remainder of each of the four preparations was then centrifuged.

(*c*) The protein content of the supernatant liquids from the four (*b*) preparations was measured. The amount of protein released from each type of treated chloroplast by osmotic shock was found from the difference in protein content between the original preparation (*a*) and the values for each supernatant (*c*).

(*d*) Consisted of the four types of chloroplast fragments left from the (*b*) preparations after the supernatants (*c*) were removed. The chlorophyll and protein content of the particles were measured. Photochemical activity was measured in experiment 1 and the digestibility of the fragments measured in experiment 3.

Experiment 2

(*e*) All chloroplasts in the original suspension were stripped of membranes. Chlorophyll and protein content and photochemical activity were measured.

(*f*) After treatment with glutaraldehyde (0, 60, 120 and 240 mM) and its subsequent removal, the four types of chloroplasts were used to study oxygen production and digestibility.

After shocking, the chloroplasts were centrifuged at 10,000*g* for 20 min. The amount of protein released into the supernatant liquid was measured. The pellets of insoluble material containing most of the chlorophyll were suspended in 1–3 ml. of water and samples were taken for nitrogen and chlorophyll analyses and studies on digestibility and photochemical activity (Table 1, *d*).

Some chloroplasts were also stripped of their outer membranes and treated with glutaraldehyde. The fragments were used for the Hill reaction and digestibility studies (Table 1, *f*).

Protein values were calculated from: (total nitrogen − (non-protein nitrogen + chlorophyll nitrogen)) × 6·25. Analyses of total nitrogen and non-protein nitrogen after protein precipitation with 10 per cent trichloroacetic acid were made by Mr D. Jordan using an automated micro Kjeldahl apparatus. Measurements of the relative proportion of soluble stroma and insoluble lamellar protein have not been made but are probably of the order of 3 : 1 (ref. 13).

Photochemical activity was measured by following polarographically the oxygen produced during the light-induced reduction of potassium ferricyanide at 20° C in the absence and presence of 2 mM NH_4Cl (ref. 14). The 5 ml. reaction vessel contained 0·4 M sucrose, 10 mM Tris-HCl, *p*H 7·8, 2 mM $MgCl_2$, 4 μmoles of $K_4Fe(CN)_6$ and chloroplasts containing 100 or 150 μg of chlorophyll.

The digestibility of the chloroplasts was assessed by the release of non-protein nitrogen when incubated with trypsin or the pancreatin enzyme complex. Digestion mixtures of 1 ml. contained approximately 600 μg of chlorophyll from each of the four treated chloroplast preparations (0, 60, 120 and 240 mM glutaraldehyde), 80 mM phosphate buffer, *p*H 8·0, and 0·2 ml. of enzyme solution (0·25 mg twice crystallized trypsin or 1·25 mg of freeze-dried sheep pancreatic juice containing 125 μg of nitrogen). Nitrogen determinations were made on 0·3 ml. aliquots after 0, 5 and 10 h of incubation at 37° C. Values are given as a percentage of the nitrogen released (10 h of incubation) from chloroplasts treated with no glutaraldehyde.

Kale chloroplast preparations with about 50 per cent of their chloroplasts intact lost 31–35 per cent of their total protein after osmotic shock. Higher losses would be expected to occur from material with a higher proportion of intact chloroplasts originally. Treatment with glutaraldehyde reduced the losses to 6–12 per cent with 60 mM and 2–3 per cent with 120 mM. There was no reduction in the digestibility of osmotically shocked complete preparations after treatment with glutaraldehyde. Their apparent increase in digestibility may result from the binding of previously soluble proteins to the chloroplasts by glutaraldehyde treatment, thus increasing the amount of protein available, although the chlorophyll content was the same. The trypsin digestibility of the shocked chloroplast fragments after soluble material had been removed was little affected by glutaraldehyde. The pancreatin digestibility was reduced to about 30 per cent of the untreated value by 240 mM glutaraldehyde. These differences between trypsin and pancreatin are not easy to explain. Chloroplasts which were stripped of their membranes before fixation and had already lost much soluble protein were more affected by the glutaraldehyde treatment. Even in this extreme case, however, digestibility was much less affected than was the average protein loss, especially at the lower concentrations of glutaraldehyde. Results all indicate the possibility of reducing protein losses without a parallel reduction in digestibility.

Using pea chloroplasts, West and Packer found that complete fixation occurred with 200 mM glutaraldehyde. With kale, it was not possible to correlate the extent of fixation with changes in chloroplast volume after osmotic shock. It is likely, however, that the chloroplasts are similar and that fixation occurs with about 200 mM glutaraldehyde. Photophosphorylation was abolished in peas by 50–100 mM glutaraldehyde. In kale, the ATP/Pi-limited (basal) rate of oxygen production was maximal with 60 mM gluaraldehyde, after which progressive inhibition of the rate occurred. The ammonia-stimulated (uncoupled) rate of oxygen production shows the progressive inhibition which was also expected from the results with peas.

Kale seems to be promising for photochemical studies. The basal rate of electron transport was stimulated three-fold with ADP and Pi, in the rather poor preparations after severe weather. An average of 4·4-fold stimulation was given by 2 mM NH_4Cl. Oxygen production values (Table 1) for the original preparations and the treated chloroplasts were made after keeping the chloroplasts for 3–6 h respectively, indicating the stability of these chloroplasts.

Drug-induced Release of ^{3}H-Norepinephrine and ^{3}H-Serotonin from Brain Slices

EFFECTS on the release of proposed central neurotransmitters have been reported for several psychotropic drugs, and may contribute to the influence of these compounds in behaviour[1,2]. Most of our information on the influence of drugs on release of cerebral monoamines is indirect; for example, from comparison of tissue or cerebrospinal fluid levels of amines or their metabolites before and after drug treatment[3]. The interpretation of such data is complicated by direct drug effects on the metabolism of brain amines. Use of isolated, superfused sections of brain tissue, which actively accumulate exogenous norepinephrine or serotonin in nerve terminal structures normally containing these amines[4–7], affords a direct and sensitive means of assessing the influence of drugs on central neurohumoral release. Using this technique we have found that several drugs profoundly affect the spontaneous liberation of labelled norepinephrine and serotonin from slices of rat corpus striatum.

Slices of anterior corpus striatum weighing about 20 mg were rapidly prepared from the brains of adult Sprague-Dawley rats as previously described[8,9]. Tissues were incubated at 37° C in a supplemented Krebs–Ringer medium saturated with 5 per cent CO_2 in O_2 and containing either ^{3}H-norepinephrine (7 Ci/mmole, 15 ng/ml.) or ^{3}H-serotonin (6 Ci/mmole; 15 ng/ml.). After 30 min the slices were transferred to individual chambers through which fresh oxygenated medium was rapidly circulated (150 μl./min). After 40 min, when the efflux of radio-

activity had fallen to a nearly steady level the superfusing medium was suddenly switched to one in which the investigational drug had been dissolved. Sequential samples of effluent superfusate, collected at 2 min intervals just before and during drug exposure, were analysed for total tritium by liquid scintillation spectrometry.

Table 1. EFFECT OF DRUGS ON EFFLUX OF TRITIUM FROM STRIATAL SLICES INCUBATED WITH ^{3}H-NOREPINEPHRINE OR ^{3}H-SEROTONIN

Drug	Net release (pCi/min) ^{3}H-norepinephirine	^{3}H-serotonin
Metaraminol	1,400±130*	135±34*
D-Amphetamine	665±180*	331±34*
L-Amphetamine	460±150†	158±40*
Desipramine	442±105*	19±3*
Reserpine	150±25*	174±25*
Cocaine	36±10†	−6·3±6·7
Guanethidine	17·2±7·9	3·8±8·2
Lysergic acid diethylamide	14·3±4·4	−20·3±15·8
None	−7·7±13	−8±5·6
Picrotoxin	−13±10	−17±17
Chlorpromazine	−29±14	−32±5·2†
Pargyline	−29±9	−24±7·8

* $P < 0.01$.
† $P < 0.05$ when compared with control levels.

Slices were incubated with ^{3}H-norepinephrine or ^{3}H-serotonin, then superfused as described in text. Reported net release represents the difference in tritium efflux during the 2 min interval from 6–8 min after onset of drug exposure from tritium efflux during the 2 min interval just before drug exposure. Predrug efflux from ^{3}H-norepinephrine-incubated tissues was 143±20 pCi/min; from ^{3}H-serotonin-incubated slices 170±19 pCi/min. Results are the mean±s.e. for 4 or more slices.

Metaraminol (10^{-4} M), D- or L-amphetamine (10^{-4} M), desipramine (10^{-4} M) and reserpine (10^{-5} M) produced a substantial increase in tritium efflux from slices previously incubated with ^{3}H-norepinephrine or ^{3}H-serotonin (Table 1). In all cases the enhanced efflux of radioactivity occurred within 4 min after beginning drug superfusion and continued for several minutes thereafter. In general, tritium release from slices incubated with ^{3}H-norepinephrine equalled or exceeded that from tissues incubated with ^{3}H-serotonin. Release induced by metaraminol or despiramine from slices containing ^{3}H-norepinephrine exceeded by ten-fold or more release from slices incubated with ^{3}H-serotonin. Cocaine (10^{-4} M) produced a relatively small, yet statistically significant, rise in tritium efflux from tissues containing ^{3}H-norepinephrine, but not from those containing ^{3}H-serotonin. Guanethidine, lysergic acid diethylamide, picrotoxin, chlorpromazine and pargyline (all 10^{-4} M) failed significantly to modify the spontaneous efflux of either monoamine.

The radioactive constituents in the effluent superfusate from seven pooled samples (two slices each) were determined by column chromatography[10,11]. The unchanged amine accounted for 29±9 per cent of the total efflux of tritium collected during the 2 min interval just before drug treatment, from slices incubated with ^{3}H-norepinephrine. After exposure of the slices to D-amphetamine for 6 min, the free amine was released without change in deaminated products so that the proportion of ^{3}H-norepinephrine in the effluent superfusate increased to 67±11 per cent of the total recovered radioactivity. Reserpine, applied for a similar period, resulted in a proportionately similar increase in both amine and deaminated products and failed significantly to alter the proportion of amine (31±3·3 per cent) to total tritium. These findings support previous evidence that amphetamine releases physiologically active amines[12,13], while reserpine liberates amines into the intraneuronal cytoplasm where they are converted to inactive amine metabolites[14,15].

The next efflux of labelled monoamines from superfused brain slices measured in these experiments presumably reflects the difference in the rates of spontaneous release from intraneuronal stores and neuronal re-uptake. The relative rates of release and recapture undoubtedly play an important part in the regulation of monoamine concentrations within the synaptic cleft *in vivo*. Drugs may influence these levels by one or more mechanisms. Metaraminol, an α-methylated phenylethanolamine, probably releases norepinephrine by competitive displacement from intraneuronal storage sites[16], and may compete with norepinephrine for neuronal re-uptake[17]. Similar mechanisms may account for the mild effect of metaraminol on serotonin release. Amphetamine, desipramine and cocaine have all been shown to be potent inhibitors of monoamine uptake into cerebral tissues[18–20]. Cocaine does not seem to enhance release so the increase in efflux may be a consequence of inhibition of amine re-uptake. A direct releasing action of D-amphetamine and desipramine is, however, probable, for inhibition of uptake alone does not markedly enhance release. This action may account for the greater liberation of norepinephrine observed with these two compounds than with drugs which only affect re-uptake.

It is likely that exogenous norepinephrine and serotonin enter the relatively abundant dorso-anterior terminals in striatal tissue[21–23], and that the pharmacological properties of these terminals differ from those of other monoaminergic neurones[24–26]. Nevertheless, the results of these experiments provide direct evidence for the effect of certain drugs on mechanisms subserving the release of norepinephrine and serotonin and support the contention that changed perisynaptic levels of specific monoamines are responsible for the psychotropic actions of compounds such as amphetamine and desipramine.

Long-term Isolation in Rats reduces Morphine Response

Recently, interest has increased in the effects of previous home environments on reactions to drugs (for example, ref. 1) and experiments have been done on various species. Long-term isolation is known to induce aggressive behaviour and biochemical changes in mice[2], and it also disrupts

behavioural and physiological reactions in rats[3,4]. Isolation in both species increases their sensitivity to toxic effects of some stimulant drugs[5,6], but shortens barbiturate sleeping times in mice[7] and rats[8], and reduces the stimulant effects of amphetamine–barbiturate mixtures on the activity of rats in a Y-maze (Clarke, Rushton and H. S., to be published). It seemed important to study the effects of long-term isolation on some responses by rats to morphine.

In this experiment therefore weanling male hooded rats (average age 21 days) were ear-marked and assigned at random from their litters to either of two housing conditions: some were housed singly in cages with solid roofs and sides, and others in groups of twelve in standard colony cages. Food and water were available *ad libitum*, and the animals were not handled again until they were tested. Forty days later, each group was subdivided into two: one subgroup received 12·5 mg/kg intraperitoneal isotonic morphine HCl, a dose which pilot experiments had shown to be moderately depressant in male rats of similar age, and the other received 1 ml./kg intraperitoneal isotonic saline. The rats were replaced in their home cages, and 1 h after injection they were tested singly for 5 min in a symmetrical wooden Y-shaped runway, 13 inches high and with arms 15 inches long and 5 inches wide[9], which has been found suitable for the measurement of dose-related morphine effects on spontaneous activity (Fig. 1). The number of "entries" animals made into the arms of the apparatus (all four feet had to be inside an arm) and the number of "rears" (scored if the rats stood up on their hind feet) were counted; the total amount of time spent rearing throughout the 5 min period was measured in addition by means of an electronic timer.

As was expected from the pilot experiments, morphine markedly depressed the number of entries in the grouped

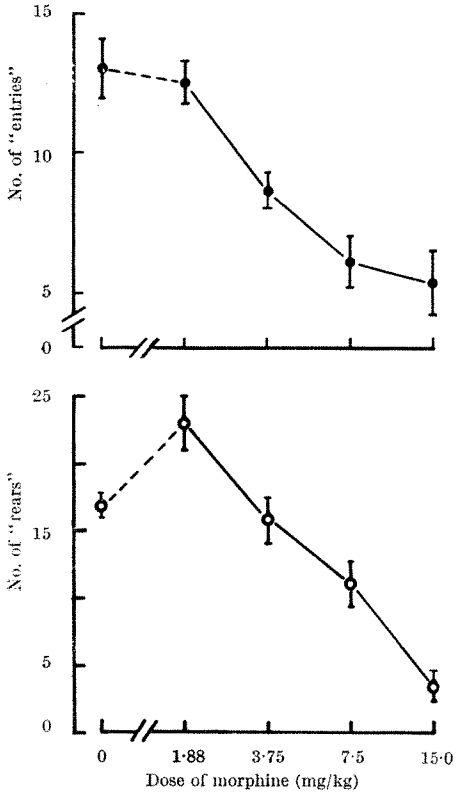

Fig. 1. Dose-related effects of morphine on Y-maze activity. The top diagram shows the mean number of "entries" ± one standard error into the arms of a Y-shaped runway made during 5 min, 1 h after subcutaneous injection of several doses of morphine, and the bottom diagram shows the corresponding results for "rears". Female rats approximately 120 days old were used, and each point represents the mean results of a different group of eight animals.

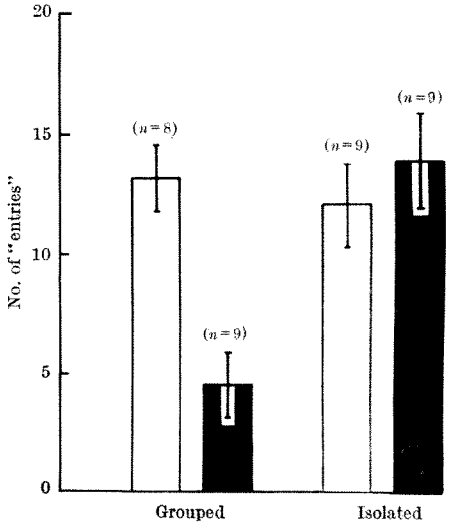

Fig. 2. Effects of morphine on grouped and isolated rats. The figure shows the mean number of "entries" ± one standard error into the arms of a Y-shaped runway made during 5 min by rats reared in groups or in isolation, which had received either saline (open columns) or 12·5 mg/kg morphine hydrochloride (solid columns). Morphine depressed activity in the grouped but not in the isolated rats.

rats and the size of the effect was also remarkably similar. In the isolated rats, however, entries were hardly depressed at all. 2 × 2 factorial analyses were performed on the results of all three measures, and the "entries" analysis revealed main effects, due to the drug and housing factors, significant at the 5 per cent level ($F = 4{\cdot}37$ and 6·07 respectively) and an interaction term, representing the different effect of morphine in the two groups, highly significant at the 1 per cent level ($F = 9{\cdot}35$). Similar trends appeared in the "rears" and "total rearing times", but only the effects due to the drug were significant ($P < 0{\cdot}001$ in both cases); for "rears", the interaction was almost significant at the 5 per cent level. The body weights of the isolated rats were significantly greater than those of the grouped rats (198·9 g ± 27·8 s.d., and 173·8 g ± 19·7 s.d. respectively; $P < 0{\cdot}01$), although there had been no difference at weaning. Examination of the activity within the 5 min period showed that the difference in response to morphine in the two groups of animals was sustained throughout the test: minute-by-minute plots showed that the two morphine groups had parallel time courses within the trial, but the curve for the grouped animals was consistently lower. In other words, the grouped animals seemed to behave as if they had received a larger dose of the drug. The "catatonic" episodes which often occur in rats treated with morphine seemed to be shorter and more sporadic in isolated than in grouped rats, and this probably accounts for the difference.

The results therefore suggest that the isolated rats were less sensitive to the depressant action of the dose of morphine used than those which had lived in groups. A number of explanations of this finding are possible. The isolated animals might have metabolized the morphine at a greater rate, for Baumel *et al.*[7] found that hepatic microsomal fractions from isolated mice metabolized hexobarbitone faster than did fractions from grouped mice. If long-term isolation reduces the rate of brain 5-hydroxytryptamine turnover in the rat in a manner similar to that observed in mice[2], then a reduction in response to morphine might be expected, for procedures which interfere with this amine can also modify responses to the drug[10–12]. It seems unlikely that the different reactions to morphine were a consequence of increased baseline "arousal levels" in the isolated rats, as the saline scores were very similar in both groups. Finally, although all animals were tested singly in the Y-maze, they did

spend the hour between injection and being tested in very different home environments, that is, singly or grouped, and this, as well as the differences in long-term housing, may have contributed to the results obtained. Experiments are in progress to investigate this possibility.

Findings of the kind reported here demonstrate how even a profound change in behaviour resulting from an opiate drug can be modified by the previous history of the recipients.

Effect of Visual Pattern Restriction in Early Life on Brain Enzyme, Body Weight and Learning in the Rat

VISUAL pattern restriction or enrichment in early life can induce significant differences in body weight gain, performance on a visual sensory reinforcement test and brain enzymatic activity in adult rats[1]. Rats raised in an enriched visual environment, however, perform better on the visual reinforcement test than rats raised in a restricted visual environment only when light-onset is used as reinforcement; if light-termination is used as reinforcement, performance differences are completely reversed[2]. Thus the effects of early visual experience may be beneficial only in some highly specific learning situations. Our experiments test the effect of visual input in early life on learning tests other than those previously used; we also looked at possible differences in body weight and brain enzymatic activity induced by early visual experience after a period of extensive handling, a food deprivation schedule and learning experience.

Thirty-two littermate, female Holtzman albino rats, weaned at 23 days of age, were randomly assigned either to a visual pattern or to a restricted visual pattern group. The animals were raised in conditions reported previously[1] except that overhead fluorescent lights were on throughout the experiment. The visual environment of the visual pattern group consisted of a board painted with 1·94 cm thick alternating black and white stripes, whereas that of the restricted visual pattern group consisted of a board painted flat white. Each rat was housed individually in a cage with a wire mesh front and was provided with unlimited food and water.

Table 1 presents mean body weights for both groups at 23, 58, 93, and 112 days of age.

As we found before, the visual pattern group was significantly heavier than the restricted visual pattern group in the first two weighing periods after exposure to the experimental rearing condition. On the last weighing period the difference between group weights, though not statistically significant, is nonetheless large in the light of the following facts. First, both groups were subjected to extensive handling, a food deprivation schedule, and behavioural testing during the ninety-third to the hundred and twelfth days of life. Second, the visual pattern group obtained less food reinforcement than the restricted visual pattern group in the behavioural test, because of their poorer performance. Finally, rats raised in enriched environments have lower body weights than rats raised in isolation[3].

Table 1. MEAN AND STANDARD ERROR OF MEAN OF BODY WEIGHT FOR VISUAL PATTERN AND RESTRICTED VISUAL PATTERN GROUPS FOR FOUR WEIGHINGS

Rearing condition	Body weights (g)	Age (days) 23	58	93	112
Restricted visual pattern	Mean	53·5	186·5	232·2	239·7
	s.e.	1·0	2·9	4·8	5·1
Visual pattern	Mean	54·1	195·2	242·4	248·7
	s.e.	1·0	2·2	2·4	3·5
	P	N.S.	< 0·01	< 0·05	< 0·10

All animals experienced handling, food deprivation and behavioural testing between 93 and 112 days of age. Levels of significance were determined by *t*-test (two-tailed).

Starting from 93 days of age, all animals were picked up and lightly stroked for 5 min a day for four days. Next, animals were trained either on a differential reinforcement of low rate of responding (DRL) operant schedule[4] or Lashley III maze[5]. The DRL test is unaffected by the drive state of the animals, so any differences between visual pattern and restricted visual pattern groups on this test could not be caused by differences in exploratory drive or general activity of the two groups. Further, if early experience indeed produced differences in exploratory drive, they should be reflected in number of alleys entered and time taken to complete the trial in the Lashley maze.

One-half of each group was randomly assigned to the DRL test and the remaining half to the Lashley maze. For both DRL and maze training, animals were put on a 23 h food deprivation cycle and, except for training sessions, continued to live in their respective rearing conditions.

Table 2. MEAN AND STANDARD ERROR OF MEANS OF SUCCESS RATIOS

Rearing condition	Reinforcements/responses ×100	Day 1	2	3	4	5
Restricted visual pattern	Mean	23·3	37·9	53·7	52·1	50·5
	s.e.	1·2	8·1	5·5	5·9	5·3
Visual pattern	Mean	12·1	17·7	20·6	30·0	32·6
	s.e.	1·3	2·9	3·6	3·9	6·6
	P	< 0·001	< 0·10	< 0·001	< 0·02	< 0·10

Values are (reinforcements/responses ×100) for visual pattern and restricted pattern groups for the first 5 days of DRL-10 performance. Significance levels were determined by *t*-test (two-tailed).

For DRL test, each animal was trained on a DRL 10 s schedule in an operant conditioning chamber (dimensions: 28·57 × 19·68 × 23·49 cm) for food reinforcement. To obtain reinforcement in this task, an animal must not press the lever for 10 s after the preceding reinforcement. Any premature lever press restarts the 10 s interval. For DRL training, each animal was first trained to press the lever where every lever press resulted in a 45 mg food pellet. After fifty such reinforcements, the animal was shifted to a DRL 10 s schedule and was trained for an hour a day until the animal reached the criterion of at least 50 per cent success ratio for three consecutive days. As is evident from Table 2, the restricted visual pattern group maintained higher success ratios than the visual pattern group for the first five days of training: thereafter the performance of the two groups did not differ significantly.

Furthermore, the restricted visual pattern group required significantly ($P < 0·05$, two-tailed t test) fewer days to reach criterion (mean = 3·6) than the visual pattern group (mean = 7·4). There were no significant relationships between body weight and DRL performance, either in terms of days to reach criterion or success ratio, or between

DRL performance and brain enzymatic activity for either group.

For the Lashley maze training, each animal was given five trials a day, and the number of entries into blind alleys and time from start to goal box was recorded. Each animal was trained to the criterion of two successive errorless days. Further, because animals raised in isolated rather than enriched environment do not differ on initial maze learning but differ on reversal[7], animals which had reached criterion were tested for reversal (start and goal box locations reversed) for five days. But the groups did not differ significantly on initial or reversal problems in time, errors or days to reach criterion. The results of these two behavioural tests show that performance differences between visual pattern and restricted visual pattern groups cannot be attributed to differences in level of general activity.

After these tests, animals were decapitated, and their brains removed and weighed. The olfactory bulbs and cerebellum were removed, and the rest of the brain was cut into four samples (anterior cortex, posterior cortex, anterior subcortex and posterior subcortex) and frozen for biochemical assay. All samples were coded so that the analyst was unaware of the experimental condition of each sample. The acetylcholinesterase activity was determined by the rate of hydrolysis of acetylcholine perchlorate using the procedure described by Rosenzweig *et al.*[8]. As reported earlier[1], the difference in subcortical acetylcholinesterase activity between the visual pattern and restricted visual pattern groups was not significant; Table 3 therefore presents mean cortical acetylcholinesterase activity only.

Table 3. MEANS AND STANDARD ERRORS OF ACETYLCHOLINESTERASE ACTIVITY IN CORTICAL BRAIN TISSUE SAMPLES FOR VISUAL PATTERN AND RESTRICTED VISUAL PATTERN GROUPS

Rearing condition	Acetylcholinesterase activity	Anterior	Posterior	Total
Restricted visual pattern	Mean	124	76	101
	s.e.	4·4	2·0	2·7
Visual pattern	Mean	133	84	109
	s.e.	5·3	1·7	3·1
	P	N.S.	< 0·01	< 0·10

Acetylcholinesterase activity is expressed in moles acetylcholine hydrolysed $\times 10^{10}$/min/mg of tissue. Total cortical acetylcholinesterase values were obtained for each animal by calculating a weighted average. Significance levels were determined by *t*-tests (two-tailed).

The visual pattern group exhibited greater acetylcholinesterase activity in anterior, posterior and total cortex than the restricted visual pattern group. But the visual pattern group shows (statistically) significantly greater activity only in the posterior cortical sample which contains the visual cortex. Again, as in the case of body weight cortical acetylcholinesterase differences between the groups were evident in spite of 19 days of behavioural testing. Krech *et al.*[7] reported that 18 days of behavioural testing obliterates the brain acetylcholinesterase differences between enriched and isolated groups. Their animals, however, were raised in multiple environmental enrichment for 30 days and were removed from the original environment during the testing period. Finally, it should be pointed out that in the earlier article[1] we reported that acetylcholinesterase absolute cortical activity levels for visual pattern and restricted visual pattern groups were lower compared with these values. This difference in absolute values is probably because in the present study all animals were raised in continuous illumination. Our later studies have replicated reported acetylcholinesterase activity values and it seems that the duration of exposure to a visual environment is a critical variable influencing acetylcholinesterase activity.

In conclusion, the nature of visual input in early life may be the critical factor in producing changes in adult animals. The importance of visual input can also be deduced from those early experience studies[3] in which no systematic attempts are made to manipulate the visual patterns of the rearing environment. Nevertheless, the visual cortex shows the greatest effects of the environmental enrichment both in anatomical growth[9] and acetylcholinesterase activity[3] compared with the remaining neocortex. Finally, early visual experience evidently does not increase generalized problem-solving ability and its effects are determined by specific characteristics of the learning situations.

Development of Normal Mice by *in Vitro* Fertilization

In vitro fertilization of mammalian ova has been successfully carried out in the rabbit[1-3] and the hamster[4,5], but development of fertilized ova beyond the two-cell stage has not been achieved[6]. Brinster *et al.*[7] have observed fertilization and blastocyst development in explanted Fallopian tubes using organ culture. More recently, Whittingham[8] has successfully fertilized mouse eggs *in vitro*, transplantation of which into pseudo-pregnant recipient mothers yielded 17 day old foetuses. The present studies confirm the results of Whittingham[8] and further demonstrate that apparently normal full-term progeny can be obtained from implantation of *in vitro* fertilized eggs that have been maintained in culture to the blastocyst stage.

The mice used in these studies were of the ICR/Ha (albino) and C57Bl/6 Jacobs strains (black). Large numbers of ova were obtained after super-ovulation of mature mice by an intraperitoneal injection of 5 IU of pregnant mares' serum (PMS) followed 48 h later by an injection of 5 IU of human chorionic gonadotropin (HCG). Ten to twelve hours after the second injection, the mice were killed by cervical dislocation and the oviducts were removed and uncoiled. Unfertilized ova were flushed from the oviduct into a Petri dish by injecting 0·5 ml. of normal saline into the ampullary isthmal junction with a 30-gauge needle. The eggs were then isolated from cellular debris by a finely drawn capillary micropipette and transferred to a Petri dish containing culture medium diluted with normal saline to half the original concentration. The composition of the medium was identical

Table 1. *In Vitro* FERTILIZATION AND IMPLANTATION

Donor strains*		Number of oocytes cultured	Number of two-cell embryos	Number of blastocysts obtained	Number of blastocysts transplanted	Recipient	Number of progeny obtained
Ova	Sperm						
A	A	130	34	13	13	B	5 (A)
B	B	123	33	12	10	A	6 (B)
Total		253	67	25	23		11

*A = ICR/Ha (albino); B = C57Bl/6 (black).

to that of Whitten and Biggers[9] with the exception that sodium pyruvate concentration was 0·55 mM rather than 0·33 mM. The *p*H of the medium was maintained at approximately 7·5 by intermittent administration of 5 per cent CO_2 in air.

Capacitated spermatozoa, as defined by Austin[10] and Chang[11], were obtained from the uteri of mice 3–4 h after mating with a proven fertile male. The two uteri were dissected out and their contents released into a Petri dish containing 1 ml. of half strength medium at 37° C. The Petri dish was immediately agitated to prevent coagulation of the sperm.

Approximately 0·3 ml. of sperm suspension was added to a cavity slide containing the unfertilized ova suspended in medium. The mixture of the eggs and sperm was then layered over with paraffin oil (Fisher Scientific, viscosity 125/135) so that the well was filled. The slide was incubated for 6–8 h at 37° C in a 5 per cent CO_2 atmosphere. Approximately the same number of ova without the addition of sperm were cultured as controls.

After incubation, both control and treated ova were thoroughly washed with normal saline and placed in culture using the method as described by Brinster[12] and Chang[2]. The culture was examined after 24 h for cleaving zygotes. The two-cell ova were separated into Petri dishes with fresh medium (full strength) and allowed to develop to the blastocyst stage. At this point, the blastocysts were implanted into pregnant or pseudo-pregnant females. Although some control eggs fragmented during culture, no actual cleavage was observed.

The recipient mothers were made pseudo-pregnant through mating with proven sterile vasectomized males. The vasectomized mice were always genetically similar to the recipient mother (coat colour), and therefore dissimilar to the implanted embryos. In some experiments, normally pregnant mice were used as recipient mothers instead of pseudo-pregnant animals. These matings were designed so that the progeny derived from the *in vitro* and *in vivo* fertilizations were clearly distinguishable by coat colour.

The appearance of the vaginal plug was taken as evidence of mating and counted as day 0 of pseudo-pregnancy. After 3 days of growth *in vitro*, the blastocysts were collected into a glass capillary micropipette connected to a small rubber tube. A surgical incision was made on the dorsal side of the recipient mouse, the uterotubal junction was punctured by the micropipette so that the open tip reached the lumen of the uterus, and the blastocysts were introduced by gentle blowing through the rubber tubing. Birth usually occurred 20–21 days after fertilization.

Table 1 shows the pooled results of six experiments. Of 253 eggs exposed to capacitated spermatozoa, 67 were fertilized, as appears from the two-cell ova, and 25 which developed to blastocysts. Twenty-three blastocysts were implanted into recipient mothers and eleven apparently normal offspring were obtained. Nine of these were from pseudo-pregnant mothers and the remaining two from normally pregnant females. In experiment 3, two female mice derived from *in vitro* fertilization were mated with vigorous males and delivered normal progeny.

If perfected, this technique could be applied to fertility and sterility problems or immunological relationships between the conceptus and the mother, as well as to problems in development, implantation and differentiation, by transfer of early embryos of specified ages to recipients at various stages of the reproductive cycle[13].

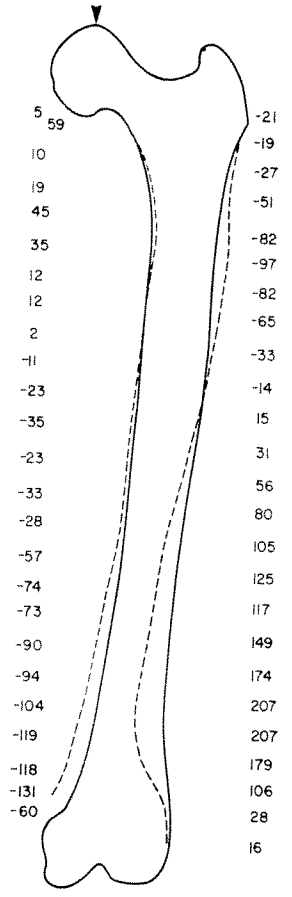
Piezoelectric Effect and Growth Control in Bone

THE adaptability of bone under impressed mechanical forces has been known since the time of Wolff[1]. A possible control mechanism for the process became apparent with the discovery of the piezoelectric effect in bone[2]. In theory this effect could translate an environmental stimulus into a biologically recognizable signal controlling growth or resorptive processes. It has been recognized that the action of the piezoelectric signal may be to alter the chemistry of pertinent macromolecules such as collagen, or to influence cellular activity directly[3]. Of the two possibilities, evidence tends to rule out the importance of the former and we consider here only the latter[4].

For ordinary piezoelectric materials and for small isolated bone samples, the magnitude and sign of the charges that will appear on application of a load can be predicted. Such calculations, however, are not possible for larger bone samples, including whole bones, because of the variable architecture present. (The direction of the symmetry axis of the piezoelectric tensor becomes a function of position.) This means we have no way of knowing what constitutes a normal or abnormal charge distribution for a given bone, and therefore no basis for comparison with observed growth patterns. Alternative considerations for relating the piezoelectric effect and bone adaptability are the signal produced and the expected physical effects at the cellular level. On loading, bone will generate a bound surface charge distribution $\rho(\bar{x},t)$. In a process typically occurring in seconds, $\rho(\bar{x},t)$ is nulled by ion current in the permeating interstitial fluid. When the process is monitored macroscopically by measuring a voltage, a symmetric biphasic pulse is seen[5,6]. The symmetry of such a pulse, however, is not characteristic of the underlying process. Consider a Gedanken experiment in which there is an observer at every bone cell. In general, no two observers will record the occurrence of the same local charge distribution on loading. Similarly, they will not agree on the charge neutralization kinetics that occur



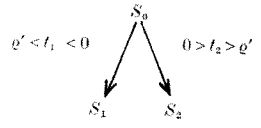


Fig. 1. Solid human femoral outline and charge distribution in pC/cm² as given by McElhaney. The medial surface is displaced at each charge location (left for growth, right for resorption) by an amount proportional to that charge. The lateral surface is similarly displaced (except left for resorption, right for growth). The dotted femoral outline is the result.

because neutralization will depend on a host of locally varying factors such as membrane shielding of the bone surface, fluid viscosity and the concentration and mobility of diffusible ions. Thus, each observer will see two processes, the creation of a $\rho(\bar{x},t)$ and its subsequent neutralization. Either process can theoretically represent a biological control signal because each possesses two of the necessary properties, variability and unidirectionality. By variability we mean that the parameters for each process will vary with cell location. For instance, for the first process some observers will note the appearance of negative regions on the adjacent bone surface, while others will see positive areas. If the former represents the biological control signal for growth, then the latter may correspond to resorption. By unidirectionality we mean that neither process generates a biphasic signal which sums to zero.

Young[7,8] postulated that the three major types of bone cells are interchangeable, the change of specialization occurring because of changes in the microenvironment which selectively activate and repress genes. We propose that either physical process described above may be responsible for switching bone cells from one kind of specialization state to another. In this case, normal bone in normal loading conditions would produce a normal $\rho(\bar{x},t)$ controlling its own remodelling, and abnormal bone (such as a healed angulated fracture) in normal loading conditions would produce an altered $\rho(\bar{x},t)$ which increases bone deposition in some areas and decreases it in others (modelling). Normal bone in conditions of no load would produce no $\rho(\bar{x},t)$ and, in the absence of this directing influence, atrophy would result.

Next we must find a relationship between one of the two processes and bone cell states. We choose the process of creation of $\rho(\bar{x},t)$. On the basis of previous work[9], polarity correlations with growth are assigned as follows

Bone cell state	Function
S_0	Resting
S_1	Building bone
S_2	Resorbing bone

where ρ' is an average over some suitable time, t_1 and t_2 are thresholds, and the rate of cellular activity in S_1 and S_2 is assumed to be proportional to the magnitude of ρ'. This scheme has been applied to the results of McElhaney[10], who subjected a whole human femur to a periodic load and measured $\rho(\bar{x},t)$. The dotted femoral outline in Fig. 1 results from connecting points plotted from the original femoral surface with a direction and magnitude proportional to each surface charge. Modelling is produced in response to $\rho(\bar{x},t)$, and the integrity of the femur is preserved. If the measured $\rho(\bar{x},t)$ was unrelated to bone adaptability, we would expect a random pattern to occur. Modelling rather than remodelling is expected here because, while the femur is anatomically normal, the loading is abnormal, for muscular effects were not included.

Further tests of these propositions require more measurements of $\rho(\bar{x},t)$ and *in vitro* studies of the interaction of charged surfaces and cells. It is clear that further study of a link between the piezoelectric effect and bone adaptability is necessary.

Dual Innervation of the Pineal of the Fowl, *Gallus domesticus*

THE occurrence of nerve fibres in the pineal of the fowl was once thought unlikely[1], but it is now accepted that many fine neurites are present[2,3]. Although myelinated fibres have been observed[4], most are unmyelinated and many of them contain the cored vesicles[4,5] which are characteristic of adrenergic nerves. In mammals innervation is probably exclusively sympathetic from cells originating in the superior cervical ganglion[3], but sympathectomy experiments have suggested that different mechanisms of stimulation may exist in the chicken[6].

In our investigation male and female Brown Leghorns aged 2 months and 6 months were decapitated and the pineal glands were removed as rapidly as possible. Fresh frozen cryostat sections were stained by a modification[7]

of the fluorescent formaldehyde condensation method for catecholamines using 0·1 per cent alcoholic solution of sodium borohydride and water to control specificity. Some birds were injected subcutaneously 2 h before killing with 10 mg per kg body weight of reserpine, a specific, pharmacological, catecholamine depleting agent.

Frozen sections of the pineals were subjected to the Coupland and Holmes method[8] for cholinesterase, control sections being treated with 0·04 mM aqueous solution of isopropylpyrophosphoramide (iso-OMPA), an inhibitor of pseudocholinesterase, and 0·5 mM-aqueous BW284C51, an inhibitor of acetylcholinesterase. Confirmation of the histochemical results was obtained by applying the cholinesterase methods of El-Badawi and Schenk[9] and of Namba, Nakamura and Grob[10].

The formaldehyde condensation method revealed numerous strongly fluorescing nerve fibres (Fig. 1) in the trabeculae in both perilobular and perifollicular locations. Fluorescent material also seemed to be located in the parenchymal cells. Fluorescence was suppressed by the above inhibitors and by pretreatment with reserpine. Auto-fluorescence was not observed in the pineals with light of between 300 to 500 nm wavelength.

Optimum conditions of incubation in the Coupland and Holmes method were found to be *p*H 6·2 for 6 h at 37° C when this procedure caused a linear precipitation of copper sulphide in the perilobular and perifollicular septa (Fig. 2). The specificity of the method for acetylcholinesterase was confirmed by the failure of iso-OMPA to suppress the reaction and the marked inhibition by BW284C51. Because fine nerve fibres occur throughout the trabeculae, we could not entirely eliminate the possibility that the relatively diffuse reactions may have been associated with some tissue component other than the nerves, but this seems unlikely. Additional evidence of the presence of both cholinesterase and neurites in the septa was provided by the method of El-Badawi and Schenk[9], although this did not demonstrate such delicate fibres as the preceding and the silver combination procedure of Namba, Nakamura and Grob[10].

These results show that the avian pineal, like the mammalian, has an adrenergic innervation, and they substantiate what had previously been suspected from ultrastructural examinations of the gland[4,5]. The presence of acetylcholinesterase in avian pineals, however, is of considerable comparative interest because several investigations[11–13] have failed to find this enzyme in the pineals of several mammalian species. It has been suggested[14] that an evolutionary shift from the purely cholinergic innervation of lower vertebrate pineals to the adrenergic innervation of mammalian pineals occurs as a corollary to the evolution of the solid parenchymal pineal from the saccular type. Our observations suggest that this may be correct because the domestic fowl has a pineal with intermediate structural characteristics and which may be innervated by both cholinergic and adrenergic fibres.

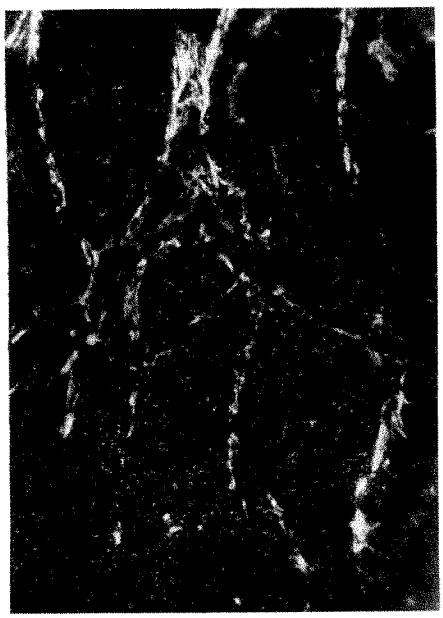

Fig. 1. Distribution of adrenergic nerve fibres in the perilobular and perifollicular septa of the pineal of the domestic fowl. Fluorescent formaldehyde condensation method. ×65.

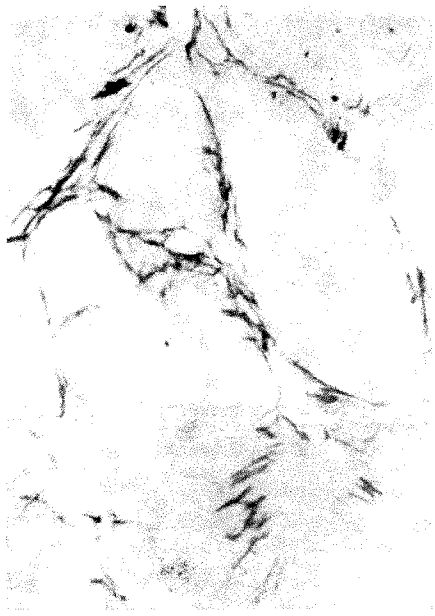

Fig. 2. Acetylcholinesterase reaction of neurites in perilobular and perifollicular locations in the pineal of the fowl. Coupland and Holmes method[8]. ×65.

Furthermore, this double innervation may have some bearing on the finding[6] that sympathetic innervation is not essential for the control of hydroxyindole-O-methyl transferase activity in the fowl's pineal. These divisions of the autonomic nerves usually produce responses opposite in direction, but in some organs they have synergistic effects. Unfortunately our findings do not explain the origin of the cholinergic fibres, for, although adrenergic fibres are undoubtedly post-ganglionic sympathetic, cholinergic fibres may represent pre or post-ganglionic sympathetic or parasympathetic efferent fibres. We have never observed neurones during the histological examination of large numbers of pineal glands from domestic fowls, so it is improbable that the cholinergic fibres are pre-ganglionic sympathetics. Elucidation of the origin and pathway of these cholinergic fibres would be of considerable interest in relation to the functional control of the pineal organ.

Wind and the Direction of Nocturnal Songbird Migration

MIGRATING birds do not seem to be drifted off course by light to moderate unfavourable winds[1–4]. Birds tend to migrate with tail winds, and various people have proposed that the migrants reduce chances of drift by selecting following winds for their particular goal-directed flights. Some reports, however, support the view that migrating songbirds (passerines) are drifted off course by unfavourable winds[5–8]. Without adequate knowledge of the goals of the birds of a given flight, both claims are debatable. We have recently obtained, by a new technique, data that clarify the issue.

During the spring and autumn of 1969 at Athens, Georgia, and at Lake Charles, Louisiana, we used a 20×60 telescope directed up a narrow light beam to observe the passage of nocturnal migrants[9]. This technique is ideally suited for the study of low-level nocturnal migration (below 700 m). We also monitored the migrations on United States Weather Bureau WSR-57 radar[10]. Winds aloft were determined at 0000 GMT and 1200 GMT by radiosonde (radar tracked balloon) and at 0600 by pibal (visually tracked balloon). We recorded surface winds hourly. All statistical analyses of flight direction data were done according to Batschelet[11].

We have selected seven nights in spring and five nights in autumn to show the influence of different wind directions on the directions of the migrants as they passed through the light beam (Table 1). All nights had clear to partly cloudy skies. Figs. 1 and 2 show significant positive correlations between flight direction and wind direction at the surface ($r = 0{\cdot}984$, $P < 0{\cdot}001$), and at 305 m above the ground ($r = 0{\cdot}932$, $P < 0{\cdot}001$). On two occasions when the winds shifted direction during the night, the bird flight directions changed accordingly (Fig. 3). On these two nights the winds changed direction about 70°, and in both cases the flight directions of the migrants

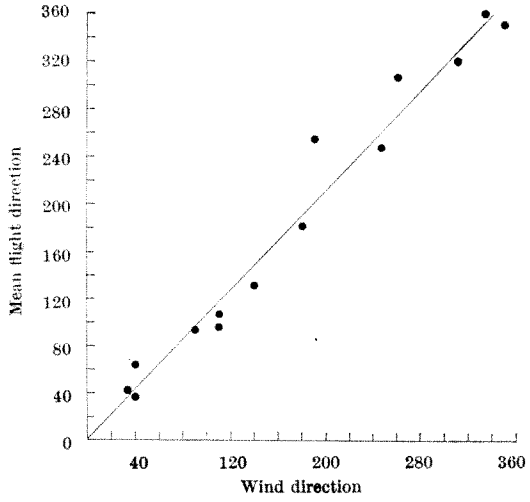

Fig. 1. A plot of the migration direction (mean vectors) on the corresponding direction toward which surface winds were blowing. See Table 1 for data.

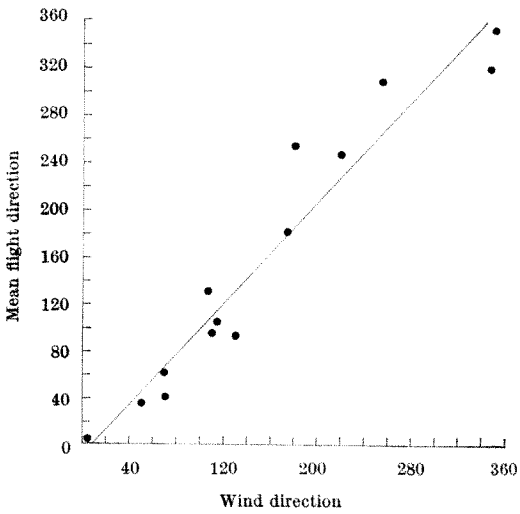

Fig. 2. A plot of the migration direction (mean vectors) on the corresponding direction towards which 305 m winds were blowing.

shifted significantly with the wind (May 10–11, $F = 0{\cdot}105$, $P < 0{\cdot}001$; September 22–23, $F = 0{\cdot}307$, $P < 0{\cdot}001$). These data show that at night songbird migrants in both spring and autumn tend to fly with the wind regardless of its direction. Movements in directions not appropriate for the season, however, are often of lower magnitude.

Table 1. INFLUENCE OF WIND ON DIRECTION OF FLIGHT

Night	Wind direction and velocity: Surface (knots)		305 m (knots)		No. of birds	Vector resultant of flight directions: Azimuth	Length (per cent)	Angular deviation
6–7 April	290°	10	295°	25	19	106°	93·0	21°
20–21 April	80	8	75	10	7	308	99·4	6

10–11 October	170	6	170	22	46	356	92·1	23
13–14 October	0	10	355	19	146	182	94·8	18

The only other direct visual studies of the direction of nocturnal migration—involving Moon watching[12,13]—also suggest that passerine nocturnal migrants tend to fly downwind. By direct visual observation we have confirmed that the misty (finely stippled) display of echoes on WSR-57 radar is produced by passerine migrants flying individually in the night sky[10]. This pattern is similar to that described by others working with radars of 10 cm wavelength[3–5,8]. The echoes from songbirds at night are nearly impossible to track on radar and, moreover, their density is usually so great during migration seasons that virtually no directional information can be obtained. In contrast, on WSR-57 and other 10 cm radars, shorebirds and waterfowl generally give strong, coherent dot echoes that can be easily tracked for several miles.

We propose that the radar evidence gathered in support of the idea that songbird nocturnal migrants compensate for wind drift might be more appropriately attributed to flocks of shorebirds, waterfowl or both. In support of this idea we give the following evidence. The proponents of the compensation-for-drift theory have not consistently employed simultaneous direct visual methods to confirm the identity of the birds responsible for the echoes they have tracked, and consequently some confusion about echo identification has resulted. Echoes from some European passerine migrants (such as thrushes) cannot be distinguished from those of shorebirds[14,15]. It is clearly stated in several reports on radar tracking

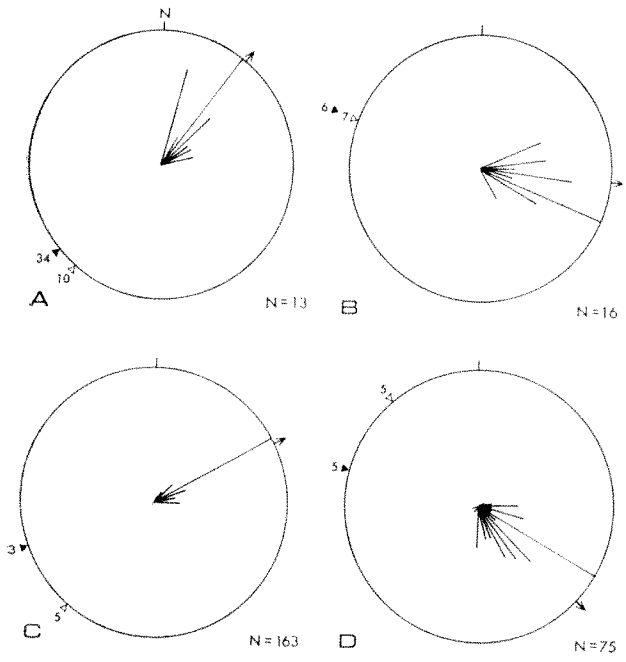

Fig. 3. Diagrams showing bird directions on two nights when winds shifted. May 10–11: *A*, 0240–0252 GMT; *B*, 0620–0645; September 22–23: *C*, 0120–0135; *D*, 0615–0645. Vector diagrams are plotted so that the radius equals the greatest number of birds in any 7·5° sector. The arrowhead is the mean direction, and the open and solid triangles represent surface and 305 m winds, respectively.

of migrants that the authors concentrated more on discrete dot echoes than on the dense pattern of fine echoes attributed to songbirds[1,16,17]. This practice has probably resulted in the selection of larger birds, flocks of birds and birds at higher altitudes. Furthermore, most radars give an inadequate representation of the migration at low altitudes (below 700 m) where most passerines fly[8]. Although our data show that small passerine nocturnal migrants often do not compensate for wind drift, preliminary results indicate that ducks, geese and shorebirds can do so at night when unfavourable winds are light to moderate. These findings support Pennycuick's assertion that crosswinds of moderate strength deflect slow birds through a large angle, but have less effect on faster birds. In general, the slower (and thus smaller) the bird, the more it is affected by unfavourable winds[18]. Our finding that songbird migrants often fly downwind regardless of the direction of the wind in the southern United States accounts for such phenomena as reversed migrations (a general movement in the direction opposite to that normal for the season) and the appearance of migrants far from their normal migration routes. The importance of proposed stellar orientation mechanisms must be re-evaluated in light of the influence of wind direction on the direction of nocturnal passerine migration.

Development of the Brain depends on the Visual Environment

IN a normal cat, neurones of the visual cortex are selective for the orientation of lines and edges in the visual field, and the preferred orientations of different cells are distributed all around the clock[1]. Hirsch and Spinelli[2] have recently reported that early visual experience can change this organization. They reared kittens with one eye viewing vertical stripes, the other horizontal, and found that out of twenty-one neurones with elongated receptive fields all were monocularly driven, and in all but one case the orientation of the receptive field closely matched the pattern experienced by that eye.

We began a related project about a year ago and this is a preliminary report of our results. Our approach was rather different from that of the group at Stanford. We allowed our kittens normal binocular vision in an environment consisting entirely of horizontal or vertical stripes. The kittens were housed from birth in a completely dark room, but from the age of 2 weeks they were put into a special apparatus for an average of about 5 h each day. The kitten stood on a clear glass platform inside a tall cylinder the entire inner surface of which was covered with high-contrast black-and-white stripes, either horizontal or vertical (Fig. 1). There were no corners to its environment, no edges to its floor and the upper and lower limits to its world of stripes were a long way away. It could not even see its own body, for it wore a wide black collar[3] that restricted its visual field to a width of about 130°. The kittens did not seem upset by the monotony of their surroundings and they sat for long periods inspecting the walls of the tube.

We stopped this routine when the kittens were 5 months old, well beyond the "critical period" in which total visual deprivation causes physiological deficits[4]. From that time the cats were taken for several hours each week from their dark cage to a small, well-lit room, furnished with chairs and tables, where we watched their visual reactions.

At first they were visually extremely inept, whether they had been exposed to vertical or horizontal stripes. Their pupillary reflexes were normal but they showed no visual placing when brought up to a table top and no startle response when an object was thrust towards them. They guided themselves mainly by touch and were frightened when they reached the edge of the surface they were standing on. But they quickly recovered from many of these deficiencies, which were probably visuomotor problems of the kind that Held and Hein described[5]. Within a total of about 10 h of normal vision they showed startle responses and visual placing, and would jump with ease from a chair to the floor.

On the other hand, some of their defects were permanent. They always followed moving objects with very clumsy, jerky head movements and they often tried to touch things moving on the other side of the room, well beyond their reach. Perhaps most telling of all, despite their

active, and as time went on increasingly frenzied, visual exploration of the room, they often bumped into table legs as they scurried around.

There were, moreover, differences between cats reared in horizontal and vertical environments. They were virtually blind for contours perpendicular to the orientation they had experienced. They showed no startle response for an approaching 'Perspex' ('Plexiglas') sheet covered with black stripes, nor would they visually place on such a pattern, if the stripes were of the inappropriate orientation. The differences were most marked when two kittens, one horizontally and the other vertically experienced, were tested simultaneously with a long black or white rod. If this was held vertically and shaken, the one cat would follow it, run to it and play with it. Now if it was held horizontally the other cat was attracted and its fellow completely ignored it.

We moved on from behavioural studies to neurophysiology when the cats were 7·5 months old. They were anaesthetized with nitrous oxide and paralysed with succinyl choline while we recorded from single neurones in the primary visual cortex, using sodium chloride filled micropipettes. The refractive states of the eyes was corrected with contact lenses, spectacle lenses and 3 mm artificial pupils. There was no evidence of severe astigmatism, which might have explained our behavioural findings.

We used thin bright slits or edges to plot receptive fields on a screen 114 cm from the cat. The luminance of the background was about 5 cd. m^{-2} and of the bright target about 17 cd. m^{-2}. Our initial procedure was to make one long penetration deep into the medial edge of the post lateral gyrus, studying every single neurone encountered. We found units on the average about 80 μm apart, so presumably our electrode was not specially selective for the cells from which it recorded. After the long penetration we moved the electrode to other positions in area 17 and sampled just a few neurones at each place. Our exploration thus covered many cortical columns[1] and quite a large area of the visual field around the area centralis.

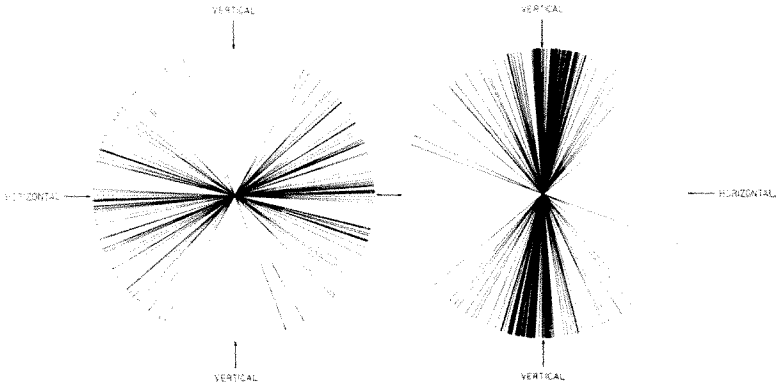

Fig. 2. These polar histograms show the distributions of optimal orientations for fifty-two neurones from a horizontally experienced cat on the left, and seventy-two from a vertically experienced cat on the right. The slight torsion of the eyes, caused by the relaxant drug, was assessed by photographing the pupils before and after anaesthesia and paralysis. A correction has been applied for torsion, so the polar plots are properly orientated for the cats' visual fields. Each line shows the optimal orientation for a single neurone. For each binocular cell the line is drawn at the mean of the estimates of optimal orientation in the two eyes. No units have been disregarded except for one with a concentric receptive field and hence no orientational selectivity.

So far we have studied 125 neurones from two cats, one horizontally, the other vertically experienced. Of all these units, only one did not have distinct orientation selectivity and it had the action potential waveform and concentric, monocular receptive field of a projection fibre from the lateral geniculate body. About 75 per cent of cells, in both cats, were clearly binocular and in almost every way the responses were like those in a normal animal. The distributions of preferred orientation, however, were totally abnormal (Fig. 2). Not one neurone had its optimal orientation within 20° of the inappropriate axis and there were, *in toto*, only twelve within 45° of it. This anisotropy is highly significant ($P < 0{\cdot}00001$: chi-squared test).

Evidently the visual experience of these animals in early life has modified their brains, and there are profound perceptual consequences. But we do not think that there is merely passive degeneration of certain cortical neurones because of under-activity. For we did not notice any obvious large regions of "silent" cortex, corresponding to the "missing" cortical columns. It seems instead that the visual cortex may adjust itself during maturation to the nature of its visual experience. Cells may even change their preferred orientation towards that of the commonest type of stimulus; so perhaps the nervous system adapts to match the probability of occurrence of features in its visual input.

We thank Patrick Jackson and Ian Creese for building the striped tubes and the MRC for research grants.

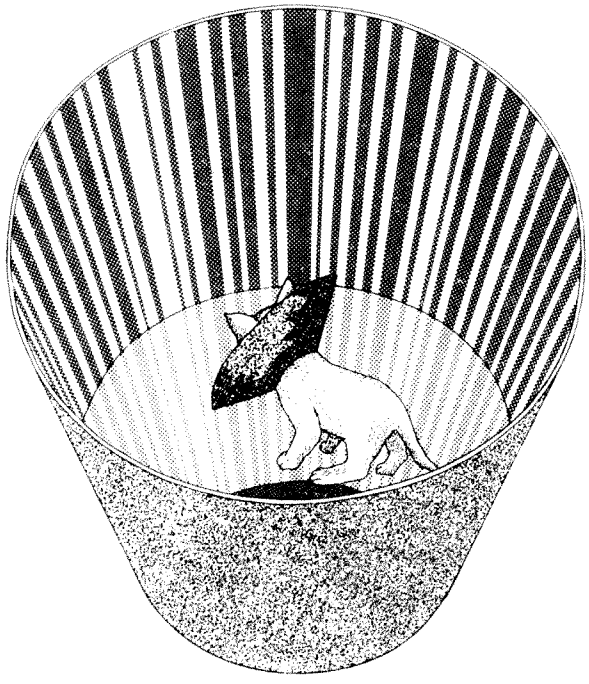

Fig. 1. The visual display consisted of an upright plastic tube, about 2 m high, with an internal diameter of 46 cm. The kitten, wearing a black ruff to mask its body from its eyes, stood on a glass plate supported in the middle of the cylinder. The stripes on the walls were illuminated from above by a spotlight. The luminance of the dark bars was about 10 cd. m^{-2} and of the bright stripes about 130 cd. m^{-2}: they were of several different widths. For this diagram the top cover and the spotlight have been removed from the tube.

Book Reviews

BERKELEY *REDIVIVUS*

Natural Law and the Structure of Matter
By Werner Heisenberg. Pp. 45. (Rebel: London, August 1970.) 18*s*.

IN 1919, during the street fighting in Munich, while the din of shooting filled the air, a schoolboy called Werner Heisenberg, installed on the roof of the seminar building, was reading the *Timaios*—a near enough approximation to the prophet receiving the law on the mountain amid thunder and lightning. In 1964, with a prodigious career of creative work behind him, Werner Heisenberg chose to ascend another height, this time the very Hill of Pnyx, to proclaim from this hallowed ground the final triumph of Plato. This sermon has been preached before, by a famous bishop of Cloyne, among others, who thought he had routed atheism, just as Heisenberg now fancies he has liquidated its modern avatar, dialectical materialism. Berkeley's judgment was dimmed by his new theory of vision: Heisenberg is led astray by his new theory of matter.

Persiflage won't do, however, with a man of Heisenberg's stature. Every one of his pronouncements deserves close scrutiny—though not every one will bear it. In trying to expose the weak point of his plea for Platonism, I am reminded of Diderot's dictum about idealism being the scandal of philosophy, not so much because it is absurd as because it is hard to refute by rational argument. How could one find fault with Heisenberg's brilliant sketch of the course of Greek philosophy, or his penetrating characterization of the essential difference between it and modern science? Yet, on closer examination, the whole picture, dazzling as it is, shows itself utterly unreal, just because it is drawn from a radically idealistic point of view, with complete disregard of the material circumstances which alone gave the events and people substance and life. From the dramatic struggle of mankind for the control of nature he makes a shadow-play of idle philosophizing—thus demonstrating, much in spite of himself, the not very novel truth that disembodied ideas are mere *flatus vocis*, signs of things, not essentially different from material sensations.

When Heisenberg comes to modern physics, it is again hard to contradict him when he reminds us of the limitations of ordinary language for the description of atomic phenomena, or when he stresses, by contrast, the universality of an abstract mathematical description. Why, however, does he stop there? Why doesn't he adduce at this point the all-important fact that our mathematical concepts are also human inventions and accordingly bear the mark of their material origin? Why does he pretend to ignore the fact that the most abstract mathematical ideas only gain meaning from reference to sensory-motoric schemes? There is nothing, alas, in the Platonic trend he perceives in atomic physics but the pertinacious illusion of wonderful harmony in the mathematical structure of the laws of nature: a harmony that is very real, but appears less wonderful when it is realized that it only pertains to a deliberately schematized description of the phenomena. "The wonder is no wonder," said the old Stevin, who was an engineer.

I am sorry to conclude that there was really very little urgency to climb the Pnyx only to conjure up such weary ghosts. To this shadowy company, by the way, belongs as well the bogy of dialectical materialism that Heisenberg seems to have invented for the pleasure of slaying it. The conflict between materialism and idealism, under various forms, has played its historical part. If Heisenberg had been content to state that it has no longer any part to play in modern science, there would be no quarrel between us. Modern science operates with modern concepts—the most powerful of which, complementarity, is the direct outcome of the greatest discovery we owe to Heisenberg's genius.

L. ROSENFELD

REVOLUTIONARY TRAVELOGUE

Science in France in the Revolutionary Era
Described by Thomas Bugge. Edited by Maurice P. Crosland. (A Series of Monographs in the History of Technology and Culture, No. 7.) Pp. xiv+239. (MIT: London, February 1970.) 93*s*.

AT the turn of the nineteenth century the French scientific community centred in Paris was dominant in the world of science to a degree that no national scientific establishment has been since, or had ever been before, the fifty-year span of which Napoleon's rise to power marks the mid-point. The vitality of scientific life alone ought to be evidence enough to redress the picture conventionally drawn by political historians which represents the Directory to have been a time of decadence between the republican élan of the year II and Napoleon's military receivership of the revolution. So, too, must its unslackening vigour in imperial France give pause to scientists and liberals who like to believe in some functional relation between science and liberty.

Pending the day when this history may be fully written, Maurice Crosland, author of an excellent study of Napoleonic science, *The Society of Arcueil* (1967), has had the happy idea of republishing major portions of the journal kept by a Danish astronomer, one Thomas Bugge (or Bÿgge as the French chose to spell it), who spent six months in Paris in 1798 and 1799 attending the sessions of an international commission, probably the first of its kind, convoked to institute the metric system, or (in the words of an official source) "to receive the meter from the hands of France". Bugge was a well known astronomer of a practical sort, then and for many years director of Tycho Brahe's one-time Royal Observatory in Copenhagen. Everybody was interested in accounts of France in the revolutionary years, and Bugge's travelogue, published in Danish in 1800, was translated into German and English in 1801.

Crosland's edition is no mere reprinting. He has based it in the main on the original English version, but where that was obscure or incomplete, he has pieced it out from the German translation, which had been overseen by Bugge himself. Crosland has also omitted (wisely, one would imagine) the account of Bugge's journey from Copenhagen to Paris and back and certain other topics of no scientific interest. Somewhat more questionable in point of editorial policy was his decision to interpolate in his own explanations lengthy passages from other contemporary observers, particularly an acidulous Englishman, Henry Redhead Yorke. Crosland's typographical devices of boldface, indentation, and separately numbered sequences in the footnotes do not always succeed in making clear to the reader at every juncture whose voice it is that is speaking, whether Bugge's, Crosland's, Yorke's, or that of some other visitor.

A little confusion, however, is a small price to pay for so intimate and vivid a scientific memoir. Primary and secondary education under the new regime, the early école polytechnique, the other technical "hautes écoles", medical education, the functioning of the Institut de

France, the Observatory in its republican eclipse, war production and an exhibition of French industry, governmental science policy and administration, the nascent metric system itself—these are the chief sights in this tour of the most highly institutionalized scene that science had yet developed, where it was first wearing its modern dress of a professional enterprise that really mattered to the state. CHARLES C. GILLISPIE

INTRODUCTION TO SOCIOLOGY

Introducing Sociology

By Peter Worsley, Roy Fitzhenry, J. Clyde Mitchell, D. H. J. Morgan, Valdo Pons, Bryan Roberts, W. W. Sharrock and Robin Ward. Pp. 416. (Penguin: Harmondsworth, Middlesex, 1970.) 15*s*.

ACADEMIC sociology has been a long time growing up. It was a relatively minor discipline until quite recently; minor in terms of the numbers of teachers and taught, and probably minor in terms of academic achievement. Its academic pretensions were huge, for it was planned by some practitioners to be no less than the general science of society of which other disciplines, like economics and psychology, were but small particular parts. At the end of the 1950s and in the early 1960s, with the rapid expansion of higher education that then occurred, sociology became an extremely popular subject, and it is now not only a large subject in its own right among honours graduates and research students but it is also an important "minor option" in many courses, particularly in science and technology. Because it is rarely taught at school, the need for good mature introductory books is obvious.

There is a problem about introductory textbooks in the social sciences, because normally a student who takes up what is, after all, predominantly a literary study could be expected to read a considerable number of books, and five or six books in a week or two will almost always give a better idea of what sociology is about than a painstaking introductory text gone through paragraph by paragraph, as presumably introductory texts to a natural science would be. Thus, the problem of introducing this subject to intelligent students of 18-plus for the first time is accentuated by a problem of methodology.

It is fair to say that Professor Worsley's collection is much better than most. It attempts to present recent research to the students as part of a process of introducing elementary sociological concepts to them, and in this way to catch their interest and to explain exactly what it is that sociologists are up to. In particular the chapter on sociological method is a model of its kind. Two drawbacks, however, remain. The first is that which is common to almost all introductory texts of sociology, an enormous, ponderous and tedious chapter on what sociology is about, in which some of the more absurd and grandiose claims still remain, though in attenuated forms. The second is a considerable weakness on the mathematical side. In so far as social sciences have academic standing, one part of their claim to intellectual achievement rests on the application of mathematical techniques to problems of the social order. This mathematical approach is virtually absent from this book. So, too, is any serious discussion of ideas as such. A French student, for example, would, I think, find this a particularly unintellectual book. Have the students perhaps been talked down to? Seeking to avoid boredom, the writers may have achieved light weight, not light heartedness.

The strongest chapter is on the family; the weakest is on education, where, disappointingly, the impression gained from a careful reading of the chapter is of a series of dispirited slogans rather than of any attempt at rigorous analysis. JOHN VAIZEY

LAB BEHAVIOUR

The Social Behaviour of Animals

By Stuart J. Dimond. Pp. 256. (Batsford: London, August 1970.) 50*s*.

THE upsurge of interest in recent years in the social behaviour of animals has been largely based on comparative field studies of various primate species. Whether openly admitted or not the hope has been to find something of the beginnings of human society. Dr Dimond offers a review of the possibilities which lie in an analytical laboratory approach—the psychologist's rather than the ethologist's. This puts more weight on the acquisition of the elements of social behaviour through early experience, and later by social motivation. Parental and sexual behaviour, aggression, status relationships and group behaviour can all be subjects for operant techniques, thus a female monkey will, for instance, press a lever which opens a window through which she can see her own infant. The strength of lever pressing gives a measure of the strength of the urge to be rewarded in this way. Cooperation between animals in obtaining rewards was first tested by Skinner; new work shows that if a rat pressing a lever for food gives a shock to another rat, the first rat's rate of pressing will go down if it can see its effect on the second one. These are all ways of measuring relationships, though one would sometimes be happier if a parallel to behaviour in the wild was more obvious.

Evidence of the operant conditioning of the autonomic system suggests to Dimond that this may be a cause of social responses. For the autonomic changes bring about changes in endogenous processes, for example, hormone production, which in their turn cause the social responses. A theory which could explain some of the effects of early experience.

All too briefly Dimond criticizes over-facile generalization from animals to man. The strength of his critique would be greater if he took more examples from the workers he takes to task.

Perhaps brevity is a fault of this book for the discussions are short and the evidence is not abundant; nevertheless, it is a useful introduction to this approach to social behaviour. J. D. CARTHY

MODELS OF THE MIND

The Computer Simulation of Behaviour

By Michael J. Apter. Pp. 180. (Hutchinson: London, August 1970.) 35*s* boards; 15*s* paper.

THIS book is intended "to examine how far one can accept the mechanist hypothesis in psychology" and "to evaluate the usefulness of computer simulation as a technique to be used by psychologists". By "mechanist hypothesis in psychology" the author has in mind the hypothesis that a machine could exhibit consciousness or self-awareness. In the final chapter on "Consciousness", an attempt is made to discuss this issue. The most significant feature of this attempt is the almost complete failure to utilize evidence or ideas drawn from the material of the preceding 150 pages on computer simulation. Even the most primitive model—that mind is to brain as program is to computer—passes unmentioned in spite of the obvious connexion it provides between the question and the study of complex computing systems. Chomsky, who, together with colleagues such as J. J. Katz, has contributed immensely to a clearer understanding of mentalism, gets no mention under this heading save for an earlier footnote (p. 138) where the reader is warned "that Chomsky's theorizing is sometimes, especially where he uses the concept 'mind', far from rigorous"!

As to the author's second objective, again there is a singular failure to juxtapose the realities of current methodologies in experimental psychology, for example,

quantitative measures of task performance, with the computer based studies he reviews. This is perhaps not unrelated to the fact that the computer programs cited are almost all drawn from the field of artificial intelligence. In these studies the question being pursued is more like "how is it possible to recognize so many versions of an *A* ?", rather than the psychologist's formulation "how long does it take to recognize an *A* ?". Among research workers active in this area (and, unfortunately, Mr Apter is not) there are very few who find it relevant to simulate models intended to account for the results obtained from such recognition tasks.

Apter's review of these programs and of their conceptual and technical basis is extremely superficial. Genuine inquirers would be well advised to read a good introductory text on computing, write and run a simple program, and then address the literature of artificial intelligence directly. Among the misleading glosses which the author puts upon this literature is to suggest (p. 30) that it has "emerged as part of a new and exciting discipline—cybernetics". The intellectual gap between artificial intelligence and cybernetics is large precisely because the kinds of programs one is interested in cannot be usefully represented as control systems. The components of a control system, comparator, reference signal, error signal, and the like, must be represented in terms of simple variables if the mathematics of control theory (the central plank of Wiener's thesis) is to be applicable to an analysis of the behaviour of the system. But the notions of comparator and reference signal in, say, pattern recognition cannot be represented in a program in such a way if the program is to achieve an interesting level of performance.

There is little doubt that artificial intelligence provides a new way of formulating and rigorously testing theories of human behaviour and of thinking about the mind. Unfortunately this book does little to illuminate that fact.

M. B. Clowes

AMERINDIAN PREHISTORY

New World Prehistory

Archaeology of the American Indian. By William T. Sanders and Joseph Marino. (Foundations of Modern Anthropology Series.) Pp. viii+120. (Prentice-Hall: Englewood Cliffs, New Jersey, August 1970.) $4.95 boards; $1.95 paper.

The literature on the prehistory of the New World is now extremely voluminous. This includes not only a large number of books on the general or regional history of Amerindians, but also a wealth of journals of general or restricted outlook—often difficult to find in European libraries. For those wishing to refer to, or recommend to students, a short general appraisal of this research on the early cultures of the Americas the literature is a problem. For this reason, this brief but meaty survey by Sanders and Marino is very welcome. If all other volumes in the "Foundations of Modern Anthropology Series" are as worthwhile as this, then it is going to be an important series of readers for students in anthropology, and to some extent for those concerned with certain other aspects of the social and biological sciences.

New World Prehistory succeeds in reviewing in surprising detail the emergence and changing culture mosaics of the Amerindians during the past 10,000 years (though acknowledging the possibility of earlier populations extending back to 40,000 years). The ecological and evolutionary aspects of early settlement and culture variation are emphasized. Associated with the text there is a chronological chart with culture change indicated on a regional basis, and there is also an extremely valuable set of maps outlining the changing patterns of environmental adaptation and social evolution occurring in these prehistoric groups.

After the introductory chapters, the authors begin with the earliest hunting and collecting level of economy and follow with chapters indicating the multilineal evolution of early agriculturalists and thence of tribes, chiefdoms, states and empires. The final chapter is a discussion of the general significance of culture change in the early New World, and to what extent the variation to be seen through time is the result of innovation (cultural evolution) and imitation (cultural diffusion). The authors discuss these fundamental questions briefly but well. They are clearly not in favour of the introduction of "new" cultural traits by trans-Pacific movements.

For those wishing to extend their reading beyond the text, there is a select series of references. This is a well produced and valuable reference work.

D. R. Brothwell

PACKAGED EVOLUTION

Evolution

By Theodore H. Eaton jun. Pp. xi+270. (Nelson: London, August 1970.) 40*s*.

In this book the author sets out on a round trip of evolutionary theory. Chapters range from a short history of the idea of evolution through the concept of species and speciation, heredity, populations in evolution, adaptation and natural selection, to the bearing of behaviour on evolution and the relevance of geographical distribution. Later chapters treat the geological record, the origin of life and aspects of vertebrate evolution including man. So much in a comparatively small space has meant a brief and superficial treatment of each topic. This raises the question: for whom is the book intended ? The blurb states that the author assumes in the reader an understanding of the range of the animal kingdom and the principles of genetics, but the book has neither enough detail nor enough bibliographical references for most third year undergraduates. Nor does it give any leads to the most modern and controversial aspects of evolutionary theory in spite of the claim on the cover that it is a thoroughly modern textbook. For instance, there is no mention of recent ideas on neutral mutations and the possible consequences to evolutionary theory. There is no analysis of the use of statistical methods in taxonomy although the author discusses problems of taxonomy at some length. Modern mathematical approaches to biogeography are not discussed in a chapter on geographical distribution.

Evolution is not for the specialist, but it can be recommended as a quick guide to conventional aspects of evolutionary theory for undergraduates at an early stage of their university career.

Wilma George

ENERGETIC JOURNAL

Journal of Bioenergetics

Vol. 1, Nos. 1 and 2. Edited by John Avery. Bimonthly. (Plenum: London, 1970.) 210*s*; $26 per volume.

At this time when all scientists are concerned with the difficulty of assimilating the published literature, there should be some justification for the creation of another journal. This new *Journal of Bioenergetics* is an example of the move away from the "general" journal to those dealing with more specialized subjects. In the present case, although "bioenergetics" could embrace a very wide range of topics the first two numbers contain 70 per cent of their space devoted to experimental work with mitochondria. If this trend continues we shall have specialization at its most extreme.

The detailed mechanism of the process whereby energy derived from some oxidation-reduction steps in the respiratory chain may be used to move ions or to synthesize ATP is unknown. This field of research is one

in which there is now an excess of bricks of information, but nobody has yet managed to construct an acceptable building from them (*Science*, **142**, 339; 1963). The reason for this situation is that the subject is very complex; there is therefore an almost infinite combination of experimental parameters.

As is proper for a journal devoted to a subject dependent on highly complex heterogeneous catalysis, the editorial and advisory boards show a wide range of expertise in different disciplines. It is to be hoped that this will be reflected in the range of the papers published and that the high proportion of morphological papers will be balanced in future numbers by papers providing information about the chemistry of the processes involved.

The journal is well printed and the quality of the photographs is adequate. If the present policy of not giving the date of acceptance of papers is continued the speed of publication will not be able to be assessed. There is no doubt that all "mitochondriacs" will feel they must add this journal to their lengthy reading list. In my view, very specialized journals could serve a useful purpose if they publish the best work from all approaches to the problem as well as providing a forum for the critical evaluation of the earlier published work. If future numbers of this journal show that this is the case, then it will have justified its creation. W. N. ALDRIDGE

PARKINSONISM

Parkinsonism

Physiology, Pharmacology and Treatment. By Donald B. Calne. Pp. xiii+136. (Arnold: London, September 1970.) 45*s*.

THE interest of the medical profession in Parkinsonism and related disorders has been revived within the past few years following the discovery that many patients suffering from this disease may be greatly helped by treatment with L-dopa. This is one of the first chronic and disabling diseases of the central nervous system in which a form of replacement therapy based upon sound pathological and pharmacological evidence has become possible. This short monograph by Dr Calne is therefore timely and, in general, it can be warmly commended as giving a succinct and topical review of the condition.

The author's short neurophysiological introduction is, in general, clear and concise, yet reasonably comprehensive, although, like many others before him, he has tended to circumnavigate skilfully the dangerous and largely uncharted territory of basal ganglia physiology. His second chapter, in which he describes the clinical features, aetiology, natural history and pathology of Parkinsonism, is much less satisfactory, largely on account of its brevity, because occasional but important clinical features of the condition, as seen particularly in post-encephalitic cases, are not mentioned. His comments on aetiology are also rather sketchy for, in a sense, he perpetuates the myth that Parkinsonism (with a capital P) may be produced by chronic trauma (sic) or that it may result from intracranial tumours, carbon monoxide poisoning, Wilson's disease or manganese intoxication. He also avoids discussing in any depth the vexed and controversial question as to whether diffuse cerebral arterial disease causes true Parkinsonism or a syndrome resembling it. Even in a monograph which, as its title implies, purports to deal essentially with physiology, pharmacology and treatment of this disorder, the informed reader deserves a more comprehensive and carefully argued commentary on aetiology; although one accepts that a definition of what one means by Parkinsonism is all-important, and although the author attempts to define the syndrome on page 18, most neurologists would agree that many of the aetiological processes referred to earlier more often give distinctive clinical syndromes which bear only a superficial relationship to the clinical condition which most would regard as classical Parkinsonism.

There are also one or two other minor points of criticism in that in chapter three, on tremor, the author fails to distinguish between action tremor on the one hand and the intention tremor of cerebellar dysfunction on the other, and, subsequently, in an otherwise admirable short summary of present views concerning rigidity, he perhaps does less than justice to recent work on alterations in the H-reflex which have been reported in patients with this disease. He is at his best in considering the pharmacology of Parkinsonism, the methods of assessing treatment, and in his comprehensive and up to date review of the place of L-dopa in treatment. All of the important and topical questions are discussed here, though he gives little if any clear guidance as to whether patients should or should not be given standard anti-cholinergic remedies along with L-dopa. It may be that the answer to this important question is not yet known; not surprisingly he has also been unable to include in this monograph reference to reports which have appeared very recently concerning the use of decarboxylase inhibitors in combination with L-dopa in patients with this disease. Nevertheless, the book is surprisingly up to date and many references to papers appearing in 1970 are included in the bibliography. The book is clearly written, the reference list is comprehensive, there is a good index, it is inexpensive, and in spite of the criticisms mentioned earlier, it is on the whole a faithful summary of current knowledge concerning the pharmacology and treatment of Parkinsonism. JOHN N. WALTON

HORMONE REGULATION

Hormones and the Environment

Proceedings of a Symposium held at the University of Sheffield, September 2–5, 1969. Edited by G. K. Benson and J. G. Phillips. (Memoirs of the Society for Endocrinology, No. 18.) Pp. xvi+629. (Cambridge University: London, July 1970.) 140*s*; $22.50.

THE increasing awareness of the importance of environmental factors in the regulation of hormonal mechanisms prompted the symposium on "Hormones and the Environment", the proceedings of which form this, the eighteenth memoir of the Society for Endocrinology. The result is a stimulating, albeit heterogeneous, collection of the twenty-three papers presented, together with the edited discussions.

There are sections dealing with the aquatic, terrestrial and biotic environments as well as neuroendocrine mediation and temporal changes in endocrine secretions. The considerable variety of subject matter in the text precludes the possibility of a single theme emerging. One requires fertile imagination to link "Intersexuality in Fishes", with "Malnutrition and the Endocrine System in Man", or with "Pheromone-endocrine Interactions in Insects". In spite of this range, however, the smoothly edited discussions of papers reveal the ability of participants to bring their own special endocrine interests to bear on the quite different problems of others. The record of the discussions is a pleasing facet of the book.

It may be argued that several of the papers in this memoir contain relatively little about hormones; notably the account of "Mechanisms of Salt and Water Transfer across Membranes in Teleosts" by Dr J. Maetz, and "Kidney Function in Desert Vertebrates" by Professor W. H. Dantzler. These two distinguished contributors, however, clearly illustrate the need for a complete background knowledge of the phenomena over which hormones may be assumed to have control.

In a symposium concerned with the environmental influences on hormonal systems, it is inevitable that

neuroendocrinological studies should have been to the fore. Contributions by Dr J. S. Tindal on "Environmental Stimuli and the Mammary Gland", Professor L. Martini on "Hypothalamic Releasing Factors", Professor W. B. Quay on "The Significance of the Pineal", and Professor H. Heller on "The Neuroendocrine Control of Water Metabolism" are notable in this respect.

The diversity of subject matter and the comprehensive manner in which it is treated within the common framework of "Hormones and the Environment" should make excellent reading for all interested workers in the field of endocrinology. The many questions raised by the contributors will undoubtedly encourage further research.

A. THORPE

ELEMENTARY OPTICS

Optical Data Processing

By Arnold Roy Shulman. (Wiley Series in Pure and Applied Optics.) Pp. viii+710. (Wiley: New York and London, June 1970.) 260*s*.

OPTICAL data processing is one of the more exciting applications of the past decade of intensive research in lasers and opto-electronics. The publishers of this text state that it "presents a thorough introduction to this new field" with "a maximum amount of physical interpretation of the basic principles". The publication of such a book would be particularly opportune but, unfortunately, this volume is far from meeting these claims. Rather, it is a compendium of elementary optics and the associated mathematics, rarely rising above the level of a first-year university course, and spiced with some practical hints on photography and holography.

Typical examples of the general mathematical verbosity are the use of three lines on p. 121 to move from $\sqrt{2\pi}/2\pi$ to $\sqrt{1/2\pi}$ and the trivial algebraic steps on p. 284, one of the sixty-one pages devoted to the elementary mathematical treatment of Ronchi gratings. The book is cluttered with much algebraic and optical trivia, yet, curiously, while eighty pages are devoted to developing Fraunhofer diffraction, the Fresnel-Kirchoff integral is quoted (on p. 389) without any derivation at all. There is an equal profusion of trivial or repetitive photographs, such as that of a rectangular aperture on p. 624 and the thirty-three Moiré patterns in appendix 6. Circumlocution extends even to the final chapter on properties and techniques for photographic reproduction, which, like the rest of the volume, could have been drastically condensed to great advantage. This book cannot be recommended, especially at a price of 260*s*.

D. J. BRADLEY

SOUNDERS AND WHISTLERS

Plasma Waves in Space and Laboratory

Edited by J. O. Thomas and B. J. Landmark. Vol. 2. Pp. 562. (Edinburgh University: Edinburgh, April 1970.) 140*s*.

THIS volume completes the published proceedings of the Røros school of April 1968, and comprises some thirty-five papers—those classified as contributions to current research rather than as reviews. Papers concerned with space rather than laboratory plasmas predominate, on both observational and theoretical aspects.

The several contributions on top-side sounders, ionosphere resonances detected by Explorer XX and the Alouette satellites, seem somewhat contradictory and confusing, until put in perspective by Benson's review of the numerous observations. The demonstration that the resonant frequencies are displaced from the integral harmonics is important for deciding between rival theories. Allowing theoretically for non-uniformities in the magnetic field is also shown to be important. A further sizable group of papers concern themselves with whistlers, both their detection and explanation. The importance of collisions in selecting the propagating (convective) modes is brought out from two angles. There are, in addition, several papers on antenna theory—these with laboratory emphasis—and two final, isolated contributions on weak turbulence and on magnetospheric drift instabilities (as the source of micropulsations).

Through using offset reproduction of an excellent typescript, this volume gives some 50 per cent more information per £ than volume one, but at the cost of closer type and occasional clumsy format. The publishers deserve congratulations for the overall good quality production at—for these days—a reasonable price. Nevertheless, I question the sense of producing current research papers this way, at perhaps double their cost in established journals. Some of the papers will no doubt retain relevance for a few years yet, but inevitably in the two years since the Røros school, many have been superseded by more recent work. As in the first volume, abstracts are annoyingly absent, so I must again deplore the lack of adequate summaries to certain of the papers. Still, for those working specifically on top-side sounders and whistlers, this volume will provide a useful collection for reference purposes, and for would-be students it supplies a convenient introduction to these topics.

M. K. WALLIS

BETWEEN THE STARS

The Interstellar Medium

By S. A. Kaplan and S. B. Pikelner. Pp. xi+465. (Harvard University: Cambridge, Massachusetts; Oxford University: London, July 1970.) 190*s*.

THOSE of us working in the field of interstellar matter have become increasingly aware of the need for a comprehensive and up to date text on this subject. During the past decade our traditional views of the interstellar medium have undergone a significant evolution. The simple, two-component picture of an interstellar medium consisting of gas and dust clouds has proved to be as inaccurate as it is naive. In addition to gas and dust, magnetic fields, cosmic rays, radiation fields and stars must be considered together as forming a system of mutually interacting components. The authors of this book have played a major part in shaping our modern view of the interstellar medium, and in their new book they expound this view in a clear and lucid manner.

The first chapter deals with interstellar hydrogen, the most abundant component of the interstellar medium. It discusses the state of ionization of hydrogen and its distribution in space, the propagation of Lyman continuum and Lyman-alpha radiation and the emission and propagation of radiowaves in the interstellar medium. Then follows a chapter on the physical state of the gas which includes a discussion of the formation of spectral lines in the interstellar gas, molecules in space and the energy balance of the interstellar gas. Next is a chapter on interstellar dust followed by one on interstellar magnetic fields and non-thermal radio emission in the galaxy. A final chapter, devoted to interstellar gas dynamics and the evolution of the interstellar medium, discusses, among other topics, the behaviour of shock fronts and ionization fronts in the interstellar gas as well as the problem of star formation from interstellar gas clouds.

The book encompasses a remarkably wide range of topics presented in a logical order with meticulous care given to detail. Theoretical discussions are often presented from first principles, and relevant observational

data are adequately summarized throughout. This makes the book a more or less self-contained thesis which could be studied independently without frequent recourse to a bibliography. A useful bibliography is, however, provided for those who need it. On the whole the authors seem to address their writing to an audience of physicists rather than one of specialist astronomers. This makes the book an invaluable text for both the specialist research worker and beginner.

My only criticism is that in a few instances the book is already out of date by five years. Omission of recent developments in the identification of interstellar molecules and certain components of cosmic dust are notable examples. This is inevitable in such rapidly evolving fields. But it seems unfortunate that the time lag between the last Russian edition and the present translation should be as long as five years. A few of the shortcomings caused by this delay are remedied in a short addendum at the end of the volume. N. C. WICKRAMASINGHE

RIFT RESEARCH

Graben Problems

Proceedings of an International Rift Symposium held in Karlsruhe, October 10–12, 1968. By J. H. Illies and St. Mueller. Pp. 316+7 plates. (International Upper Mantle Project Scientific Report, No. 27.) (Schweizerbart'sche Verlagsbuchhandlung: Stuttgart, 1970.) $23.10; DM 82.

THIS book contains the scientific contributions presented at the third symposium of the international Rhine graben research group held at the University of Karlsruhe on October 10–12, 1968. There are four papers of a general nature on the world rift system, thirty four papers on the Rhine graben and six papers on the East African rift system.

The proceedings are introduced by Leon Knopoff giving a clear discussion of the concept and importance of rigid plate tectonics. This is followed by two excellent review articles on graben tectonics, the first of a geological nature by J. H. Illies and the second geophysical by St. Mueller. These are followed by an interesting article by J. P. Rothé on the seismicity of oceanic and continental rifts. It is often forgotten that it was Professor Rothé who paved the way to the recognition of the world rift system by his observation in 1954 that the seismic zone of the African, Carlsberg and mid-Indian Ocean rifts continues around Africa to join with the mid-Atlantic rift. Rothé here gives many more interesting pieces of information including the fact that for the period 1953–1965, only 1·5 per cent of the world's total seismic energy is liberated along oceanic rifts. This is in contrast to island arcs and deep trenches where most seismic energy is liberated, this being caused by the plunging of cold, rigid plate into the upper mantle.

These four opening chapters are followed by five papers on stratigraphic evidence pertaining to the development of the Rhine graben. These are noteworthy for their dependence on data from oil companies which have enabled the production of excellent isopach maps of the region. These are followed by five more geological papers on basement and structure.

Five geothermal papers show that the Rhine graben, like other rifts, has high heat flow. These are followed by two papers on volcanism emphasizing its basaltic nature. Next come four papers on seismotectonics; two of these are on seismicity studies and two on geodetic levelling and also plans for laser distance experiments (Kuntz *et al.*). Ahorner has collected data from 1600 to 1967 in a very comprehensive survey of the seismicity of the Rhine graben. This indicates that in the neighbourhood of Mainz, the active rift zone of the upper Rhine turns north-west towards Amsterdam rather than continuing north-north-east through the Hessian depression. For the period 1600 to 1967 the most seismically active region was between Köln and Aachen. It must be remembered, however, that the seismic activity is relatively very small, the seismicity of the whole of the Rhine area being about 1 per cent of that of southern California!

German scientists have been especially active in pursuing seismic studies including application of refraction and reflexion techniques, the use of spectral transfer ratios of long period body waves and the dispersion of Rayleigh waves. This has led to a very complicated structure for the crust beneath the Rhine graben. Emphasis is placed on a "cushion" (7·6 to 7·7 km s^{-1}) above the "Moho" beneath the rift. Above the cushion, evidence is claimed for two low velocity channels in the crust of 5·5 and 6·2 km s^{-1} respectively.

Papers on gravity, magnetic surveys and palaeomagnetism are followed by a final Rhine graben section entitled "Magneto-Telluric Deep Soundings". These reports confirm the existence of a high conducting zone beneath the rift, but there remain some uncertainties concerning its depth and temperature.

The book concludes with six articles on the East African rift system. These include three papers (by Knetsch, Tazieff and Schaeffer) giving preliminary results of recent reconnaissance expeditions to the inhospitable Afar triangle of Ethiopia. The book ends with a very useful article by Wohlenberg on the seismicity of the rift system in East Africa.

These conference proceedings show the thoroughness and intensity of the work on the Rhine graben; the German scientists are to be congratulated on the way in which they have assembled so much material and conducted new geophysical experiments, many of them at small or moderate costs. It is disappointing to see how few geologists (with the notable exception of Laubscher) interpret their observations in the light of Knopoff's opening lecture on plate tectonics. Otherwise, criticisms are minor. Many of the papers are in German; in these days when there is so much literature to be read it is regrettable that the editors did not insist on at least abstracts in English for the German papers and abstracts in German and French for the English papers. There are no lists of references at the ends of each paper; they are collected together at the end of the book. I found this irritating, especially on discovering several omissions and inaccuracies. The book is well produced, has clear illustrations and some beautiful photographs. It is somewhat expensive but is well worth it. R. W. GIRDLER

MODERN VOLCANOLOGY

Volcanoes

By Cliff Ollier. (An Introduction to Systematic Geomorphology, Vol. 6.) Pp. xiv+177. (MIT: Cambridge, Massachusetts and London, June 1970.) 68*s*.

CLIFF OLLIER has contrived to write an interesting and readable text, in which, although the subject matter is never profoundly treated, he nevertheless conveys a sense of appreciation beyond the evident limitations of length.

There are, however, some sections, for example chapters one and eight, which, although they are no doubt necessary for the sake of completeness, are unduly elementary and contribute little to a publication of restricted length. Nevertheless, the book is both useful and justified, for there is no modern text on vulcanology. The only comparable publications are reprinted or revised older works, but the considerable interest and advances in the study of vulcanology justify an entirely new publication.

The list of references is wide, representative and useful. B. C. KING

Correspondence

Restrictions on Soviet Scientists

SIR,—The depressing story of the attempts by Dr Medvedev to accept an invitation to a conference in Sheffield (*Nature*, September 19) prompts me to raise the following issues. I have been to three conferences during the past month in various parts of Europe. At each conference papers by Soviet scientists were listed in the programme and abstracts were included; on each occasion none of the Russians turned up. One of these conferences was in Yugoslavia and on that occasion neither the Russian nor a Czech contributor was able to turn up, although both were due to give major addresses. At each of these conferences the organizers were caused embarrassment as well as regret by the inability of the speakers to come, and last-minute changes had to be made to the timetable in consequence. A further important consequence of these cancellations is that Western scientists are deprived of the benefit of meeting their Soviet opposite numbers.

At one of the conferences I attended, a letter was sent to the organizer by a Russian who was unable to come (such letters are not always sent, and sometimes the speakers simply do not turn up without notice or explanation). In the letter the scientist concerned expressed his regret at his inability to come and added that he was looking forward to seeing his contribution printed in the official proceedings of the conference. The question then arose whether his contribution should in fact be printed, and it was agreed that this should not be done. It is, of course, hard on a Soviet scientist, who would have liked to attend a conference but has been prevented by the failure of his authorities to grant permission, not to see his work printed. On the other hand, as I pointed out, if the work is printed then the Soviet authorities receive, as it were, indirect kudos without even having put up the resources to enable the speaker to deliver his paper in person; the Soviet authorities would have progressively less reason to permit their scientists to go abroad if their work is published as though they had been at the conference.

I submit therefore that it would be likely to be of long-term benefit to our Soviet colleagues and make it more probable that they would more often be allowed to come in future, if as a matter of principle conference organizers were to decline to print contributions from people who have not actually turned up in person at the conferences in question.

I should be interested to know the views of other readers concerning this suggestion.

Yours faithfully,

R. W. CAHN

University of Sussex,
Falmer, Brighton, Sussex.

Accelerating Somatic Cell Genetics

SIR,—In your leading article on October 24 (*Nature*, **228**, 318; 1970), you attribute to Watkins and myself a discovery that we did not make. Watkins and I were the first to fuse together cells of human and murine origin, and we observed that in the fused cells DNA replication was markedly inhibited in the human nuclei. However, the discovery that human chromosomes are preferentially lost from proliferating man–mouse hybrid cells was not made by Watkins and myself, but by Mary C. Weiss and Howard Green (*Proc. US Nat. Acad. Sci.*, **58**, 1104; 1967).

Yours faithfully,

HENRY HARRIS

Sir William Dunn School of Pathology,
University of Oxford.

Population in Nigeria

SIR,—I wish to make some comments on your leading article of September 12 relating to the discussion at the meeting of the British Association (*Nature*, **227**, 1073; 1970). You are, of course, correct in your reporting, but there is a possible danger of misunderstanding from the comment which you attributed to me which states that I doubt whether Africa has a population problem. I would not like to leave an impression which would be wrong. What I did say was that we are sceptical of the great efforts being made on population control in Africa by some advanced countries. We are sceptical because our main problem is not that of high birth rate which would likely be followed by a great increase in population, but rather the problem of a high infant mortality rate.

To be more specific, may I explain in this way: the population of Nigeria is calculated at about 60 million. A large majority of these 60 million are young people of not more than 15 years of age and most of these young people will never live beyond the age of 15—this is a medical fact. The result is that the effective population of Nigeria as regards her manpower is certainly not 60 million but may be between 20 and 30 million. It is obvious therefore that our concern should not be, as was suggested in the question directed to me, that we should control birth rate by limiting the number of children in each family (which is the current practice in population control) but that of preventing the high infant mortality rate.

Yours faithfully,

T. ADESANYA IGE GRILLO

Department of Anatomy,
University of Ibadan, Nigeria.

Evolution of Rifting in Africa

SIR,—In his interesting comments (*Nature*, **227**, 699; 1970) on our paper[1], it seems that McConnell thinks we consider the phenomenon of sea floor spreading to be taking place in the rift zone of East Africa. This is not so. The purpose of our communication was to bring together evidence from seismicity, age of faulting, age of volcanoes and interpretations of gravity anomalies and to suggest that they together indicate that rifting in East Africa is probably associated with attenuation of the lithospheric plate. This process, we envisage to precede spreading. The rift in East Africa cannot be a site of spreading for

it is likely from geophysical and geological data that sialic Pre-Cambrian material underlies the rift floor. We stated that the positive gravity anomaly indicates the presence of an intrusive body which could be within 1 km of the rift floor . . . this suggests that extreme crustal thinning has taken place, but as yet there is no crustal separation as in the Red Sea. Unlike McConnell who uses the term "spreading" twelve times, we were careful to use it only once and then in parenthesis with the word analogous.

We agree with the comments on the age of volcanoes and McConnell's doubts are expressed by the long error bars in our Fig. 4. We plotted all the age data available at the time of writing and it remains to be seen whether the trend is born out by future data. We were careful not to use these data alone but to bring together five sets of data to support the suggestion of plate attenuation.

Yours faithfully

R. W. Girdler

Obituary

Professor A. E. Alexander

Albert Ernest Alexander, professor of physical chemistry at the University of Sydney, died on May 23 1970. In Britain and Australia, he made important contributions to colloid and surface chemistry.

Alex, as he was always known, was born in Ringwood, Hampshire. He began his university career at Reading in 1932, continuing at King's College, Cambridge, in 1935. After obtaining a first in chemistry in Part II of the Natural Science Tripos, he joined the Department of Colloid Science in Cambridge under E. K. (now Sir Eric) Rideal, a step which largely determined the direction of his future research; his fellowship thesis at King's College in 1939 was entitled "Molecular Orientation and Reactions in Monolayers". During the war, although much of his time was taken up by war research, he continued to produce papers on surface chemistry and allied topics such as liquid interfaces, interfacial tension and ageing effects, built-up films, the structure of films, the role of hydrogen bonding, and the application of the Gibbs adsorption equation. On the biological side he was interested in the penetration of membranes and surfaces and in the properties of protein films.

In 1944 he was appointed an assistant director of research in the Department of Colloid Science at Cambridge. At this time, he was very successful in fostering friendly relations with the chemical industry. The summer school on colloid science, which he organized in collaboration with the Royal Institute of Chemistry in 1945, is still spoken of warmly.

It was a great loss to Cambridge science when he accepted the Foundation chair of applied chemistry in the New South Wales University of Technology at Sydney, becoming the first head of the Chemistry School there and dean of the Faculty of Science. In 1956, having built up a flourishing department, he moved to the chair of physical chemistry at the University of Sydney, where he remained until his death. In Australia, as in England, Alexander was enthusiastically concerned with surface chemistry and its application to such things as water evaporation, the efficiency of cattle dipping preparations and the effectiveness of drugs. He was author or co-author of more than 130 papers on these subjects.

Alex married happily twice but had much more than his fair share of personal tragedy. Cathie, his first wife, died in 1965 after a long illness and in 1967 he married Giesela, the widow of a university colleague. Shortly afterwards, his daughter Naomi was killed in a car crash. With his hidden resources he was soon back in action, but tragedy struck again late in 1969, when he himself became fatally ill. He leaves Neil, the son of his first marriage, Giesela and her two children.

Announcements

University News

Professor G. C. McVittie, professor of astronomy at the University of Illinois, will be a visiting professor at the **University of Kent** during 1971.

Miscellaneous

Professor Ralph W. Chaney, University of California, Berkeley, has been awarded the **Paleontological Society Medal.**

Mr Ray Creasey, director of Advanced Systems and Technology, British Aircraft Corporation Preston Division, has been elected a fellow of the **American Institute of Aeronautics and Astronautics.**

Lord Penney of East Hendred, rector of the Imperial College of Science and Technology, University of London, has been awarded the **James Alfred Ewing medal** for his services to engineering. The **1970 S. G. Brown award and medal** has been won by **Dr D. C. Simpson** for his work on the development of externally powered artificial limbs.

The report of six new species of seaweed found in South Africa (*Division of Sea Fisheries Investigational Report No. 86*, Cape Town, 1970), which was mentioned in *Nature* (**227**, 779; 1970), unfortunately contained several errors and is to be reissued at a later date.

An **American Red Cross National Fractionation Center** has been established under the joint sponsorship of the American Red Cross and the National Heart and Lung Institute. The centre will provide facilities and staff for the large scale isolation from blood and other tissues of specialized proteins, plasma and cellular enzymes, membrane fractions and so on, which are not available from commercial sources. Further information can be obtained from Dr G. A. Jamieson, American Red Cross Blood Research Laboratory, 9312 Old Georgetown Road, Bethesda, Maryland 20014, USA.

Entries are invited for the £50 prize of the **Plastics and Polymer Group of the Society of Chemical Industry,** awarded annually for the best paper submitted on any aspect of pure or applied polymer science. The paper must be in English, and may be a description of original

work, an essay or a review. Entrants must be under 35 years old at the closing date, March 31, 1971, and if from overseas must be members of the society, although all British subjects are eligible. Further information can be obtained from the Plastics and Polymer Group, c/o Society of Chemical Industry, 14 Belgrave Square, London SW1.

ERRATUM. In the review "Ion Molecule Reactions" by P. F. Knewstubb (*Nature*, **228**, 392; 1970), the word "although" in line 7 of the first paragraph should read "even if" and the date in line 9 should be 1965 and not 1964.

International Meetings

June 7–9, 1971, **Symposium of the Association for Research on Exploration and Production Techniques,** Rueil-Malmaison (M. le Secretaire du Colloque ARTEP, Division Production, Institut Français du Petrole, 1–4 Avenue de Bois Préau, 92 Reuil-Malmaison, France).

June 9–11, 1971, **Carbon-13,** Los Alamos (E. S. Robinson, PO Box 1663, Los Alamos, New Mexico 87544, USA).

June 9–11, 1971, **Radiation-induced Voids in Metals,** Albany (Professor J. W. Corbett, Physics Department, SUNY/Albany, New York 12203, USA).

June 10–11, 1971, **Metabolism and Disease,** Ottawa (Mr R. S. Meldrum, Technical Secretariat, Food and Drug Directorate, Tunney's Pasture, Ottawa, Canada).

June 14–17, 1971, **Identification and Measurement of Environmental Pollutants,** Ottawa (M. K. Ward, c/o National Research Council of Canada, Ottawa, Ontario, Canada).

June 27–July 2, 1971, **Carbon,** Bethlehem, Pennsylvania (Professor Henry Leidheiser jun, Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015, USA).

July 5–7, 1971, **Rare Earths and Actinides,** Durham (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

July 5–8, 1971, **Acetylenes, Allenes and Cumulenes,** Nottingham (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN).

July 5–8, 1971, **Shock Tubes,** London (Symposium Secretary, Department of Aeronautics, Imperial College, Prince Consort Road, London SW7).

July 5–9, 1971, **Crystalline Growth,** Marseilles (B. Mutaftschiev, Laboratoire des Mécanismes de la Croissance Cristalline, Faculté des Sciences de Marseille, Saint-Jerome, 13 Marseille 13e, France).

July 6–9, 1971, **Major Loss Prevention in the Process Industries,** Newcastle upon Tyne (Institute of Chemical Engineers, 16 Belgrave Square, London SW1).

July 11–15, 1971, **Health Physics Society Meeting,** New York City (Lee Gemmel, Health Physics Division, Brookhaven National Laboratory, Upton, New York 11973, USA).

July 12–16, 1971, **Society for Analytical Chemistry Conference,** Durham (Mr C. A. Johnson, Honorary Secretary SAC Conference, 9–10 Savile Row, London W1X 1AF.

July 13–16, 1971, **Synthesis in Organic Chemistry,** Cambridge (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN).

July 18–23, 1971, **Fluorine Chemistry,** Durham (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN).

July 20–23, 1971, **Mechanized Information Storage and Retrieval Systems,** Cranfield (Mr Cyril Cleverdon, Cranfield Institute of Technology, Cranfield, Bedford).

British Diary

Monday, November 2

Cryogenics and the Fawley Motor (6.30 p.m.) Mr A. D. Appleton, Institution of Electrical Engineers, in the Electrical Engineering Laboratories, University of Liverpool.

Development, Use and Requirements of STOL Aircraft (5.30 p.m. informal discussion) Institution of Civil Engineers, at Great George Street, London SW1.

Protective Coatings for Gas Pipe Lines and Storage Vessels (7 p.m.) Dr J. T. Harrison, in the Bullock Lecture Theatre, Hull College of Technology, Hull.

The Chemical Industry and Government-Sponsored Corporations (6.30 p.m.) Sir Frank Schon, Society of Chemical Industry, in the Scientific Societies Lecture Theatre, 23 Savile Row, London W1.

The Pharmacology of Neuromuscular Transmission (6 p.m.) Professor W. C. Bowman, University of London, at the Royal Postgraduate Medical School, Du Cane Road, London W12.

The Soviet Engineer (6.30 p.m.) Mr V. S. Chousovitin, Institution of Electrical Engineers, at Byng Kendrick Suite, University of Aston in Birmingham, Gosta Green, Birmingham 4.

What is the Future for Linkage Synthesis? (6 p.m. Discussion) Institution of Mechanical Engineers, Applied Mechanics Group, at 1 Birdcage Walk, London SW1.

Tuesday, November 3

Industrial Technology and Management (6.30 p.m.) Professor C. W. Page, Institution of Electrical Engineers, at the University of Leeds.

Mycenaens and Phoenicians at Kition (5.45 p.m.) Dr V. Karageorghis, University of London, at the Institute of Classical Studies, 31–34 Gordon Square, London WC1.

The Chemical Composition of the Lunar Surface; Results from Unmanned and Manned Missions (5.30 p.m.) Professor A. A. Turkevich, University of London, at Imperial College, London SW7.

The Storage and Secretion of Hormones (5.30 p.m.) Dr A. D. Smith, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Fourth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

The Surge Transference Characteristics of Generator Transformer Installations (6 p.m.) Mr E. L. White, Institution of Electrical Engineers, at the Carlton Hotel, Edinburgh.

When Palm Trees Grew in London (1.20 p.m.) Dr W. G. Chaloner, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

Wednesday, November 4

Analytical Aspects of Environmental Pollution (3 p.m.) Mr J. Robinson, Mr G. F. Longman, Mr P. G. Jeffery and Mr A. E. J. Eggleton, Society for Analytical Chemistry, at the Wellcome Building, Euston Road, London NW1.

Bench Wear Testers (6 p.m. discussion) Institution of Mechanical Engineers, Tribology Group, at 1 Birdcage Walk, London SW1.

Compensation for Death and Injury in International Air Transport (3 p.m. symposium) Royal Aeronautical Society, Air Law Group, at 4 Hamilton Place, London W1V 0BQ.

Control of Triglyceride Fatty Acid Uptake by the Tissues (2 p.m.) Dr D. S. Robinson, University of London, at the Royal Postgraduate Medical School, Du Cane Road, London W12.

Formation of Deep Water in the N.W. Mediterranean (5.45 p.m.) Mr T. Sankey, Challenger Society, at the Linnean Society, Burlington House, Piccadilly, London W1.

High Speed Fuses for the Protection of Diodes and Thyristors (7.30 p.m.) Mr E. Jacks, Institution of Electrical Engineers, at the Assembly House, Norwich.

How Things Move (5.30 p.m.) Professor G. Porter, FRS, Royal Institution, at 21 Albemarle Street, London W1. (Lecture for Fourth Form pupils from Schools in London and the Home Counties. To be repeated on November 5, 10 and 11.)

Kant's "Universal Natural History and Theory of the Heavens", 1755 (1 p.m.) Dr G. J. Whitrow, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street. London W1.

Metrication (6.45 p.m.) Mr F. Mundy, Oil and Colour Chemists' Association, jointly with BPMA, at the Carlton Hotel, North Bridge, Edinburgh.

Microwave Generation Devices (6 p.m.) Mr K. Wilson, Institution of Electronic and Radio Engineers, Components and Circuits Group, at 9 Bedford Square, London WC1.

Performance Monitoring Techniques (2.30 p.m. colloquium) Institution of Electronic and Radio Engineers, Joint IEE/IERE Computer Group, at the Institution of Electrical Engineers, Savoy Place, London WC2.

Recent Advances in the Chemistry of Unnatural Products (7.15 p.m.) Professor R. B. Woodward (Harvard), Pharmaceutical Society of Great Britain, in the Large Lecture Theatre, The School of Pharmacy, 29/39 Brunswick Square, London WC1.

The Value of the Computer to the Electronic Engineer (6.15 p.m.) Mr R. H. Williams, Institution of Electrical Engineers, jointly with IERE, at the University of Manchester Institute of Science and Technology, Manchester.

Thoughts on the Future of World Communications (7 p.m.) Professor E. C. Cherry, Institution of Electrical Engineers, at Dorking Hall, Dorking, Surrey.

Thursday, November 5

Airborne Microbes: Their Significance and Distribution (4.30 p.m.) Dr P. H. Gregory, FRS, Royal Society, at 6 Carlton House Terrace, London SW1.

Automation and Computer Techniques in Clinical Chemistry (5.30 p.m.) Professor T. P. Whitehead, University of London, at the Institute of Child Health 30 Guilford Street, London WC1. (Fifth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

How Much Does One Pay for High Efficiency in Fluid Plant? (6 p.m. discussion) Institution of Mechanical Engineers, Fluid Plant and Machinery Group, at 1 Birdcage Walk, London SW1.

Quantitative Microbiology (symposium) Society of Chemical Industry, Microbiology Group, at the Borough Polytechnic, Borough Road, London SE1.

The Recruitment Circus (5.30 p.m. informal discussion) Institution of Civil Engineers, Education and Training Group, at Great George Street, London SW1.

Friday, November 6

ESR and Flash Photolysis (1 p.m.) Dr K. A. McLaughlan, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Extraction and Refining (two-day residential course) Institution of Metallurgists, at the Grand Hotel, Eastbourne, Sussex.

The Open University (9 p.m.) Dr Walter Perry, Royal Institution, at 21 Albemarle Street, London W1.

Tricks of the Trade (5.30 p.m.) Dr R. A. Chalmers, Society for Analytical Chemistry, Scottish Section, in the Thomas Graham Building, University of Strathclyde, Cathedral Street, Glasgow C1.

Monday, November 9

Batteries mW to kW (6.30 p.m.) Mr C. J. Bruce, Institution of Electrical Engineers, London Graduate and Student Section, at Savoy Place, London WC2.

How Does the Introduction of SI Units Affect the Mechanical Engineer? (6 p.m. discussion) Institution of Mechanical Engineers, Thermodynamics and Fluid Mechanics Group, at 1 Birdcage Walk, London SW1.

Proofs: Positive and Presumptive (5.30 p.m.) Mr B. Gower, British Society for the Philosophy of Science, in the Joint Staff Common Room, University College London, Gower Street, London WC1.

Semiconductor Gamma Camera System (6 p.m.) Mr E. Moss and Mr W. Gore, Institution of Electronic and Radio Engineers, Joint IEE/IERE Medical and Biological Electronics Group, at 9 Bedford Square, London WC1.

Another Round of SALT

THE resumption of the SALT negotiations in Helsinki this week is an important occasion. In the past year, the governments of the United States and the Soviet Union have been able at least to bring out into the open some of the issues which must attend any attempt to regulate strategic weapons systems. In the previous meetings, the United States representatives have put forward a number of suggestions as to how the deployment of strategic weapons systems might be controlled by international agreement. From the proceedings at Vienna earlier this year, it is clear that many important issues will have to be hammered out in the weeks ahead —the extent to which short range missile systems based in Europe, or tactical strike aircraft, should be included in a SALT agreement, for example. At Helsinki, however, the immediate interest will be the response of the Russian government to the various suggestions so far put forward, chiefly from the American side. From the tenor of the Russian reply, it should be possible to glean some inkling of the outcome of the SALT negotiations. The hope is that the Russian reply will be constructive, which is not to suggest that there can be a quick settlement—the technical problems are too complicated for that. By the same test, a negative reply to the American suggestions put forward earlier this year could easily bring the negotiations to a halt—and there are some who argue that a quick ending to the talks would be preferable to a long drawn out and unproductive negotiation.

Would protracted talks be a danger in themselves? This is one of the arguments put forward in the past few weeks by those in the United States who fear that the continuation of the negotiations will provide opportunities for the Soviet Union to steal a march on the United States in the deployment of strategic weapons. This reflects the anxiety now prevalent in the United States about the rapid growth of the Russian long range rocket system, particularly in the deployment of the very large SS-9. By now, the chances are that the number of launching sites for SS-9 missiles is greater than the number of Minuteman sites in the United States. At the same time, the carrying capacity of the new Russian missile is thought to be large enough to accommodate either a large number of independent warheads or the kind of explosive power needed to deliver damaging attacks on underground missile silos. In short, many Americans fear that underneath the umbrella of the SALT negotiations, the Soviet Union is acquiring a capacity to make a successful attack against the retaliatory strength of the United States. This, the argument goes, would upset the present balance between East and West. It is therefore only proper to acknowledge that this fear would be real only on a much longer time scale. If the deployment of SS-9 missiles continues for much longer at the present rate, and if the warheads are able to accommodate independently manoeuvrable missiles capable of reaching missile silos with precision, there will be reason to fear that the balance of terror as it is called has been upset. But is not that state of affairs a long way in the future? For one thing, the accuracy of the Russian independent warheads is unlikely, at this early stage of the game, to be great enough to ensure a first strike capability. And, after all, only when a nation is almost sure that an attack against its opponent's missiles will succeed will it seriously contemplate the risk of retaliation against its population centres. In this unpleasant game, a first strike is feasible only if it is literally devastating. And there is at present no prospect that the deployment of the Russian force of SS-9s will be effective against the missile launching submarines. It will be the late seventies before countermeasures against submarines are a threat to their strategic credibility, and only then will there be reason to fear that the American strategic force is vulnerable to a pre-emptive attack. By then, no doubt, the development of independently manoeuvrable warheads in the United States will have done much to redress the balance. There is even the possibility that the anti-ballistic missile system will by the late seventies be efficient enough to give American rocket silos an appearance of immunity against attack. In short, the complaint that the SALT talks may serve as a cloak for a destabilizing development of the Russian force is probably exaggerated or, more accurately, premature.

Another danger is that protracted talks will create a climate in which a meaningless or even a dangerous agreement may be produced. It is therefore important that the great difficulty of negotiating a treaty to limit the deployment of strategic weapons should be widely appreciated. So far, the guiding principle behind the American proposal has been the wish to conserve a measure of stability. Restricting the numbers of delivery systems of various types deployed by

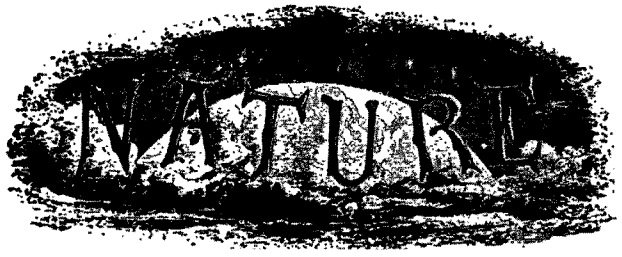
each of the two powers is not an objective in itself although it may be a means to such an end. To the extent that such restrictions may form part of a SALT agreement, it must also be anticipated that both parties will continue with research and development intended to make the fullest use of the launching platforms (the only verifiable components in the system) permitted. This is why the American proposals (not made public) seem also to have included a limitation on the sizes of the warheads to be deployed, but here it must be acknowledged that such strictly physical considerations will tell against the Russians, not the Americans. The issue of verification is also, of course, a serious obstacle to any easy negotiation. To be sure, the United States government seems to have overcome its traditional rigour about the need for accurate verification to the extent of supposing that external methods of inspection (including satellites) will suffice to warn of potential violations. It is, however, improbable that Congress—the ultimate arbiter in the United States of the acceptability of international treaties—will be easily assured that all is well. In other words, for a variety of reasons, many of them technical, a workable agreement will not easily be reached and may even be unattainable.

So is Helsinki bound to be merely a talking shop? The preoccupation with strategic missiles and their deployment, which goes back to the early sixties, may in the long run be misleading. If the objective is to reduce the cost of weapons development, to preserve the strategic balance and even to enhance its stability by spelling out its essential characteristics, it should also be acknowledged that other methods may be useful. An extension of the nuclear test ban treaty to underground tests would be a useful step to consider, even though there is something in the view that a certain amount of routine testing is necessary to ensure that warheads on the shelf have not deteriorated. In this sense, the isolation of the SALT negotiations from the broader discussions on arms control at Geneva may be a misfortune if it continues for too long. Attempts to limit the destabilizing effects of multiple warheads and of anti-ballistic missile systems by prohibiting the testing of such devices are probably unrealistic, if only because they cannot be verified. It might, however, be of great value to think of other methods of increasing the stability of the strategic balance—even outrageously unorthodox schemes such as the requirement that both sides should publish fuller information about the weapons systems which exist. And there is probably much in the view that the potential disputes within SALT about the restrictions to be placed on short range missiles would disappear if there were a European agreement for the control of weapons systems, coupled if necessary with inspection.

Suicide by Pinprick

THE treatment now being meted out to scientists in Czechoslovakia is probably no worse, on a personal level, than that which other citizens have to endure. But science, more than other professions, depends on free communication between its practitioners and stands to suffer directly in proportion to the extent that communication is impeded. Everybody deplores the Lysenko affair, but few stop to consider how far it may be responsible for the present standing of Soviet biology, mediocre both on an international basis and in comparison with what Soviet scientists have achieved in other fields. The connexion between the persecution of scientists and the decadence of their trade is by no means a cause and effect relationship, but it is sufficiently credible to make the more thoughtful commissar pause a little before he tightens the noose.

Exactly what is happening in Czechoslovakia cannot yet be known, although it seems that scientists along with other members of the academic community are being compelled to submit to the anachronism of a loyalty test and several of the heads of institutes of the Czechoslovakia Academy of Sciences have been forced to resign. Two recent episodes, though trivial in themselves, are distinctly gloomy indications of the level of personal vindictiveness that now seems to govern the relationship between rulers and ruled. According to the letter on page 589 of this issue from Dr Zemlicka and Dr Chladek, it is now official policy to prevent Czechoslovak authors resident abroad from having their papers published in Czechoslovak journals. Whether or not the refusal to publish a scientific paper for purely political reasons is unprecedented in the history of science, it is hard to conceive of any self-inflicted insult that further epitomizes the qualities of pettiness, pointlessness and pusillanimity.



The second incident is not unprecedented—it is unfortunately a habit all too common in the Soviet Union—but for the rest is much like the first. Earlier this month the International Union of Biological Sciences held its general assembly in Washington DC. Among the list of speakers was Dr Ivan Malek, the director of the Institute of Microbiology of the Czechoslovak Academy of Sciences. A few days before the conference began Dr Malek sent a telegram to the organizers confirming that he would come. Then followed a second telegram saying that because of "new difficulties" he could not come.

There are, of course, a score of possible reasons for Dr Malek's absence, but it is hard to conceive that he would have allowed anything other than a government veto on his journey to force him to disappoint at one blow the IUBS, of which he is a vice-president, the scientists who had come to hear his talk, and the

National Academy of Sciences which was host to the meeting.

These practices, and the policies that lie behind them, do not amount to an inquisition, but nor are they mere irritations. They are weeds that if allowed to flourish may block up the channels of scientific communication and turn Czechoslovak science into a backwater. It is one thing to humiliate the members of the Writers' Union and force the signatories of the *Two Thousand Words* to recant—the connexion between literature and economics is remote and in any case the masterpiece suppressed today may be published tomorrow. It is another matter to impede, however slightly, the flow of information and ideas among scientists, because that circulation is vital to the body it sustains. The officials responsible for these pinpricking restrictions, should consider whether the injury they do to their own scientific community, and the dismay they evoke among scientists abroad, are really a price worth paying for whatever goal they have in mind.

100 Years Ago

NOTES

In stating that we believe that the English Eclipse Expedition is now finally arranged, it is due to the Government to add, and we do so with the greatest pleasure, that it is now quite clear that only a small part of the blame, which certainly attaches to some one, can be laid at their doors. In fact, explanations certainly are due from those who have had the management of the now famous Joint Committee. It appears that a deputation was named, and accepted the trust of representing the requirements of Science to the First Lord of the Treasury, which trust they neither fulfilled nor handed back to the Committee in order that another deputation might be appointed. We next hear of a letter written to the wrong Government department; and last of all, we are informed that the letters of the Government department—the last, we believe, written not later than the beginning of September—stating, among other things, that an application should be made in October, when the possibility of granting ships could be better discussed—have not yet been brought before the Joint Committee, which has just been summoned by the Secretary for the 4th of November, that is, to-morrow. It is not for us to censure such conduct as this, but it is our clear duty to point it out, and we hope the matter will be taken up. In spite of this mismanagement, however, we hear that the Government are prepared to aid both by money and ships when an application shall be made, and we cannot doubt that application will be made. There is still ample time to organise an expedition which shall do much good work, though perhaps it is too late to send out and erect the largest class of instruments. Large instruments, however, will be in the hands of the members of the American Government Expedition, so that this is the less to be regretted.

OLD WORLD

DEFENCE

World Armaments

In spite of the slow progress being made in the Strategic Arms Limitation talks which reopened in Helsinki this week, the latest yearbook of the Stockholm International Peace Research Institute (SIPRI) offers some hope for arms limitation. The yearbook (Gerald Duckworth and Co., 125*s* bound; 63*s* paper) reports that total world military expenditure did not rise in 1969, and probably fell a little in 1970. This improvement arises chiefly from American policy in Vietnam which has reduced direct expenditure on the war by increasing the part played by the Saigon government forces. But as a direct result of this policy, sales of weapons to underdeveloped countries increased to $1,500 million in 1969—the third highest figure ever.

While the number of intercontinental ballistic missiles and submarine launched missiles continues to rise rapidly both in the USA and USSR (see *Nature*, **227**, 1077; 1970), SIPRI suggests that both sides now have second strike capability but neither has a first strike capability. This is a position in which the nuclear deterrent really does deter, and provides the most stable situation except for total disarmament. The SIPRI yearbook suggests that the best possibility for progress in disarmament now lies in Europe, where, although the Warsaw pact countries have superiority in numbers over the NATO countries, the NATO strategy of defence (which requires less force than an offensive strategy) and the marked superiority of its air forces should encourage NATO not to allow numerical disparity alone to become an immovable block to any moves towards disarmament. Any such moves should be welcomed as an opportunity to reduce the very large stockpiles of tactical nuclear weapons in Western Europe.

The least encouraging aspect of the confrontation between the USA and USSR lies in their response to the relatively new types of warfare, notably chemical and biological warfare (CBW) and the opening up of the sea bed. Although the US Senate is expected to ratify the Geneva protocol on CBW, like many governments it chooses to exclude the use of defoliants and tear gases from the restrictions of the protocol. Chemicals dangerous to plants but not human life are not specifically banned by this agreement because, when it was drafted in 1925, no such chemicals existed; but it is clear that they fall within the spirit of the agreement. Official US figures give the total amount of defoliant used in Vietnam as over 50 thousand tons, spread over some 20 thousand square km, so that the ratification of the Geneva protocol in the form proposed is rather an empty gesture.

Development of the joint USA/USSR treaty on the use of the sea bed, which is now being drafted, also gives some cause for concern. Originally proposed by the USSR as a treaty banning the use of the sea bed for any military purposes, it has been emasculated to the stage where it now bans only mass destruction weapons. No such weapon systems capable of operating on the ocean bed exist, and in any case the most likely military use of these regions lies in the provision of submerged bases for servicing and arming nuclear submarines.

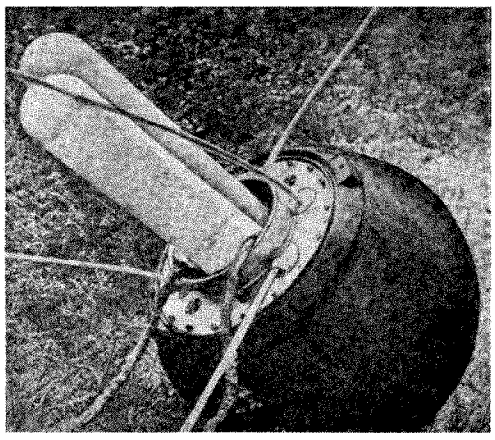
Only the success of the Treaty of Tlatelolo, signed in

1967 to ensure that Latin America remains free of nuclear weapons, provides any real hope in this somewhat gloomy picture. This treaty has now been in operation for three years, which shows that adequate supervision is possible, and encourages the hope that other similar zones may be established elsewhere.

Medvedev Reinstated

Dr Zhorez Medvedev, the Soviet scientist who was arrested last May (see *Nature*, **226**, 887; 1970), has been allowed to resume his scientific research. He has recently been appointed Senior Scientist at the Laboratory of Proteins and Amino Acids of the Research Institute of the Physiology and Biochemistry of Agricultural Animals. The institute is situated about 18 miles from Obnisk, where Dr Medvedev is now living. He plans to continue his research into molecular aspects of ageing.

Dr Medvedev's arrest and subsequent detention in a mental hospital sparked off a storm of criticism and protest within the Soviet Union and among members of the scientific community in other countries. This eventually led to Dr Medvedev's release, but until his appointment last week, he had been effectively barred from carrying on his scientific research.



MOON ROCKS

Luna-16's Cargo

from our Soviet Correspondent

The first results of the Luna-16 flight were announced last week at a special conference organized jointly by the Academy of Sciences of the Soviet Union and the Soviet Ministry of Foreign Affairs. The highlight of this conference was the information presented by Academician A. P. Vinogradov, a leading Russian geologist, about the lunar rock recovered by Luna-16.

The rock was recovered from a point in the Sea of Fertility, at 0° 41′ S and 56° 18′ W (some 900 km from the landing site of Apollo 11), and it consists of friable surface material (regolite) only. It was reported at the conference that after the drill struck against what was either solid bedrock or a large detached fragment of bedrock, further penetration "did not exceed 5 mm". The total weight of the specimen was a little more than 100 g, and it represents a sample of the top 35 cm of the lunar surface.

Container used for transporting Moon rocks in Luna-16.

The specimen is a dark grey, almost black, powder which has been divided into six zones of different granularity. For identification purposes, these fractions have been retained separately along the length of the coring device. The first two zones (0–15 cm along the coring device) consist of fine-grained material with small amounts of the coarse fraction. The next zones (from 15 to 33 cm) consist of material of varying granularity, containing inclusions of bedrock and other particles more than 3 mm in diameter, and the final zone (from 33 to 35 cm) consists of large-grain material, with fragments of the bedrock, which the drill hardly penetrated.

The average size of small particles (less than 1 mm) varied along the coring device from 70 μm at the surface to 120 μm at the deepest point. The mean specific gravity was 1·2, and the mean porosity at a depth of 35 cm was 50–60 per cent.

The composition of the specimen may be divided into basalt-type rocks, feldspar-type rocks, grains of various individual material (including plagioclase, olivine, pyroxene and ilmenite) belonging to the basalt group, brecchia, metallic iron particles and small vitreous spheres.

Some 70 chemical elements, including a number of isotopes and short-lived radio-nucleids, have been identified in the Luna-16 specimen and its composition, compared with that of the Apollo-12 specimens, is given in Table 1.

Table 1

	Basalt rock Luna-16	Fine fraction Luna-16	Basalt rock Apollo-12	Fine fraction Apollo-12
SiO_2	43·8	41·7	40	42
TiO_2	4·9	3·39	3·7	3·1
Al_2O_3	13·65	15·32	11·2	14
FeO	19·35	16·8	21·3	17
MgO	7·05	8·73	11·7	12
CaO	10·4	12·2	10·7	10
Na_2O	0·33	0·37	0·45	0·40
K_2O	0·15	0·10	0·065	0·18
MnO	0·2	0·21	0·26	0·25
Cr_2O_3	0·28	0·31	0·55	0·41
ZrO_2	0·04	0·015	0·023	0·09

The preliminary conclusion, according to Academician Vinogradov, is that the rocks of the surface of the lunar seas, as exemplified in this specimen, are basaltic, but differ somewhat in the content of their individual chemical elements. They are closely related to the primitive basalts of the Earth. He also suggests that the lunar seas have at some time been subjected to inundation by volcanic lava, and the basaltic rocks were therefore formed because they were the fraction most easily melted in the conditions which existed within the Moon. He argues that "the general course of differentiation of the substance of the Earth and Moon, and, probably, of the other planets of terrestrial type will follow converging paths, although they will have reached different stages of development".

GOVERNMENT

Zoologist in the Hot Seat

LORD ROTHSCHILD, whose appointment as head of the Central Policy Review Staff was announced last week, is a welcome, if somewhat surprising, addition to the small band of scientists holding senior positions in the higher echelons of the Civil Service. The news of his appointment has provoked widespread interest and comment for two reasons. First, the Policy Review Staff is a new venture whose success is by no means guaranteed, and it would seem to demand an economist rather than a zoologist to steer it through the inevitable early storms. Second, Policy Review is an important and controversial item in the Conservative Party's plans for reforming the apparatus of government, and so it is curious to find it left to the tender mercies of a Labour peer.

Lord Rothschild.

But Lord Rothschild is no stranger either to government or to administration. He was chairman of the Agricultural Research Council for ten years, and has been coordinator of the research activities of the Royal-Dutch Shell group since 1965. These positions are a fitting apprenticeship for public office, and he was already on the Treasury's select list when Sir William Armstrong, head of the Civil Service, came to choose his new troubleshooter.

Lord Rothschild will not find himself academically isolated when he takes up his new appointment, for his old friend and colleague Sir Solly Zuckerman, chief scientific adviser to the Government, is also a zoologist. Lord Rothschild's research, which earned him Fellowship of the Royal Society before he was 45, was concerned with the physiology of spermatozoa, both in marine animals and mammals. In particular, he was interested in the way in which spermatozoa move and derive energy for swimming, and in the process of fertilization.

Scientists and politicians seem to agree that the appointment of Lord Rothschild is an enterprising gamble which deserves success. Certainly there are few men better equipped for the job, but time alone will tell whether he can add the role of inter-departmental peacemaker to his multifarious talents.

CHEMICAL WARFARE

Wraps Off at Nancekuke

THE question of what is going on at Nancekuke was answered to the satisfaction of almost everybody when the Chemical Defence Establishment (CDE) outstation above Portreath Bay, Cornwall, opened its gates to the press last week. In all the rumours of nefarious and arcane activities, it seems that the establishment is doing no more than it has always claimed; it manufactures the riot control chemical, CS; it tests the feasibility of manufacturing and storing new chemical weapons; it produces minute quantities of nerve gas for research purposes, and it is Britain's sole source of P2S, an essential component of the only effective remedy for nerve gas poisoning.

Nancekuke houses the Process Research Division of CDE Porton Down, the hub of Britain's chemical and biological warfare activities. Public anxiety about the outstation has centred chiefly around the nerve gases which are manufactured there and transported to Porton for field testing. Nerve gas has not in fact been produced in any quantity since 1955, and the equipment for its manufacture now stands derelict and partially dismantled. A small plant which can be used to make minute quantities of nerve gas when required is still functional, but was last used two years ago when approximately 20 pounds of the nerve gas VX was produced. The remains of this batch of gas, claimed to be Britain's entire stock of nerve agent, reside in three steel canisters in the locked and sealed nerve gas store at Nancekuke. The report of a working party chaired by Professor R. H. S. Thompson of the Middlesex Hospital Medical School published recently (HMSO, 1970, 1*s* 6*d*) was reassuring about the risk to the public and to the environment from the manufacture and transport of these small quantities of nerve gas.

The chief role of Nancekuke is to determine whether novel chemical weapons developed at Porton can be manufactured and stored cheaply and efficiently. This is claimed to be a defensive and not an offensive measure. Before any new substance can be regarded as a realistic threat in the hands of an aggressor, it must be known whether large scale production is feasible—milligrams of a nerve agent may prove lethal in laboratory trials, but on a field scale the dose must be measured in kilograms. Throughout 1969 and 1970, only one such substance, the nature of which was not disclosed, has been undergoing production trials at Nancekuke.

The real question hanging over Nancekuke is whether its productivity justifies its existence. The buildings are shabby, and they are rearranging the chemical plant once used to make nerve gas to manufacture the antidote P2S. The staff is much under strength, and finance is a mere £330,000 annually. All the station's activities—such as the manufacture of P2S antidote and CS—could, at a pinch, be moved elsewhere; perhaps to safety, for the vast expanse of the outstation represents an ideal target. The continued existence of CDE Nancekuke seems not so much sinister as merely inefficient.

SPACE

New Satellite Consortium

On November 3, the day on which the European Space Conference reopened to discuss the Lefevre mission to Washington, the setting up of a new European satellite consortium was announced. The British partner in the linkup, which involves seven companies, is Marconi Space and Defence Systems Ltd, who recently won a British government contract for the Skynet 2 military communications satellite programme.

The consortium is planned to be a loosely grouped concern with little or no central organization and the chairman of the managing board, appointed for a year, is Commander D. W. Malim, of Marconi Space and Defence Systems. The leadership of any particular project will be undertaken by whichever firm seems to have the most appropriate expertise; capabilities range widely through aerospace technology, telecommunications and electronic systems.

Although the new group will obviously look towards Europe and possible European association with the American space shuttle plans, it also hopes to tender for possible satellite contracts with countries such as India, Australia and Canada. Several of the companies involved in the consortium have considerable experience in launcher work which could be particularly useful for smaller satellite projects. In particular, the French company Société Nationale Industrielle Aérospatiale (SNIAS) has been actively involved in both the launcher and satellite programmes of ELDO and ESRO.

The other five members of the consortium are Etudes Techniques et Constructions Aérospatiales (Belgium), Société Anonyme de Telecommunications (France), Messerschmitt-Bölkow-Blohm and Siemens (Federal Republic of Germany) and Selenia (Italy).

PHYSICS

Particles and Telescopes

from our Soviet Correspondent

Within the past two weeks, two "unique" achievements in physics have been announced in the Soviet press. The first of these concerns the Joint Nuclear Research Institute at Dubna, where there is a synchrophasatron, now accelerating deuterium nuclei to energies of 11 GeV. This is claimed to be the first accelerator in the world to accelerate complex atomic particles to velocities approaching the velocity of light. The director of the Dubna Institute, Academician N. N. Bogolyubov, said in an interview in *Pravda* that the "transformation of the synchrophasatron into a 'relativistic' nuclear accelerator" is an "outstanding achievement". It penetrates into a new field of research in which it is hoped that many important and interesting data will be accumulated.

At the same time, the new wide-band UTR-2 radio telescope of the Ukrainian Academy of Sciences went into operation. Operating in the 10–20 MHz frequency band, this telescope, with an area of 150,000 square metres, comprises 2,040 linked antennae. It is T-shaped, extending 1,860 m in the north-to-south direction and 900 m east-to-west.

This instrument is particularly important because it is designed to work in the low frequency band where very little information has been gathered. There are similar arrays in British Columbia and at Clark Lake in the USA, but the development of radioastronomy lately has been towards higher frequencies where observations are less troubled by ionospheric disturbances.

So far, the general level of Soviet radioastronomy has not been highly regarded in the rest of the world. This does not detract from the valuable contributions which are being made to this field in the USSR, but their first claims are usually treated with even more caution than those of western radioastronomers. It is to be hoped that with the opening of this new telescope and the expected rapid completion of another very large instrument now being built in the Caucasus and designed to operate at high frequencies, Soviet radioastronomy will achieve a reputation comparable with that of the best western work.

COAL

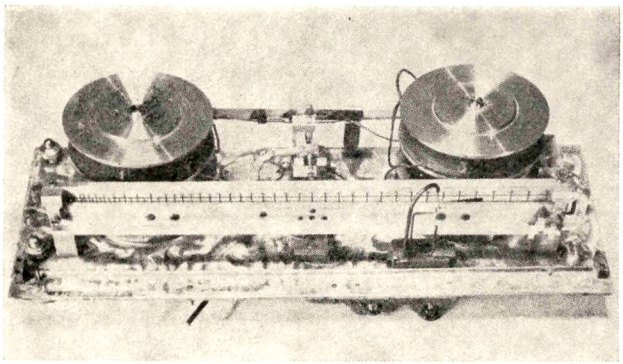
Smokeless Fuel Fiasco

Years of patient Parliamentary work, starting with the first clean air legislation in 1955, seem in danger of falling temporarily by the wayside this winter as shortages of solid smokeless fuels place more and more smokeless zones in jeopardy. Among the alternative smokeless fuels, only gas (now produced chiefly from oil or piped from the North Sea) looks reasonably certain to be dependable throughout the winter. The supply of electricity, which now accounts for about 50 per cent of the national coal output of 160 million tons a year, could all too easily suffer because of the Electricity Generating Board's disappointing prediction that there will be only a 9 per cent surplus over the estimated maximum demand, coupled with low stocks and the threat of industrial unrest within the coal industry.

This solid fuel shortage, now running at about 300 to 400 thousand tons a year, will cause the lifting of at least 127 smoke control orders and probably many more. This is, however, by no means a return to the murky days of the nineteen fifties; coal consumption in London, for example, will remain well below 10 per cent of the figure for 1952—the year of the great smog. The situation would be even worse if central and local government had not adopted a definite policy of looking to other smokeless fuels. This alone is expected to save about 450,000 tons of smokeless fuel a year, and in addition the gas boards expect to have supplied large concerns with about 7,000 units during 1970 for conversion of solid fuel boilers to gas.

The annual output of smokeless coal is now running at about 8 million tons of which about 4·5 million comes from the National Coal Board and about 2·3 million from private firms. The remainder has in the past been a byproduct of gas production from coal, but supplies from this source have dwindled from 1·6 million tons in 1969/70 to 0·97 million tons in 1970/71 and the Coal Board claims that this method of gas production has been

phased out much more quickly than expected. Some uneconomic gasworks are being especially retained at an annual cost of £300,000 to produce 170,000 tons of coke.



The National Coal Board's contribution, which includes the naturally occurring smokeless anthracite, has been marred by some conspicuous failures, the most notable of which is the production of so-called Bronowski bullets by the treatment of a variety of types of coal to form a fluid which could be cast into blocks. Even now, 15 years after the idea was first conceived, only 130,000 tons a year are produced by this method, compared with the millions of tons originally envisaged. Other efforts to bolster up supplies are exemplified by the purchase of 75,000 tons of briquettes from France produced from otherwise useless South Wales anthracite dust.

HISTORY OF SCIENCE

Kelvin Collected

It is appropriate that a scientist of the stature of Lord Kelvin (formerly Sir William Thomson) should be remembered in some permanent way by the University of Glasgow where he held the chair of natural philosophy for more than fifty years until 1899. A book (*Kelvin's Instruments and the Kelvin Museum*; University of Glasgow; 1970, £1) has recently been published as a complement to the collection of Kelvin's instruments in the Department of Natural Philosophy and it completes a fitting memorial to his experimental talent which ranged over the field of electrical measurements and even extended to the production of marine instruments.

Professor P. I. Dee took up his post as head of the Natural Philosophy Department at Glasgow in 1945 to find "a positive aura of Kelvin everywhere in the place" which he decided should be preserved in the shape of a small museum. By 1954 the Kelvin Museum had a permanent home in the new research block and the result was an almost complete collection of more than one hundred Kelvin instruments, among them the famous current balance, together with several pieces of equipment used by his co-workers Joule and Kerr. Although Mr J. T. Lloyd, one of the authors of the book, was chiefly responsible for collecting and displaying the exhibits, it was the late Dr George Green, scientific secretary to Lord Kelvin in the three years before the latter's death in 1907, who has provided the personal link with the man and his work which enabled a full account of the development of Kelvin's instruments to be produced and included as the kernel of the book.

Current balance (length 46 cm).

Parliament in Britain

Concorde

Another £95 million has been added to the estimated research and development costs of Concorde. Mr Frederick Corfield, Minister of Aviation Supply, announced last week that the latest estimate is £825 million at June 1970 prices. The previous estimate, made in October 1969, put the research and development costs at £730 million and the increases are made up of £35 million for improvements to the propulsion system, £20 million for other adjustments to the programme and £40 million for pay and price increases since October 1969. The British and French governments have already spent £460 million between them on Concorde and the new estimates therefore provide for a further £165 million to be spent by the British government and £200 million by the French government.

Mr Corfield also announced that the flight tests of Concorde should be completed by the middle of December, and evaluated by March or April 1971. The British and French governments will then review the project thoroughly, taking into account the commercial prospects of the aircraft. So far, airlines have taken options on seventy aircraft, and no firm orders are expected until the flight tests have been evaluated. (Oral answers, October 28.)

Teacher Training Enquiry

Lord James of Rusholme, Vice-Chancellor of the University of York, has agreed to be chairman of the Committee of Inquiry into the Training of Teachers. This was announced by Mrs Margaret Thatcher, Secretary of State for Education and Science, who also said that she is consulting all interested parties about the composition and terms of reference of the committee. The committee of inquiry should start work early next year, and it will have available the evidence taken last session by the Select Committee on Education and Science. (Written answers, October 22.)

Warfarin Resistance

Mr Anthony Stodart, Parliamentary Secretary to the Minister of Agriculture, gave an assurance that it is not difficult to control Warfarin resistant rats if occupiers and local authorities follow advice available from the Ministry of Agriculture. He also said that the spread of Warfarin resistance should not increase the number of rats or the dangers to public health. Warfarin resistant rats are confined chiefly to Shropshire and Montgomeryshire, but they have also been found on farms elsewhere in Great Britain. Mr Stodart also said that intensive use of Warfarin in some towns has resulted in large increases locally of the proportion of mice resistant to the poison. (Written answers, October 27.)

Industrial Reorganization Corporation

Mr John Davies, Secretary of State, Department of Trade and Industry, gave further details about the winding up of the Industrial Reorganization Corporation. The corporation will undertake no new commitments and its existing commitments will eventually be taken over by the Government. Loans will be recovered according to the terms of the various agreements and equity investments will be realiezd when such opportunity offers. (Oral answers, October 30.)

BAC 3-11 and European Airbus

THE British government's request for more time to consider the issues involved in rejoining the A-300B European Airbus project is a good indication of the fierceness of the battle which is going on in the aircraft industry. Ostensibly, the government is faced with a choice between rejoining the European aircraft project or backing a rival airbus, the BAC 3-11, which is being developed by the British Aircraft Corporation (BAC). The situation is, however, complicated by the financial position of Rolls-Royce, whose involvement in the BAC 3-11 may be critical for its future, and by the government's obvious desire not to blot its copybook in its negotiations for entry to the Common Market. There is also little doubt that a decision either way will have important implications for the future of the British aircraft industry.

The offer from the governments of West Germany, France and Holland for Britain to rejoin the A-300B project was timed almost to perfection. On the one hand, it gives the British government an opportunity to demonstrate its willingness to participate in European projects and thus, by implication, if the offer were turned down it could be used as an argument against Britain's entry into the Common Market. And, on the other hand, the initial capital outlay involved in rejoining the A-300B is considerably less than that involved in backing the BAC 3-11. The European course is therefore likely to appeal to a government which is committed to reducing public expenditure.

The European offer, which was first made two weeks ago, is for Britain to rejoin the project which she left in 1968 when it seemed to be getting too expensive. West Germany, France and Holland then decided to carry on with development of the A-300B and are now offering Britain a stake in development of a new B-7 version of the airbus, for an outlay of about £20 million. In return, the European partners, and in particular West Germany, are willing to put about £25 million into Rolls-Royce for development of the RB 2-11 engine which could be offered to customers of the A-300B as an alternative to the scheduled General Electric engine.

The A-300B is a 250-seat airliner, which will be powered by twin General Electric CF6-50A engines, and sales are expected to reach more than 350 aircraft. The airliner could be in production by 1974, about a year ahead of the BAC 3-11, but the time difference is not crucial because it is widely accepted that the demand for such aircraft will not reach its peak until towards the end of the 1970s.

About £45 million has already been spent on development of the airframe and West Germany, France and Holland have guaranteed a sum of £180 million for research and development of the airframe and another £300 million for full-scale production costs. If Britain entered the project, the £20 million entry fee would therefore be devoted almost entirely to development of the B-7 version which has been tailored chiefly for British European Airways.

The alternative airliner—the BAC 3-11—is a short to medium haul aircraft powered by Rolls-Royce engines. The proposal which the government is considering is that the cost of research and development of the airframe would be shared equally by the government and the British Aircraft Corporation. At the last estimate, these costs were put at £150 million, and the company would give an undertaking, under any agreement, to meet cost overruns. BAC has already spent about £3 million on research and development on the 3-11, and it has now reached the point where it must abandon the project if government backing is not forthcoming.

But that is only half the cost which the government would face if it decided to back the BAC 3-11. Development of the Rolls-Royce RB 2-11 "Dash 61" engines which have been proposed to power the aircraft could cost about another £75 million and the government would be expected to provide all the money necessary for this development.

But it is paradoxically the position of Rolls-Royce in the airbus debate which could sway the government in favour of backing the BAC 3-11. Rolls-Royce has in the past year been feeling the pinch, chiefly because the company has sunk a large amount of capital into development of engines for the Lockheed Tristar, and it has yet to see any return on its investment in the research and development of the RB 2-11. The BAC 3-11, with its expected sales of some 280 aircraft, would therefore provide Rolls-Royce with a much-needed long and profitable production run. In addition, if the company does not develop the "Dash 61" follow-up to the RB 2-11, it would find itself slipping badly behind in production of civil aircraft engines towards the end of the 1970s.

The offer of £25 million to Rolls-Royce from the partners in the Eurobus is much less attractive than participation in the BAC 3-11 for several reasons. Firstly, General Electric has already been involved in the A-300B project, and even if its participation in the production stage is not guaranteed by contractual commitments, the company would be expected to pick up much of the engine sales. The BAC 3-11, on the other hand, would be built around the "Dash 61" from the start, and would virtually ensure Rolls-Royce of a substantial return on its investment.

Another important factor which the government must take into account is the effects that a decision to back the European Airbus may have on the future balance of payments. Sir Anthony Milward, chairman of British European Airways, has already declared his support for the BAC 3-11, and has hinted that if the government decides not to support the 3-11, BEA would not have the European Airbus forced down its throat.

On the face of things, the economic arguments for joining the A-300B project seem to be attractive, but the government is obviously under great pressure from the British aircraft industry to back the 3-11. It would be difficult, however, for the government to justify supporting the high costs of Concorde and at the same time sink more money into the BAC 3-11. On the other hand, it would be politically unwise to pull out of the Concorde project in addition to turning down the A-300B offer.

NEW WORLD

Call to Remake Federal Science Policy

by our Washington Correspondent

A MAJOR restructuring of the federal support for scientific research is advocated by the House Subcommittee on Science, Research and Development, in a report issued this week. The chief target of the report* is the Office of Science and Technology (OST) which is held to be understaffed, misused and inadequate. To remedy this and other structural weaknesses the subcommittee calls for the Administration to set up a task force which would draft a national science policy for the United States.

The background to the subcommittee's recommendations is the hearings on national science policy held this summer during which some sixty witnesses gave their views on the present parlous state of the national science effort. But the subcommittee and its chairman, Representative E. Q. Daddario, are also drawing on the experience of previous (and still unheeded) hearings in their plans for remoulding the present organization of science. By way of preface Mr Daddario calls attention in the new report to the way in which the annual rate of increase in the federal support of science has plunged from about 12 per cent in the mid-1960s to a negative 5 per cent for the present financial year. Allowing for inflation, this represents a decline in present purchasing power of from 20 to 25 per cent compared with the peak years of 1965–68.

The Daddario subcommittee lays much of the blame for this state of affairs at the door of the Office of Science and Technology. The Office was charged in 1962 by President Kennedy with the duty (transferred from the National Science Foundation) of developing "the pursuit of a national policy for the promotion of basic research and education in the sciences". But neither the National Science Foundation nor the Office of Science and Technology has ever occupied a sufficiently commanding post in the federal hierarchy to implement such a policy, the report observes. Part of the trouble is that the Office of Science and Technology, which should be the focal point for the government's sponsorship of scientific activities, is "fragmented as to mission and badly overburdened as to operation". Its presiding officer has also to serve as the President's science adviser, chairman of the President's Science Advisory Committee, and chairman of the Federal Council for Science and Technology, and many of the staff of the Office have similarly diffuse responsibilities.

The Office itself, the report observes, seems often to be used by the Executive Office for tackling immediate crises, whether scientific or otherwise, which leaves little opportunity for planning the welfare of federal science. The result is that the Office "does not fulfil even its few statutory obligations". In particular it has failed to take the lead in formulating basic government science policy and has also neglected the duty of evaluating and reporting on overall government research activities. The better to fulfil these existing obligations, as well as becoming patron of the nation's scientific effort, the Daddario subcommittee recommends that the Office of Science and Technology should be strengthened both in statutory backing and in staff and money, as well as being separated from any direct administrative connexions with the President's science adviser or the President's Science Advisory Committee (PSAC). "This is not to say that OST should be removed entirely from the PSAC arena, if the President wishes to call upon it; but it should not be one of the chief components through its director and staff. . . . It should be relieved of the time-consuming, often delicate, often classified, support function it now provides the President's science adviser".

As part of its trusteeship for the national scientific endeavour the Office of Science and Technology should submit an annual report to the President and Congress reviewing the status of research and development in the United States and recommending a programme of research and development for the coming year. The Daddario subcommittee also recommends that the Office should have the job of setting the criteria by which mission oriented agencies might decide whether to support particular areas of basic research. In other words OST would become the arbiter of the concept of relevance by which until recently the Department of Defense was bidden to eschew all basic research not obviously relevant to its military mission.

Besides a revamping of the OST the Daddario subcommittee urges several other institutional changes in the federal support of science.

- Setting up of the proposed National Institutes of Research and Advanced Studies (NIRAS). The proposal, not yet given substance by the Administration, was put forward by the subcommittee last year as a means of bringing under one organization the federal programmes for the support of academic research that are now scattered among several agencies.
- Setting up of the Office of Technology Assessment, another of the subcommittee's projects that has yet to be taken up by Congress. Mr Daddario recently tried without success to introduce the necessary legislation in the form of an amendment to the Congressional reform bill.
- Creation by Congress of a Senate committee having centralized jurisdiction over science and technology, as does the Committee on Science and Astronautics (the parent of Mr Daddario's subcommittee) in the House of Representatives.
- Action by the Office of Management and Budget to ensure that the funding of scientific research is maintained at a stable level and preserved from precipitate cutbacks.
- An increase in block grants to universities and other institutions, to be channelled through the National Science Foundation.

* *Toward a Science Policy for the United States* (US Government Printing Office, 1970). n.p.

The subcommittee's proposals have been discussed informally with Dr David, the President's science adviser, and with the staff of the OST, but official reaction has yet to come from the Administration. If, as is possible, the only reaction is silence, the subcommittee proposes to hold hearings next spring in lieu of the task force it has asked the Administration to set up. The hearings would discuss science policy in a more directed way than those held in July to September this year. Meanwhile Mr Daddario, who is leaving Congress to become (if fortune and the polls favour him) governor of Connecticut, has this parting reproach for those who over the last few years have let science starve: "Research teams have been decimated or disbanded. Promising projects have been slowed or shelved. Science and engineering enrolments at academic institutions are down. Medical schools, particularly the non-State schools, are in serious financial straits. Graduate student-teachers have had to postpone their schooling and often abandon their research fields. Planning of any kind for the future by the research community is difficult and in some instances impossible. Research industry stocks are down disproportionately. Small companies are disappearing. Most serious of all, many of the nation's brightest young people who would otherwise enter the science arena are passing by without any real exposure to its attractions and potential. There is little question that the morale of the scientific community is at a low ebb."

Is the picture really as black as Mr Daddario paints it ? Has science been seriously wounded by the budget cutbacks or is there still more fat, as the saying goes, to be squeezed out of the system ? In a speech given on October 13 to mark the sesquicentennial of the University of Indiana, Dr Philip Handler, president of the National Academy of Sciences, delivered a more guarded review of the status of science. He too alluded to a 20–25 per cent reduction in federal funds over the last four years, a trend that "most commentators agree . . . reflects principally growing public disenchantment with science and the technology it makes possible". Dr Handler also admitted that United States leadership in certain areas of science is now slowly moving abroad, but "in view of the international character of science, that cannot be seriously objectionable, of itself". But he was unable to point to any gaping wounds on the scientific body politic: "Relatively few academic laboratories known to me have yet been really seriously injured. Only a few major national facilities have been closed and I presume these to have been only marginally productive."

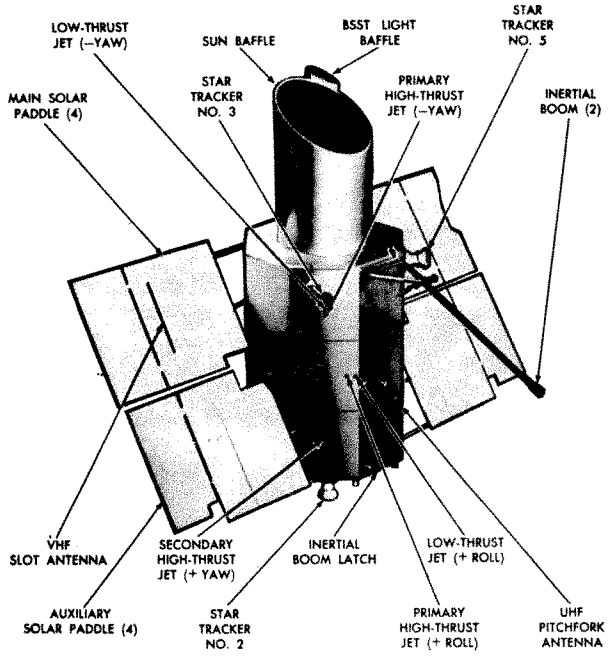
If Dr Handler was presenting a more hard-nosed analysis than might be expected from one in his position, that may reflect in part the fashion of the times. For example, an Assistant Secretary of the Treasury, Mr Murray L. Weidenbaum, told a recent meeting of the American Institute of Aeronautics and Astronautics in Houston that he had often been struck by the absence of "that objectivity and hard, factual, quantitative analysis that I associate with the core of the scientific method. I am amazed when scientists say we should embark upon a major technological project on faith . . .". Mr Weidenbaum was not one of those who sees a cutback of research dollars as no less a sin than the suppression of truth; to his mind a professor asking for $100 million of the taxpayers' money to build a linear accelerator should have to justify it "not in the soft, theological terms so often used by the natural scientists in these matters, but in the hard, objective manner of the social scientist".

Mr Weidenbaum explained his paradoxical inversion of the hard/soft scale by saying that natural scientists should justify their works in relation to criteria such as expected benefits versus costs, whether important elements of cost such as pollution have been included in the analysis, and whether alternative uses of public funds would not be profitable. These prescriptions, if followed, would demand a new order of ingenuity in the filling out of grant application forms but there is nothing necessarily wrong in that.

NASA

Is Space Worthwhile?

by our Astronomy Correspondent



ASTRONOMY in the United States is having a thin time. The most urgent need continues to be the building of new radio telescopes. But the most severe blow that has been dealt this year is widely considered to be the cancellation in September of two Apollo missions, conceivably because the cancellation brought home how much the new astronomy has been scientific spin-off from the American space programme. It must therefore rankle that many astronomers are refusing to endorse the new projects in manned spaceflight that NASA considers vital if it is to survive with anything like its present strength. To whip up support for schemes such as the shuttle and the twelve-man space station was the chief aim of the NASA contingent attending a conference in New York last week on the planning of space missions. Much of the justification of the meeting, organized by the New York Academy of Sciences, was to relate current questions in astronomy to the hardware that NASA would like to have available in the seventies. At the same time the supporters of manned spaceflight ingeniously grasped every opportunity for shedding light on the problems of the day. Communications satellites are now being justified not for their superfluity of circuits but by favourably comparing the pollution from rocket motors with that from cable-laying ships.

Only Dr Norman Baker of Columbia University surprised his audience by launching a protest against the NASA programme, after delivering his review paper on variable stars. There is not much evidence that NASA cares about astronomy, he said, and what is really needed is a few per cent of the space budget to be diverted to the construction of ground-based optical and radio telescopes. At that stage of the meeting most of the NASA representatives had already left, and Dr Zdenek Kopal of the University of Manchester was the first on his feet to dissociate himself from Baker's views. Baker's firecracker soon fizzled out, indeed, leaving an overall impression of dumb acquiescence with the agency's programme.

Dr Wernher von Braun staked out his new philosophy for NASA. An era in space is coming to an end now that the enthusiasm that characterized the Moon landings is subsiding, and from now on the space effort must stand on its own feet. In this light the space shuttle, he claimed, is a major step maximizing the return for space applications and science. The burning

question continues to be whether the shuttle should have a delta wing, giving manoeuvrability and a consequent wider choice of landing sites, or a more straightforward design with stubby straight wings imparting a lower lift to drag ratio at hypersonic speeds, a narrower choice of landing sites, but easier handling for the pilot. But von Braun agreed that in the present budget situation it is impossible that NASA will be able to tackle the shuttle and the space station simultaneously, and it would be best to tackle the shuttle first.

The meeting had its lighter moments. Dr T. B. Taylor, president of International Research and Technology Corporation, wanted to see a resurrection of the scheme whereby a space vehicle rides the shock waves from a series of nuclear bombs exploded behind it. A project along these lines was one of the panic reactions to the first sputnik, and survived until 1965 after a surprising $10 million had been spent. The test-ban treaty and an understandable lack of confidence in the technology finally finished off the project, but Dr Taylor appeared convinced that its potentiality could be demonstrated using the work already done and a limited number of underground tests. Oddly enough, he thought that a vehicle along these lines would be a fine medium to begin international cooperation in space. On the scientific side Dr F. Johnson of Electro-Optical Systems, Inc., delighted the meeting with his theory that the diffuse interstellar absorption lines are due to the magnificent molecule $MgC_{46}H_{30}N_6$—one of the porphyrins.

The Orbiting Astronomical Observatory to be launched on November 17. Its height is ten feet and weight 4,680 pounds, making it the heaviest scientific satellite so far.

It was hard to see what the new NASA programme had to offer the astronomers while so much remains to be done with conventional rockets. The development of electric propulsion, for example, would open up the solar system to a new generation of probes that could be launched by the Titan class of rockets. Typically a payload of 500 kg would reach Pluto in five years without the need for the gravitational boost on which the grand tour missions depend, and 1,000 kg to Jupiter would take less than one year.

In the circumstances the agency must be hoping that the launch this month of a massive satellite devoted to astronomy will redeem some of its tarnished image. The satellite is the latest of the Orbiting Astronomical Observatories which began with the expensive failure of OAO 1 in 1966, and the highly successful OAO 2 launched nearly two years ago. Although few of the data from OAO 2 have yet found their way into the scientific literature, what has been released makes it clear that important discoveries are being made. OAO 3, to be launched on November 17, is basically a 38-inch Cassegrain telescope with a spectrometer covering 1000 to 4000 Å, and Dr Albert Boggess of the Goddard Space Flight Center is the principal investigator. The pointing accuracy is expected to be one arc second and the telescope should be able to record down to twelfth magnitude.

ANTIBIOTICS

Swann Report Exported

from our New York Correspondent

THE immense and often indiscriminate use of antibiotics around the world has led in recent years to increasing fears that bacteria are developing resistant strains faster than scientists can turn out new antibiotics. Scientists from eleven countries met last month under the auspices of the New York Academy of Sciences to discuss these problems, especially as they relate to infections from drug resistant bacteria in hospitals and to the increasing number and kinds of drug resistant bacteria found in food animals.

It has been known for a number of years that disease-causing bacteria have built up resistance to antibiotics that were originally able to control them. A few years ago, Professor Tsutomu Watanabe of Keio University School of Medicine, Tokyo, discovered that this resistance, or R-factor, can often be transferred to bacteria that are not already resistant to drugs and in fact have not been exposed to antibiotics.

There was general agreement at the conference that many hospitals are now a major source of contamination of R-factor bacteria. Studies have shown that patients are more resistant to antibiotics after being in hospital for several weeks than they are when they enter. A more controversial area of concern is the widespread use of antibiotics in animal feed. Since the 1950s antibiotics have been added to feed both for disease prevention and for increasing weight in food animals. It is estimated that 80 per cent of the animal protein consumed in the United States comes from animals fed medicated feed during part or all of their lives.

Soon after antibiotics began to be used to prevent disease, it turned out that they also increased growth by acting against growth-depressing micro-organisms in the intestinal tracts. An even more important result of feeding antibiotics to domestic animals is in preventing the effect of so-called stressful conditions, such as crowding, shipping and vaccination. These uses have had a tremendous impact on both the drug and the food industries. It has been estimated that from 20 to 25 per cent of all the anti-

biotics produced in the United States are used in animals, a $400 million a year market. As for the farmers themselves, chicken breeders alone have saved an estimated $240 million from 1950 to 1965 by using antibiotics.

The Federal Food and Drug Administration, the agency that is responsible for approving all animal drugs as safe and effective, has always monitored the use of antibiotics in feed. The increase of antibiotic resistant strains in animals and the fear that such strains can be transferred to man, thereby increasing the already dangerous level of resistant strains produced by man himself, has, however, put pressure on the FDA to follow the recommendations of the Swann Commission report which was published in Britain ten months ago and should soon be put into effect. The Swann report recommended that the use of therapeutic antibiotics be limited to treating diseases and be available only on prescription by veterinarians, not automatically added to feed as preventive medicine, as has been the case. The growth antibiotics do not usually develop multiple drug resistance and are not known to cause the transfer of resistance, and so were not included in the restriction.

The FDA responded last April by setting up a task force to study the problem and report back to the commissioner, probably by this December. The charge of the task force is to take an "in-depth review of the usage and actual value of low-level antibiotics in feeds, the acquisition of the R-factor by organisms through animal feeding practices, the possibilities of transference of R-factor to human pathogens, and the economic impact of restricting the use of antibiotic feed additives on both the manufacturers and the users". Dr C. D. Van Houweling, director of the FDA's Bureau of Veterinary Medicine and chairman of the task force, pointed out last week that the restrictions already imposed by the FDA on the use of antibiotics are far tighter than they were in Britain at the time of the Swann report, that the general animal inspection and sanitary standards are higher in the United States, and that much of the outcry in Britain was caused by an outbreak of disease from natural overspill of organisms from calves to humans not directly related to the R-factors.

The conference participants generally agreed that it is too early to say that the presence of R-factors in animals is related to R-factors in the human population or that animal R-factors are themselves dangerous. Professor Thomas H. Jukes of the University of California at Berkeley argued that while all feed additives need continuing surveillance, "if antibiotics in animal feeds produced an increase in resistant pathogens, the effectiveness of antibiotic feeding would have disappeared long ago". Dr John R. Walton of the Animal Health Trust Stock, England, noted that scientists have been looking for a connexion between animal and human R-factors for ten years without success. Such lack of information, he added, must not be allowed to give rise to complacency, but from our present knowledge of drug resistant bacteria in human foods "one can only assume that antibiotics are being used carelessly and that hygiene is being neglected at many levels of food production".

Professor Watanabe believed that while animal R-factors are probably responsible for some of the R-factors in humans, they account for only a very small proportion. He pointed out that in Japan antibiotics have not been used until very recently for cattle, poultry and fish raising, yet R-factors are present in humans to a much greater extent than they are in the United States, due to the excessive amounts of antibiotics used by the Japanese themselves.

Considering the present state of uncertainty that surrounds the transfer of R-factors from animals to humans, coupled with the probably considerable pressure from the agricultural and drug lobbies against any sort of ban, it seems fairly certain that the FDA will not take strong measures to curtail the use of antibiotics in animal feed merely as a safety precaution. Dr Van Houweling stated at the conference that "food animal drug uses are largely a matter of economics. If animal drugs make it possible to produce more food more efficiently and, therefore, economically, it is advantageous to all consumers for these drugs to be utilized. Proposals to curtail, restrict or prohibit drug uses must therefore be supported by evidence that the drugs are not effective, are not safe. . . . Decisions are always subject to review." The review will probably be a long time coming.

STRATEGIC ARMS

Fears of a Sham at SALT

by our Washington Correspondent

THE third round of the Strategic Arms Limitation Talks (SALT) opened this week in Helsinki to the fears as well as hopes of their well-wishers. Apprehension that the talks might be leading up to a sham treaty was voiced this week by the Strategic Weapons Committee of the Federation of American Scientists, a small but intellectually heavyweight lobbying group concerned with arms control problems. A treaty that limited only the total numbers of strategic weapons without reference to their quality, the committee said, "would legalize an accelerated arms race directed towards qualitative improvements and the deployment of ever more dangerous weapons".

One method of limiting qualitative improvements in a verifiable way, the committee suggests, would be to agree to allow only such changes as do not alter the external appearance of a weapon or launching vehicle; such an agreement, though it would by no means halt the arms race, could at least dampen it enough to effect major savings. The members of the committee are Dr Herbert Scoville, assistant director of the Arms Control and Disarmament Agency under President Johnson, Dr Marvin L. Goldberger, chairman of the physics department at Princeton and a former member of the President's Science Advisory Committee, and Dr Morton H. Halperin, a former staff member of the National Security Council under President Nixon.

Other features of a SALT agreement the committee would welcome are a restriction on anti-ballistic missile systems which either ban them entirely or limit them to the defence of Moscow and Washington, and a halt to the testing, production and deployment of missiles carrying multiple, independently targetable warheads (MIRV). But by all accounts there seems to be little hope of bolting the stable door on MIRVs at least, in part because of the stage of development now reached on these weapons, but also because of the intractable problems of verification in deciding whether a launching vehicle carries one or many warheads.

NEWS AND VIEWS

Artful Model Building

IRREVERENT people who scoff at model building in molecular biology will have their opinions reinforced by two articles in this issue of *Nature*. They will be comforted to see that two teams of model builders have arrived at contradictory theses to explain how DNA is transcribed into RNA. Building models of nucleic acids has been in vogue ever since Watson and Crick successfully proposed that DNA is a double helix, but the foundations of such model building are perhaps more brittle now than at any time since 1953.

Molecular biologists of a more experimental turn of mind will maintain that the platonic relationship of the model builder with his subject makes this approach more art than science. After all, they will argue, you can construct innumerable models for, to cite an example, the transcription of DNA into RNA, but the crucial question remains unanswered: what mechanism is used in the cell? Thus it will be held that only those workers who dirty their hands to collect data by experiments in the laboratory can hope to resolve this problem.

How far is this cry supported by reason rather than prejudice? Certainly, even the most obsessed model builder must admit that nucleic acid models have been conspicuous recently for their lack of success, compared with the renowned spectaculars which elucidated the structure of DNA and formulated the clover leaf model for tRNA. The latter was a triumph of model building which is acknowledged by even the most grudging critics. Several possible models for secondary structure were constructed from the primary sequence of nucleotides and these models gave different predictions for how various parts of the tRNA molecule would react to enzyme or chemical attack. The use of these criteria then singled out the clover leaf model from the others. But now, with incompatible models abounding for tRNA tertiary structure, the model builders seem to have all but suspended their activities in despair, to await the experimental data expected from X-ray crystallography.

Compared with more recent attempts to construct models for DNA and RNA, the elegant formulation of the double helical structure of DNA shines out as though derived from the supernatural. No convincing model has yet been produced to explain the mechanism of replication of DNA or of its transcription into RNA, chiefly because of the lack of sufficiently detailed information about these processes and in particular about the way in which the replicating and transcribing enzymes interact with their templates. A formidable difficulty is the extensive ignorance of how DNA unwinds (see *Nature*, **227**, 1294; 1970).

Undeterred by this, however, Florentiev and Ivanov present on page 519 a model to account for how a DNA duplex might unwind to allow RNA chains to form by complementary base pairing with one of the exposed DNA strands. But on page 522, Riley resuscitates an old idea that DNA need not unwind to transcribe RNA, and postulates that the new RNA strand could grow in the wide groove of the DNA double helix.

Both models attempt to explain how a region of local distortion could move along the DNA template at the growing point where RNA is being synthesized. The Russians take as their starting point what is known (organochemically speaking) about the details of how phosphodiester bonds are made and broken. They propose that first the 3′ hydroxyl of the last nucleotide added to the RNA chain attacks the 5′ phosphate group of the incoming nucleotide; then pyrophosphate is released by breakage of an ester bond of the triphosphate.

Because the first step requires energy but the second liberates it, Florentiev and Ivanov suggest that the two processes may be coupled together. This demands a change in the stereochemical conformation of DNA from its usual B-form to the normally unstable A-form, which could be stabilized at the site of RNA synthesis. One way to achieve the B to A transition might be to extrude water from the section of DNA bound to the polymerase.

Riley circumvents the problem of how DNA unwinds by proposing that the duplex retains its integrity in transcription. He suggests that bases of the RNA chain could specifically hydrogen bond with the base pairs of the DNA template if the conformation of the sugar-phosphate backbone is distorted so as to tilt the nucleotide bases in the helix. This could be achieved by a perturbation of the DNA progressing in a wave-like manner, with the maximum distortion at the growing point of the RNA chain.

That it is possible to propose two such conflicting models illustrates the level of ignorance about the mechanism of transcription. Such models risk achieving the remarkable distinction of being at once too complicated and too naive. They are too complicated, because, allowing that the available data can be interpreted to support either model, any number of models can be propounded, all consistent with what is at present known about transcription. And they are too naive, because transcription is enzymatically catalysed and is not merely a chemical process; so little is known about the details of how RNA polymerase interacts with the DNA template

that it is safe to say that the environment of DNA surrounded by protein is virtually unknown.

Should yet more model building be encouraged, therefore, to define the limits of what little is known and perhaps to suggest further experiments, or is this approach at present premature? It is clear, for example, that one (at least) of the two models presented here for transcription must be wrong. But it is hallowed scientific tradition that it is useful to construct models—be they of a theoretical or more practical nature—which make predictions that can be put to experimental test. The trouble in this instance, however, is that it is difficult to suggest practical experiments which will sort out even the bedevilled question of whether DNA unwinds in transcription. It is tempting to enter a plea for less speculation and more experimentation until at least this elementary fact is known.

Cell Surfaces and Neoplastic Transformation

A SET of observations which may be as relevant to an understanding of cancer as the discovery of RNA dependent DNA polymerase is reported on page 512 of this issue of *Nature*. Burger and Noonan report that the pattern of growth of transformed mouse fibroblasts in culture is restored to that of untransformed fibroblasts when certain binding sites on the surface of the transformed cells are covered by fragments of concanavalin A. Furthermore, this change is reversible.

Concanavalin A is one of about a dozen phytagglutinins or lectins, glycoproteins isolated from various plant seeds, which bind to and agglutinate animal cells. Various phytagglutinins have been available for several years, but only recently, as a result of the work of Burger and his co-workers at Princeton and of Sachs's group at Rehovoth, have they assumed great importance to cancer researchers. The key observation is that the extent to which a cell binds phytagglutinins is correlated with its sensitivity to contact inhibition of growth in cultures. Burger has shown that cells transformed *in vitro* by chemical carcinogens or tumour viruses, and spontaneous transformants selected by growing cultures of cells at high densities, always bind concanavalin A and the other plant agglutinins, while untransformed cells only bind these substances when they are actually in mitosis or just recovering from it. (There are exceptions to this rule; a phytagglutinin extracted from soya beans, for example, binds to untransformed cells but not to transformed cells; the pattern of differential binding is reversed.) Because of this phenomenon, cultures of untransformed cells which have reached their saturation density, with the cells in contact with each other, and have stopped or almost stopped increasing in density, do not bind phytagglutinins. On the other hand, cultures of transformed cells, which are not subject to contact inhibition of growth, always bind phytagglutinins.

This difference provides another criterion for judging whether or not a cell is transformed, but Burger and his colleagues believed that it had more significance than this. They suggested, and now seem to have proved, that the change in the cell surface on transformation, which results in the exposure of sites which bind concanavalin A and its relatives, is directly related to the fact that transformed cells are not subject to contact inhibition of cell division. First, Burger discovered that if monolayers of untransformed cells, which have stopped dividing because the cells are in contact and have also stopped binding concanavalin A, are briefly exposed to dilute solutions of trypsin, the cells undergo at least one more round of division. And parallel cultures similarly treated were found to become capable of transiently binding concanavalin A.

Burger and Noonan (page 512) now report the reciprocal experiment. They transformed with polyoma virus some 3T3 mouse fibroblasts, which before transformation stop dividing when they form a monolayer culture. The transformed cells, Py-3T3, however, continue to multiply even when the culture becomes very crowded and there are sufficient cells to form several monolayers. Furthermore, the transformed cells always bind concanavalin A. Burger and Noonan asked what happens if the sites which bind concanavalin A, and which are permanently exposed on Py-3T3 cells, are covered by a fragment of concanavalin A. This fragment, produced by digesting concanavalin A with trypsin, retains the property of binding to cells but cannot agglutinate or kill them. Burger and Noonan reasoned that if the exposure of the surface binding site reflects a change in the cell surface which renders the cells unsusceptible to contact inhibition, recovering these sites with a fragment of concanavalin A might restore contact inhibition. This was indeed what they found.

Transformed Py-3T3 cells plated at a low density and grown in the presence of sufficient fragmented concanavalin A stop multiplying at about the same density as that reached by untransformed 3T3 cells. This indicates that in the presence of fragmented concanavalin A, transformed cells behave in culture as do untransformed cells. Contact of cell with cell is crucial in inhibiting the multiplication of transformed cells when concanavalin A is present to bind to and form a covering layer on the surface of the cells. The significance of contact inhibition of cell division, as opposed to contact inhibition of cell movement, has been questioned, but at least as far as mouse 3T3 cells are concerned Burger and Noonan's experiments show the former as well as the latter to be real.

The restoration of growth control by fragmented concanavalin A is reversible as expected. When the agglutinin is removed from resting transformed cells they start to divide once more. And from the kinetics of the inhibition of cell division achieved by adding

fragmented concanavalin A, Burger and Noonan suggest that all Py-3T3 cells in a dense culture are potentially susceptible to inhibition within one cell cycle of exposure, but that inhibition can only occur if the concanavalin A is bound at a particular stage in the cell cycle. Cells in the G1 phase are immediately prevented from dividing, while cells which bind concanavalin A at other stages complete the cycle and stop dividing when they reach the G1 phase of the succeeding cycle.

Burger and Noonan propose a simple model to explain these results. They suggest that the phytagglutinin receptors are part of a whole subsurface layer of cells. In untransformed cells this layer is covered by some, so far uncharacterized, substance or architecture, whereas in transformed cells or untransformed cells treated with trypsin the subsurface layer is, respectively, permanently or transiently exposed. Fragments of concanavalin A bind to receptors in this exposed layer and, at least in a functional sense, cover it, rendering it cryptic. Burger and Noonan further suggest that a cell can only propagate and/or respond to short range chemical messages which lead to a cessation of cell division when this subsurface layer containing the phytagglutinin receptors is cryptic. Moreover, a cell's permeability or lack of it to specific ions, nutrients or specific growth controlling factors may vary according to whether this layer is exposed or covered. They suggest that when the agglutinin receptor layer is exposed, cells may not be able to recognize and respond to the near presence of other cells. On the other hand, when the layer is covered the social behaviour of the cells is restored.

PROTEINS

Natural History of the Ribosome

from our Molecular Biology Correspondent

THE state of ribosomes in bacterial cells, and the operational relation between polysomes, 70S monomers and their subunits, remains a controversial and confusing topic. In mammalian systems the fog has not yet gathered, and a good clear account of the situation in mouse liver by Falvey and Staehelin offers the hope that it may be averted altogether. In their first article (*J. Mol. Biol.*, **53**, 1; 1970) they observe that the polysomes cannot be broken down to the ribosomal subunits, without irreversible inactivation, which is caused by removal of magnesium. This, of course, is not new, and other workers, notably Wool and his colleagues, also found ways of preparing subunits which could be made to reassociate to functional 80S ribosomes. The work of Falvey and Staehelin enlarges on these observations.

The dissociation of the complex of ribosomes with messenger and peptidyl-tRNA can best be achieved by allowing the ribosomes to complete synthesis of their polypeptide chains in a cell-free system, and run off the messenger. These resulting monomers can be made to dissociate with some ease, simply by making the solution 0·5 M in potassium chloride. The 60S and 40S subunits are then separated by centrifugation and collected by precipitation with ethanol (a useful technical trick that had previously escaped practitioners in the field). When the subunits are redissolved in a solvent containing magnesium, they forthwith associate to 80S ribosomes, which perform satisfactorily in a poly U-stimulated cell-free system.

In their second article (*ibid.*, 21) Falvey and Staehelin consider how this property of reversible dissociation of the messenger-free ribosome relates to the protein synthesis cycle. Labelled 40S subunits were added to the cell-free system. Examination of the 80S ribosomes accumulating on release showed the incorporation of counts. The 80S ribosomes alone, on the other hand, showed only very slow assimilation of labelled subunits. Neither is there appreciable exchange at initiation, for when the components of a cell-free system were added to a mixture of 80S and labelled 40S particles, and after an appropriate interval potassium chloride was introduced, the ribosome–messenger-tRNA complex, which alone remains undissociated, contained no label. It follows that 80S ribosomes, and not their subunits, attach to the messenger at initiation (at least in the unphysiological poly U system, which requires no initiation factors). The principal message of this work then is that dissociation of subunits occurs at the end of each traverse of the messenger. The small fraction of undissociable 80S particles found in the cell lysates is thought to represent a quite different state of unknown significance.

A different approach to the same problem is that of Okubo and Raskas (*Biochemistry*, **9**, 3458; 1970), who have studied the incorporation of newly synthesized ribosomes into polysomes *in vivo*, using KB cells. The label identifying new RNA appears first in the small, then in the large, subunit. Thereafter the labelled subunits turn up in the polysomes, and only later in monosomes, with a lag of six hours before the label is uniformly distributed among all the ribosomal particles in the cell. This is in excellent accord with the findings of Falvey and Staehelin, except that six hours is much longer than the matter of minutes required for completion of one protein chain. It is too short, on the other hand, to be explicable simply in terms of the utilization of the new ribosomes only in new cells. Several explanations are possible—that dissociation of the 80S particles does not occur at each cycle or, more satisfactorily, that equilibration depends on the rate of distribution of new ribosomes through the cytoplasm.

HYBRID CELLS

Suppressing Malignancy

from our Cell Biology Correspondent

PROFESSOR HENRY HARRIS entertained his audience for an hour when he gave the sixth Michael Cross memorial lecture at the Royal College of Surgeons on October 27. He summarized the work which he and his colleagues at Oxford and his collaborators in Dr George Klein's laboratory in Stockholm have done during the past few years. He believes that this work indicates that malignancy behaves in Mendelian terms as a recessive trait, and in Darwinian terms as a property selected from a population of cells in which the chief source of genetic variation is the loss of chromosomes.

Professor Harris's approach to the genetic questions posed by malignancy was centred on the exploitation of the technique of cell fusion mediated by Sendai virus. He asks: is the hybrid cell produced by fusing a malig-

nant to a non-malignant cell malignant or non-malignant, and what can the properties and chromosomal composition of such hybrids and variants derived from them tell about the chromosome(s) which carry the determinants for malignancy ? It is well known that he and his colleagues found that when several sorts of highly malignant mouse cells were fused with non-malignant A9 mouse cells the hybrids were by several orders of magnitude less malignant than the parental cells, as judged by their capacity to induce tumours in irradiated newborn mice. Moreover, the cells of the few tumours which did arise had far fewer chromosomes than the hybrid cells inoculated.

Professor Harris interprets these results as showing that malignancy is recessive and that the non-malignant hybrids must lose chromosomes to regain malignancy. But chromosome loss *per se* does not generate malignancy; hybrids cultured *in vitro* until they have lost many chromosomes are not malignant.

But A9 cells, the non-malignant partner in the hybrids, are an established cell line and Barski, Defendi, Ephrussi and others have reported that hybrids formed by spontaneous fusion between malignant cells and normal mouse fibroblasts are malignant. Professor Harris and his colleagues therefore repeated their experiments using normal diploid fibroblasts freshly put in culture, instead of A9 cells. When Ehrlich cells were the malignant partner such hybrids were malignant, but they also lost chromosomes extremely rapidly, which, according to Professor Harris, is the way to generate malignant cells. He and his colleagues therefore used SEWA cells, which are malignant but have a karyotype closer to that of normal cells than Ehrlich cells. Three clones of hybrids between SEWA cells and normal fibroblasts were much less malignant than SEWA cells alone, and moreover these three hybrids lost chromosomes more slowly than clones of similar hybrids which were malignant. Professor Harris interprets these results as showing that normal fibroblasts can suppress malignancy in the same way as A9 cells, but that this suppression only occurs if the hybrids have a stable chromosome composition. If, on the other hand, the hybrids are unstable and readily shed chromosomes, they form an ideal population from which to select *in vivo* cells which have lost the particular chromosomes which suppress malignancy. Professor Harris commented that he was now certain that antigenic differences between the hybrid cells and the recipient mice were not responsible for the results he reported. Unfortunately he did not present in detail the evidence from which his conviction stems, and it is the cornerstone of his interpretations, for the results could be interpreted in terms of the selection for the loss of a chromosome which determines foreign histocompatibility antigens rather than the suppression of malignancy.

ENZYMES

Recombining Nucleases

from a Correspondent

INTEREST in the processes of recombination has recently focused on a new class of deoxyribonucleases which seems to be widely distributed in bacteria (*J. Biol. Chem.*, **245**, 767; 1970). These ATP-dependent nucleases are interesting from both mechanistic and biological viewpoints. Their absence in certain mutants (*rec*) of *Escherichia coli* which are deficient in recombination suggests that these enzymes play an important part in this process.

A new enzymatic property reported by Goldmark and Linn (*Proc. US Nat. Acad. Sci.*, **67**, 434; 1970) may provide a clue to the function they fulfil. Goldmark and Linn purified from *E. coli* an ATP-dependent activity that cleaves single stranded circular phage fd DNA. This endonucleolytic activity is lacking in *recB* and *recC* recombination mutants, as is the previously described ATP-dependent exonucleolytic activity.

Apart from its ability to make a first endonucleolytic cleavage of circular single stranded fd DNA, Goldmark and Linn's preparation of enzyme has properties similar to those described for ATP-dependent deoxyribonucleases from *Micrococcus lysodeikticus* and *Escherischia coli*. Double stranded circular DNA is not attacked, but linear single stranded and linear double stranded DNAs are degraded in a sequential fashion: any molecule of DNA attacked is completely broken down into oligonucleotides before the enzyme relinquishes it to attack another molecule of DNA. This is shown by the lack of accumulation of products of intermediate size and a rate of change of viscosity relative to the appearance of acid soluble products that is characteristic of exonucleolytic activity. At the *p*H optimum for the exonucleolytic activity (above 9·5) native DNA is a better substrate, but at neutral *p*H denatured DNA may be better.

It remains to be shown whether a single enzyme in *E. coli* embodies both the endonucleolytic and the exonucleolytic activities, but these properties are evocative of a nuclease that does not require a free end, but rather might act best at a site in DNA where both single stranded and double stranded DNA are present, namely a branch point. The action of the ATP-dependent DNase might in one way be analogous to the 5′ to 3′ exonucleolytic activity of *E. coli* DNA polymerase (*Nature*, **224**, 495; 1969) which cleaves oligonucleotides from non-homologous single stranded branches. In genetic recombination, on the other hand, structures with homologous single stranded branches are plausible intermediates that would require trimming by one or another mechanism.

A prominent difference between the experiments of Goldmark and Linn and earlier ones is the presence of an inhibitor of the ATP-dependent endonucleolytic action. Extracts of *recB* and *recC* mutants have an inhibitor, which is not present in *recA* mutants or *rec*$^+$ wild type that specifically inhibits the endonucleolytic action on fd DNA but does not seem to inhibit the exonucleolytic action on native DNA. The existence of this inhibitor raises some questions about the exact relationship of *recB* and *recC* genes to the ATP-dependent activities, because no evidence has yet been produced that these genes code for the ATP-dependent DNase.

CYCLIC AMP

Transmission and Development

from our Neurophysiology Correspondent

CYCLIC AMP is in vogue as an important intermediary in cellular control processes. It is now plain that this

nucleotide has an important function in the nervous system; indeed, Rasmussen (*Science*, **170**, 404; 1970) suggests that it has a role whenever there is intercellular communication. He points out that elements common to both neural and humoral transmission are: calcium ions, cyclic AMP, intracellular microtubules, microfilaments, secretory vesicles and protein kinases. He elaborates this suggestion in order to postulate a common origin, followed by divergent evolution, of neural and humoral signalling systems.

In the light of this it is interesting that Goodwin and Cohen (*J. Theoret. Biol.*, **25**, 49; 1969) suggested that the nervous system itself might have evolved from a developmental control system needed for the precise ordering of cellular events in embryogenesis. This suggestion gains weight with the growing evidence for the involvement of cyclic AMP in neural processes (H. Mellwain, *Nature*, **226**, 803; 1970; *Neurosciences Research Program Bulletin*, **8**, 221; 1970). In the only developmental control system that has so far been analysed in any detail, cyclic AMP also acts as an intermediary. In this case it is the chemotactic attractant controlling the aggregation of some cellular slime moulds (Konijn, Barkley *et al.*, *Amer. Naturalist*, **102**, 225; 1968). All the elements Rasmussen mentions, with the exception of vesicles, have been observed in this developmental control system, and so the suggestion of a common origin for developmental control systems and neural and humoral systems may not be too far fetched. In any case, a general theory of biological signalling processes in which excitation occurs through membranes is clearly developing.

In Rasmussen's model there are two fundamental intermediary signalling agents, cyclic AMP and calcium ions. Both are increased by membrane excitation of the enzyme adenyl cyclase which converts ATP to cyclic AMP. An increase in cyclic AMP activates phosphorylating enzymes which make products that are sensitive to calcium ions. The structure of these products can be changed by calcium ions, leading, for example, to contraction, or to a change in their interactions with other cellular components, allowing, for example, release of vesicle-containing transmitters. Calcium ions can also affect their own rate of transport through the cell membrane. In a similar way it has been postulated that the reception of cyclic AMP by aggregating slime mould amoebae can initiate amoeboid movement, the release of a further cyclic AMP signal and, eventually, differentiation.

ENVIRONMENT

Conservation in the Tropics

from a Correspondent

THE trials which beset ecologists working in the tropics were aired on October 21, when the Tropical Ecology Group of the British Ecological Society met in London. The complexities of tropical ecosystems were well described by Dr J. S. Weir (University of Leicester), discussing elephants, termite mounds, diversity and stability in savanna ecosystems. Some *Macrotermes* mounds contain concentrations of biogenic resources (such as minerals and water) and have ecological attributes (such as thermal stability, well aerated soil and refuge from fire and flood) which maintain a diverse and specialized flora and fauna. Stability is theoretically associated with species diversity in tropical ecosystems. These mounds, which may be very old (more than 700 years in one dated case), form mosaics of high species diversity, and their destruction is likely to have far reaching effects on the savanna ecosystem. Recent studies have shown that *Macrotermes* has deserted its mounds in areas of National Parks where there are large numbers of elephants; the reasons for this are not yet clear, but seem to be related to the damage which the elephants cause to the habitat.

Dr M. E. D. Poore (Nature Conservancy) pointed out that sustained use of a natural resource may be compatible with the conservation of an ecosystem, but that when land use is intensified these aims often cease to be compatible and very careful planning is essential. The best balance must be struck between human needs and the resources available; imbalances should not be introduced into the system until it is known how to control them, and it is important to maintain freedom of choice.

In Western Malaysia, Dr A. G. Marshall (University of Aberdeen) said, the virgin rain forest is being increasingly exploited and destroyed as a consequence of the rapid growth of human population and economic development. Conservation is no new idea there, but there is no organization to coordinate efforts. One delegate pointed out that air photographs suggest that one-third of the rain forest of Borneo has been destroyed since the Second World War. In Brazil, although the number of National Parks and designated protected areas has been increased recently, as Mr I. R. Bishop (University of Leicester) showed, it is extremely difficult to enforce conservation laws in remote areas. A large scale road building programme is leading to the destruction of Amazonian forest at an alarming pace, and farmers are moving in, often ahead of the road, to clear the very diversified forest with the intention of replacing it with a monoculture of grass for cattle. The extreme poverty of nutrient salts in the soils means that the land is likely to deteriorate rapidly after the removal of forest cover.

The priorities, problems and practice of the conservation of natural resources in tropical Africa were discussed by Drs M. J. Coe (Animal Ecology Research Group, Oxford) and M. J. Delany (University of Southampton), who found that there has been a great increase in the number of field biologists there in the past ten to fifteen years. But efforts badly need to be coordinated, both between workers with similar interests in different territories and between people traditionally thought to have conflicting interests. Even within one country departments may have conflicting policies, for example with respect to the conservation of game or its control for medical or veterinary reasons. In the francophone territories, recently visited by Dr C. H. Fry (University of Aberdeen), much has depended on the enthusiasm of a few individuals. Certain schemes call for regional consideration, such as a suggested river diversion for hydroelectric power which might lead to desiccation of much of Lake Chad. Clearly the need for more ecological work in tropical areas is urgent, and a meeting is being planned to consider ways of encouraging and helping with this. Not only are scientific studies and the coordination of accumulated data required, but there is still often a need for the authorities to be made aware of the importance of sound ecological advice.

NUCLEAR PHYSICS

Direct Proton Decay

by our Solid State Physics Correspondent

A FORCEFUL reminder of how important scientific results can be collected by the exploitation of chance situations is contained in the discovery by J. Cerny *et al.* of the process of direct proton decay in an excited nucleus of cobalt (*Phys. Lett.*, **33**; 1970).

The extraordinary feature of this experiment is that direct proton decay, long predicted to occur in highly unstable nuclei, has been observed in a relatively stable isomer of cobalt-53 with a half life of about a quarter of a second.

About sixty years ago Lord Rutherford first identified alpha decay as a means by which a nucleus could be transmuted by radioactive decay. Beta decay was also recognized at about the same time and about 1940 a third decay process was reported, in which the nucleus breaks up of its own accord in spontaneous fission. The possibility of observing direct proton decay has recently excited a lot of interest particularly among Soviet physicists, but calculations showed that this fourth process of decay could only occur in very unstable nuclei beyond the reach of present day accelerators.

Cerny and his team were first alerted to the possibility of observing proton decay at the Atomic Energy Research Establishment at Harwell. They were studying the interaction of calcium nuclei with a beam of oxygen-16 on the heavy ion cyclotron when they found, unexpectedly, that protons were being produced in the reaction. Although the intended product was nickel-53, the most obvious explanation was that an unbound isomer of cobalt-53 had been synthesized and was then decaying to give iron-52 with the emission of a proton and two neutrons.

But the experiments at Harwell were inconclusive. Although the energies involved were such as to eliminate nickel-53 as a source of protons, the interaction of nuclei of oxygen and calcium is complicated and it proved difficult to identify all the particles accurately. Moreover, it was not feasible to rule out the possibility of delayed proton decay, in which the fundamental mode is beta decay with the proton ejected from the excited nucleus only as a secondary process.

On returning to California, Cerny and colleagues at Berkeley carried out some experiments designed to measure direct proton decay. They bombarded iron-52 nuclei with protons from the Berkeley cyclotron. In this reaction two neutrons were again emitted yielding the same excited nucleus of cobalt-53. They succeeded in identifying the decay of the nucleus by opening and shutting the beam about once a second. Those protons detected in the dead time must then have come from the short lived cobalt nucleus.

Several questions are naturally thrown up by these experiments. Why was proton decay observed in a nucleus with a deficiency of only six neutrons (from the stable state) when theory had demanded a deficit of ten neutrons ? And by what process did the protons escape ? Cerny *et al.* suggest that the escaping proton is not energetically bound to the nucleus but is held in by barriers from other physical effects. They anticipate that proton decay will be observed widely among exotic nuclei, but not among more stable ones. In any event, they foresee the need for rethinking some of the basic ideas about nuclear structure.

X-RAY STARS

Iron Lines from Sco X-1

by our Cosmology Correspondent

RECENT confirmation of emission lines of iron in the X-ray spectrum of Sco X-1 (L. W. Acton *et al.*, *Astrophys. J.*, **161**, L 175; 1970) shows that the model of this source being built up by theoreticians is essentially correct. Sco X-1 is of particular interest to both theoretical and observational astronomers because it has been the strongest single emitter of X-rays in our galaxy ever since its discovery more than ten years ago. Most X-ray stars are very short lived as emitters of X-rays, flaring up and dying away in months rather than years. This makes their study very difficult, particularly when detectors have to be flown above the atmosphere in order to measure their X-ray emission at all and balloon or rocket borne experiments are planned months in advance.

Sco X-1 has therefore been seen by astronomers as the key to unlock the secrets of X-ray stars—once its properties are explained the properties of all other X-ray stars might, with luck, be explained by similar mechanisms operating on a smaller scale. It is equally likely that Sco X-1 will turn out to be completely different from "normal" X-ray stars, but astronomers have become used to gleaning a wealth of information from small quantities of data, and there are few pessimists left in a field where so few data are available.

One feature of the optical spectrum of Sco X-1 has been the presence of many lines associated with heavy elements; taken with the necessity for very high temperature before X-rays can be produced, this has encouraged speculation that the line radiation of heavily ionized iron (Fe^{+24}, Fe^{+25}) might be seen in the X-ray emission band of the source. Several attempts have been made to detect these lines; one proved successful in finding features in the expected part of the spectrum (S. Holt, E. Boldt, and P. Serlemitsos, *Astrophys. J.*, **158**, L155; 1969), but the features had too low a significance to be conclusive on the basis of a single experiment.

Now, however, Acton *et al.* have independently carried out a similar experiment, using a large area proportional counter carried above the atmosphere in an Aerobee rocket. They too have found a feature which may arise from the radiation of highly ionized iron. The feature occurs at 6·6 keV, and has a significance of about six standard deviations relative to the background noise. Taken together, these two experiments show conclusively that Sco X-1 contains at least the amount of iron expected from averaging the quantities of all the elements in our galaxy. Probably there is rather more iron than this actually present, for the high densities and pressures in Sco X-1 ensure that much of the radiation is scattered by electrons to produce broad lines which seem less important than they would if the emission were coming from a less dense source.

This addition to the information which has been gained about Sco X-1 in recent months fits in well with the ideas of the theoreticians, suggesting that the eventual union of all this information into a reasonably complete model of the source may not be too far away.

100 m Radio Telescope in Germany

by
R. WIELEBINSKI
Max-Planck-Institut für Radioastronomie, Bonn

The world's largest steerable radio telescope is coming into operation at Effelsberg. In this article Dr Wielebinski describes the 100 m dish.

ADVANCES in experimental sciences are often connected with the completion of new instruments. In radio astronomy the development of antennae has made an important contribution to the accumulation of observational data. In one very familiar form of radio telescope, the paraboloidal reflecting antenna, size and surface accuracy are the two important criteria. Size is limited, among other factors, by rapidly increasing building costs, and the improvement of surface accuracy depends on improvements in structural design. Apart from its imposing size, the most outstanding feature of the 100 m radio telescope nearing completion at Effelsberg, about 40 km south-west of Bonn, is its high surface accuracy.

Usually improved surface accuracy is achieved by providing stiffer structural members. With a large structure, such as a 100 m fully steerable paraboloidal reflector, however, increased stiffness requires, apart from enormous expenditure, so much additional steel that only marginal improvement in surface accuracy can be obtained. For some time there has been talk of dynamic and static methods of surface correction and in the case of the 100 m telescope[1] the latter have been applied rigorously. In the static method, often called homology design[2], a light steel structure is designed in a way that under all loads, such as movement in elevation and varying loads such as wind, the surface remains a paraboloid. Absolute deflexions of up to 10 cm are allowed, but the r.m.s. surface accuracy is expected to remain within 1 mm in all conditions of operation. Movement of the focus which ensues requires continuous correction, an easy task for a computer.

Two companies, Krupp and Man, submitted designs to the set specifications. In each case elaborate computations were required to meet a converging homology design. In the end the Krupp design was preferred and the two companies were asked to form a joint organization —Arge-Star—which was given the task of constructing the telescopes. The finance for the project, some DM32,000,000, was principally guaranteed by the Volkswagen-Stiftung. Construction began in 1968 at Effelsberg. The choice of site was dictated by the desire to remain within the boundaries of North Rhine–Westphalia, while being protected from the many sources of electrical interference. The site is a deep valley running north–south and the telescope is just visible above the neighbouring ridges when in the zenith position. The dimensions and other features of the telescope are given in Table 1.

Table 1. THE 100 M TELESCOPE

Reflector diameter	100 m
Focal length	30 m
Gregory reflector diameter	6·5 m
Gregory focal length	~360 m
Azimuth track diameter	64 m
Height of elevation axis above azimuth track	50 m
Elevation axis length	45 m
Elevation gear radius	28 m
Azimuth movement	±360°
Elevation movement	+5 to 94°
Maximum azimuth drive rate	40°/min
Maximum elevation drive rate	20°/min
Expected positional accuracy	6″
Total moving weight	~3,200 tons

The first stage of construction was preparation of the site and foundations. About 140 piles, 7–10 m long, were required to form the support for a ring foundation for the azimuth track. This ring foundation is 4 m high and rests on a 4 m wide base connected to the piles. At the centre of the ring a pivot-cone was constructed as the central turning axis of the telescope. A forged steel track carries the four bogies, each with eight wheels, which form the azimuth drive system for the telescope. The elevation drive is made through two double gear-motor systems which are carried on the 56 m diameter elevation gear wheel, and connected through two pinions to the elevation platform. The elevation platform is supported on a tetrahedron connected to the azimuth base structure.

The elevation axis is made up of a cross-like structure to which are attached, in one direction, the four supports for the primary focus cabin and, in the other direction, four members which form an octahedron supported at two points. The 100 m shell which supports the reflecting panels loads the octahedron basically at two points—just above the elevation platform at the bottom of the octahedron and at the centre of the elevation cross. In designing the telescope, care was taken to ensure that the

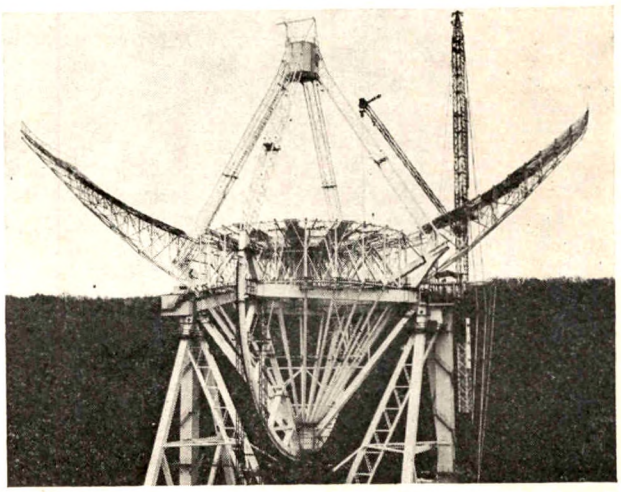


Fig. 1. An earlier construction stage showing the octahedron support and the partly assembled 100 m shell.

deflexions at the upper point of suspension, the elevation cross and paraboloid apex were identical. This umbrella-like construction is obvious in Fig. 1. The result is that the 100 m reflecting structure is virtually supported only at one point, the lowest apex of the octahedron.

The reflecting panels are constructed in three ways. The inner 60 m of the diameter has an aluminium sandwich construction in which two formed aluminium sheets are glued to a honeycomb inner sheet. Measurements have shown that by this method of construction r.m.s. surface accuracy of 0·22 mm has been achieved. The panels covering the next 20 m of the diameter are of aluminium "cassette" construction. Aluminium sections support a formed aluminium sheet. The r.m.s. accuracy of this type of panel is 0·27 mm. The outermost ring of cassette panels was made using perforated sheet to join the surface aerodynamically to the outer panels. The outer ring of panels from 85 to 100 m was made using 6 mm square stainless steel mesh. The measured r.m.s. surface deviations are 0·55 mm for the mesh panels. Each of the panels is supported on four adjusting screws. It is expected to operate with full efficiency down to 5 cm wavelength. Operation down to 8 mm wavelength is hoped for, using the 60 m central section of the telescope. The fully assembled telescope is shown in Fig. 2.

The telescope has a focus to diameter ratio (f/D) of 0·3. This is intermediate between those of the deep dishes, such as Jodrell Bank MkI (f/D = 0·25), and shallow dishes such as Parkes (f/D = 0·41). The 100 m telescope is a Gregorian reflector system which allows both prime focus operation and secondary focus work. A "collar" has been added around the aperture to reduce local interference to a minimum. For prime focus operation, a tube, about 3 m long and 1 m in diameter, will be projected through the centre of the secondary sub-reflector. A receiver box will be inserted from the prime focus cabin into this tube, which is rotatable for polarization measurements. In the secondary focus cabin, provision has been made for at least nine independent feeds. The feed horns of the hybrid-mode type will be able to operate at various frequencies. The prime focus will be used for all short wavelengths (5 cm and below) and for all wavelengths of 18 cm and above. Initially the secondary focus will provide feed horns for 6 cm, 11 cm and 13 cm (space) receivers. Multibeam operation is intended in this mode of observation.

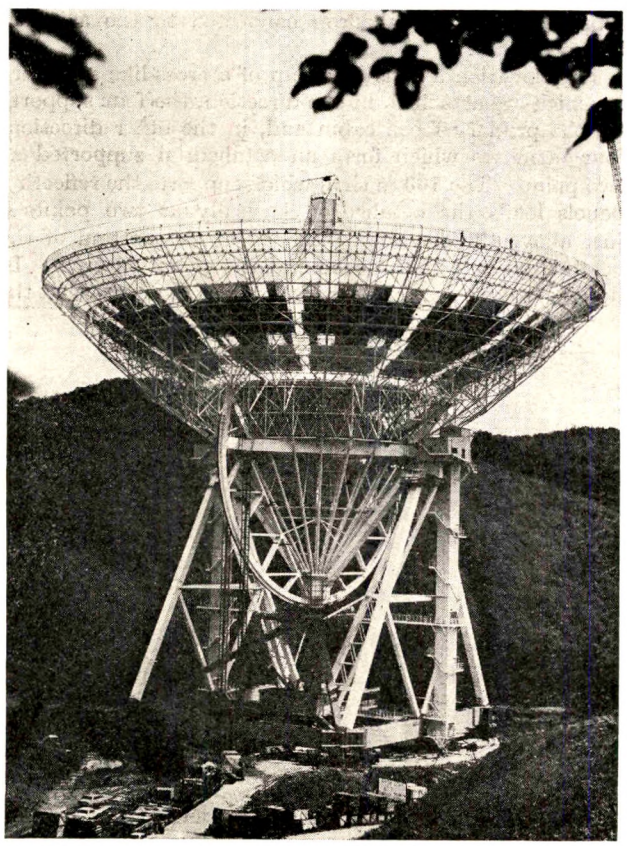

Fig. 2. Completed steelwork of the 100 m telescope.

A radio telescope of this size requires an elaborate receiving installation. Cryogenically cooled parametric amplifiers are being provided for wavelengths of 21 cm, 18 cm, 11 cm, 6 cm and 3 cm. Receivers for decimetre wavelengths will also be available. For centimetre wavelengths low noise front ends are being developed. A rubidium clock will be used for the basic timing reference for the universal oscillator in line measurements, for pulsar timing and for VLB observations. Radiometers are available for continuum measurements. Multi-channel filter receivers with bandwidths of 100, 16, 8 and 4 kHz are being constructed. An elaborate data processing system is being provided for the observers.

The basic data processor and steering computer is a Ferranti ARGUS 500. The purpose of this digital computer is to coordinate transformations, to control the telescope drive and the receiver and to process real time data.

From the control desk the ARGUS 500 computer allows the observer to choose a system of astronomical coordinates and to determine the method of scanning. The computer carries out the coordinate transformations and instructs the telescope drives of necessary drive velocities in azimuth and elevation. Because only a portion of the computer cycle is necessary for these functions, the computer is able to store data on magnetic tape, operate a fast line printer and a Calcomp plotter, as well as carrying out some on-line data processing. Further special purpose digital data processors to be provided are a 1,024 channel memory for pulse height analysis and a 384 channel autocorrelation spectrograph for line observations. At the institute in Bonn a Control Data 3300 digital computer system is available for further analysis of data.

The construction of a large instrument of this sort required the formation of a research organization and, from the Radio Astronomy Institute of the University of Bonn, a Max-Planck-Institut für Radioastronomie was formed. Three directors (Professor O. Hachenberg, Dr P. G. Mezger and myself) head an institute of about sixty scientists, forty of them astronomers. Three "service" divisions are entrusted with the operation of the telescope, data processing and electronics. An astronomical division will be responsible for the observational programmes, planned to embrace galactic and extragalactic radio astronomy. With supporting technical and administrative personnel the staff of the Max-Planck Institute is expected to grow to 150, and research students will also be able to carry out supervised research. Provision is being made for guest observers, both from Germany and from other countries. An international board of visitors meets annually to discuss and assess the performance of the institute.

Nomenclature of Immunoglobulins

by
D. S. ROWE
WHO International Reference Centre for Immunoglobulins, Lausanne, Switzerland

As the problem of biological nomenclature grows, the effective system worked out for the immunoglobulins can provide a model for the clarification of a confused situation.

THE gentle art of good name calling does not come easily to most scientists, at least in regard to the objects of their study. None the less, clear and unambiguous names are needed for described phenomena and if possible the name and the phenomenon should be logically associated. There are special problems of nomenclature in immunology which arise partly from the complexity of the immune response itself, and also from the great rate at which knowledge is acquired. The great variability of immunoglobulins has presented a major problem of nomenclature. This article is concerned chiefly with the nomenclature of immunoglobulins in man, and is intended as an introduction for non-specialists. It also indicates one way in which problems of nomenclature have been tackled on an international basis.

Although the phenomenon of antibody activity in plasma has been recognized since 1890 from the work of von Behring and Kitasato on tetanus antitoxin, the finding that antibody molecules belong to a distinguishable group of plasma proteins had to wait for the development of adequate techniques of protein analysis. In 1938 Tiselius and Kabat laid the foundation for subsequent work by showing that antibody to diphtheria toxoid in man was found in the γ-globulin electrophoretic fraction. γ-Globulin preparations, although now made by methods such as Cohn's ethanol fractionation procedure rather than electrophoresis, contain most of the antibody present in human serum. They are used therapeutically in man when the passive transfer of antibodies is required.

The idea that all antibodies were to be found in a homogeneous group of proteins did not, however, survive for long. Analysis in the ultracentrifuge, for example, showed that some antibodies were present in two molecular forms, sedimenting at different rates. The γ-globulin concept finally became outmoded by Grabar and Williams's simple and elegant technique of immunoelectrophoresis, which revealed several immunochemically distinct proteins within the γ-globulin region. These proteins were electrophoretically heterogeneous, and overlapped into the β-globulin regions.

What then was the relationship between these various proteins in the β and γ-globulin regions and antibodies? Three of the proteins which could readily be distinguished by immunoelectrophoresis were soon discovered to include molecules with antibody activity. These, according to their immunoelectrophoretic designation, were γ-globulin, β_{2A} or γ_{1A}-globulin and β_{2M} or γ_{1M}-globulin. Diversity of nomenclature had already appeared. The major protein, γ-globulin, was further designated by names such as γss (γ-sensu strictu) by a classically trained school of immunologists; and 7S γ-globulin where the orientation was perhaps more towards physicochemical concepts than towards dead languages. Moreover, β_{2M}-globulin turned out to be none other than a protein designated 19S γ-globulin on the basis of ultracentrifugal analysis.

This confusing situation was not a novel one in science. It reflected the rapid progress of the protein chemistry of γ-globulins. None the less, the diversity of names was confusing and could seriously have retarded progress in research and its application to medicine. A novel way was available to solve this problem. In 1963 the World Health Organization (WHO) established its immunology unit, charged with the responsibility of ensuring the effective development of immunology for human welfare on an international scale. The first WHO meeting on the nomenclature of human immunoglobulins took place in Prague in 1964, and WHO has subsequently sponsored a series of meetings and publications on this subject (refs. 1–5). In the publications some of the leading scientists in the field have made proposals for solving problems of nomenclature. Many of the proposals have found general acceptance, and have resulted in great simplification; an exception is the proposal concerning the nomenclature of genetic markers of immunoglobulins which has appeared less appropriate in the light of subsequent research, and is not generally accepted.

In 1964, the term "immunoglobulin" was proposed as the generic name for all types of proteins with antibody activities, and for structurally related proteins. "Immunoglobulin" thus superseded "γ-globulin". Two symbols were proposed to indicate immunoglobulin; Ig was regarded as the logical abbreviation, but the symbol "γ" was also retained in recognition of its historical association with immunoglobulins. As will be seen, although the γ nomenclature suffers from a degree of ambiguity, both Ig and γ are now well established symbols, and immunologists remain typically faithful to the symbol of their choice.

Classes and Types of Immunoglobulins

Names were also proposed in 1964 for the different classes of immunoglobulins. Clear distinction between classes is essential, for these proteins differ widely in their biological properties. The major protein in the γ-globulins was designated IgG; the macroglobulin characteristic of 19S γ-globulin (γ_{1M} etc.) was recognized in the symbol IgM, while for the previous β_{2A} or γ_{1A}-globulin, the highest common factor was indicated in IgA. In this way rational-

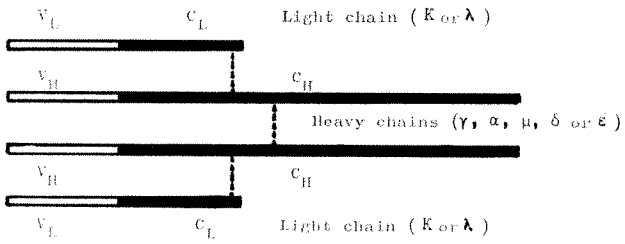

Fig. 1. A diagram of the structural unit of immunoglobulins and its constituent polypeptide chains and regions. Immunoglobulin molecules may consist of one or more of such units, for example, IgG molecules comprise one unit, IgM molecules five units. See text for a description of the symbols used for the regions.

ity was introduced while preserving a form of continuity with previous terms. The terminology provided for the introduction of names for new classes of immunoglobulins; IgD and IgE have since been added. The names of these proteins, together with their salient characteristics, are shown in Table 1.

These terms IgG, IgA and so on served to define the major classes of immunoglobulins. At the same time a terminology was established for the constituent polypeptide chains of immunoglobulin molecules. The fundamental unit of structure of immunoglobulins irrespective of their class, consists of two pairs of identical chains as shown in Fig. 1. The larger chains were designated heavy chains and the smaller chains light chains. Because differences between classes of immunoglobulins are due entirely to differences between their heavy chains, these were designated by the Greek letter corresponding to their class, for example, the heavy chains of IgG as γ-chains, the heavy chains of IgA as α-chains and so on. The light chains are common to all immunoglobulin classes but occur in two forms or types. These were designated type K or type L and the chains as κ or λ. At the time when this nomenclature was established the evidence of heterogeneity of chains was derived almost entirely from immunochemical analyses. Subsequent studies of the primary structure of immunoglobulins have shown that the differences between chains are due to major differences in primary structure.

Table 1. CLASSES OF HUMAN IMMUNOGLOBULINS

Name	Median serum concentration (mg/ml.)	Molecular weight	Biological properties
IgG (γG)	1·2	150,000	The major immunoglobulin in serum
IgA (γA)	0·4	180,000	The major immunoglobulin in secretions. Does not activate complement
IgM (γM)	0·12	900,000	"Early" antibodies often occur in this class
IgD (γD)	0·003	186,000	Function unknown
IgE (γE)	0·00025	200,000	Responsible for immediate type sensitivity

Sub-classes and Genetic Markers

Further sub-divisions of immunoglobulins are now recognized. For example, sub-classes occur in IgG, IgA and IgM. Human IgG can be divided into four sub-classes on the basis of antigenic differences between γ-chains. These are designated IgG1, IgG2, IgG3 and IgG4 in the order of their relative serum concentrations. Differences between sub-classes are due to a series of differences of amino-acid residues within heavy chains. Sub-classes are functionally distinct, for example, IgG1 and IgG3 sub-classes readily activate complement, whereas IgG_2 activates weakly and the IgG4 sub-class not at all.

Whereas all immunoglobulin sub-classes are present in all (normal) members of the species, genetic markers or allotypic specificities of immunoglobulins are present in some, but not all, individuals. In man, genetic markers have been found in γ and α-chains and in λ-chains, and allotypic specificities have also been recognized in rabbits and other animal species. Two principal series of factors have been recognized in man. Grubb, working with antiglobulins present in the serum of patients with rheumatoid arthritis, was the first to recognize one series of factors which he designated Gm. This indicated that the factor was present in gamma-globulin. More than twenty Gm factors are now recognized, usually designated by symbols such as Gm a, Gm f, although a numerical notation has been proposed[2]. Individual Gm factors are associated with individual sub-classes of IgG and Gm factors in the different sub-classes are found to be genetically closely linked. A second unrelated genetic system present in man is designated by the symbol Inv, described initially by Ropartz to be present in the serum of patient V. The factor is a property of λ chains. Inv a+ differ from Inv b+ light chains by the substitution of leucine for valine at residue 191 in the constant region of the chain (discussed later). Another variability, termed Oz, has been demonstrated at a similar position in the constant region of κ chains. Oz, however, differs from InV in that both Oz+ and Oz − κ-chains can occur in the same individual,

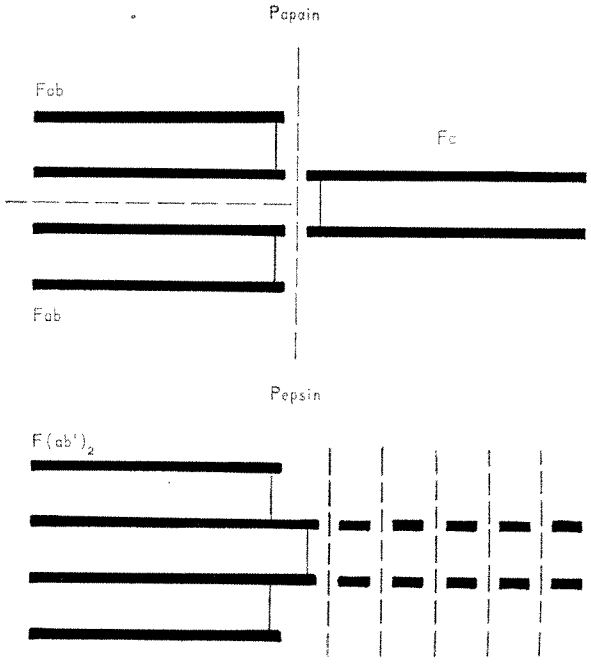

Fig. 2. The actions of papain and pepsin on IgG. Papain yields two identical Fab fragments and one Fc fragment. Pepsin yields one $F(ab')_2$ fragment, the carboxy terminal halves of the heavy chains are split into small peptides.

Enzymatic Fragments

Names have also been given to the fragments of immunoglobulins obtained by enzymatic digestion (Fig. 2). The system which has been most extensively studied is the action of papain on IgG. Three major fragments are produced and the study of these has been valuable in

elucidating the molecular structure of IgG and in assigning different functional properties to different regions of the molecule. The fragment which is composed of the carboxy terminal halves of the heavy chains is sometimes crystallizable and is designated Fc (fraction crystallizable) on this account. The two remaining fragments are identical and each comprises the amino terminal half of a heavy chain and one light chain. When obtained from antibody molecules these fragments can bind antigen, and so have been designated Fab (fragment antigen binding). That part of the heavy chain included in Fab has been designated Fd. Pepsin cleaves the heavy chains of IgG at a site slightly closer to the amino terminus, yielding one $F(ab')_2$ fragment, the remaining part of the heavy chain being further split into several smaller fragments. Most of the biological properties of IgG antibody molecules other than antibody binding are present in the Fc fragment, for example, the ability to activate complement, to attach to cells as cytophilic antibody and to be transferred across the placenta.

Constant and Variable Regions

Studies of primary structure have shown that light chains may be divided into two approximately equal regions. These are the carboxy terminal half of the chain where within a given type the sequence is invariable (except for Inv and Oz differences I have noted), and the amino terminal half of the chain where numerous differences in sequence are found, even among light chains of the same type. These two regions are therefore referred to as constant regions and variable regions. Light chain type is determined by the sequence of the constant region. Variable regions do not consist of an infinite variety of amino-acid sequences; rather a distinct group of variable regions has been found to be associated with a constant region of given type, that is, one group is found in κ-chains, and a different group in λ-chains. Further patterns of variability have been recognized within groups. On the basis of existing sequence data, three sub-groups of κ variable regions and five sub-groups of λ variable regions can be distinguished in man.

Heavy chains also have constant and variable regions. The variable regions of the heavy chains are at the amino terminal and and are of approximately the same length as the variable regions of light chains. The variable regions of heavy chains are also comparable with those of light chains in the occurrence of groups of distinctive sequence patterns. Contrary to the light chains, however, there is evidence that the groups of individual patterns may not be restricted to heavy chains of a given class, that is, the same individual pattern may occur in γ, α and μ chains. There is much indirect evidence that the antigen binding activities of immunoglobulins are determined by the primary structure of the variable regions of heavy and light chains.

The constant region of heavy chains which has been most extensively studied is that of IgG. Three linearly arranged adjacent regions have been found which have sequence similarities both to each other and to the constant region of the light chains. These three regions have been called homology regions. In addition, that region of the heavy chains close to the site of the action of papain is notably rich in proline residues and evidence derived from electron microscopy suggests that this is the most flexible region of the immunoglobulin molecule. This general region is therefore sometimes referred to as the "hinge region".

Symbols have been proposed for these different regions of immunoglobulin molecules. Constant regions of heavy and light chains are indicated by CH and CL respectively. Variable regions are similarly indicated as VH and VL. To specify a particular class or sub-class of heavy chain the symbol H could be replaced by the symbol of the chain. Thus the constant region of α-chains would be indicated by the symbol Cα. Similarly, to indicate an individual type of light chain the symbol L could be replaced by the symbol for the chain, for example, the variable region of κ chains would be indicated by V_κ. A more detailed account of proposals for the nomenclature of the regions, of half-cystinyl residues, and for formulae for immunoglobulin molecules will be found in ref. 5.

Immunoglobulins in Species other than Man

The nomenclature I have described has been developed primarily with regard to the immunoglobulins of man. Nomenclature in other species is more confused; diverse systems have grown up partly based on evidence from within a species, and partly on comparisons with other species. It would be desirable that the nomenclature which has been successfully applied to the classes and types of human immunoglobulins also be used for other species. The logical basis of such nomenclature would be the demonstration of evolutionary homology between the immunoglobulins of different species. Thus names for immunoglobulins in species close to man would be relatively easy to assign, whereas nomenclature in more distant species could prove to be more difficult.

The firmest ground for the demonstration of evolutionary homology is the finding of similarities of primary structure. Although rapid progress has been made it is hardly to be expected that this information will soon be available for many species, especially for those immunoglobulins which are difficult to isolate in purified form. In these circumstances antigenic cross reactivity forms a valuable tool for the investigation of similarities of structure, and it seems reasonable to designate immunoglobulins on this basis. Other types of comparison are on less sure ground. Criteria such as molecular weight and carbohydrate content must carry less weight than those based on primary structure.

Functional criteria could be seriously misleading. For example, it was generally considered that IgA was the major immunoglobulin of colostrum and other secretions, but in the bovine species a protein more closely related to IgG seems to be the major immunoglobulin of colostrum, whereas the protein more comparable with IgA is only a minor component.

In summary, the nomenclature of human immunoglobulins, although necessarily complex, has now been placed on a rational and generally agreed basis which is sufficiently flexible to accommodate new information. Studies of immunoglobulins in other species have important applications to the understanding of the activities of comparable proteins in man, and the establishment of homology is therefore of broader significance than its applications to questions of nomenclature. None the less, a satisfactory nomenclature for the immunoglobulins of various species can hardly be established before adequate evidence for homology is obtained.

Restoration of Normal Growth by Covering of Agglutinin Sites on Tumour Cell Surface

by
MAX M. BURGER
KENNETH D. NOONAN
Department of Biochemical Sciences,
Princeton University,
Princeton, New Jersey 08540

By covering sites on transformed cells with monovalent concanavalin A, the growth pattern of transformed fibroblasts is restored to that of normal cells. The process can, moreover, be reversed.

NORMAL fibroblasts in tissue culture stop growing when they have reached a confluent monolayer; that is, they are sensitive to growth control, the mechanism of which is not known. Virally transformed cells grow past the monolayer stage and therefore may be considered to have lost this type of growth control. Even though this phenomenon, called contact inhibition of growth or density-dependent inhibition of growth[1], is dependent on factors in the growth medium, normal cells do show a clearly different sensitivity to the growth factors compared with that of tumour cells. A correlation between tumourgenicity and loss of contact inhibition of growth has been shown earlier[2].

We have previously described a change in the surface membrane of tumour cells which seems to be correlated with the loss of contact inhibition of growth in several tissue culture lines[3,4]. This change consists in the appearance of certain agglutinin receptor sites on the tumour cell surface which were not available on the surface of normal cells, but which could be exposed by a brief and light proteolytic treatment[5]. On the basis of these findings we postulated that among the changes brought about by such a proteolytic treatment, some may be directly related to the loss of contact inhibition of growth.

Two entirely different types of experiments could lend support to such a working hypothesis and both should be able to shed some light on the mechanism of contact inhibition of growth. First, an attempt may be made to bring about a transient escape from growth control by treating the cells in a monolayer with proteases, thereby temporarily producing the type of surface change seen in transformed cells. Second, an attempt may be made to recover growth control in virally transformed cells by covering up the exposed layer of surface receptors and thereby mimicking the surface structure of normal cells. We have recently substantiated the first prediction by demonstrating a transient escape from growth control after a brief proteolytic treatment which lasts approximately as long as the surface change persists, that is, until the surface is repaired[6].

We describe here an attempt at the complementary experiment where it is proposed that covering the agglutinin sites on the tumour cell surface should bring about a reversion of the growth pattern of transformed cells to that of normal cells. We demonstrate that if one covers the agglutinin sites on tumour cell surfaces such cells will phenotypically revert to normal growth behaviour and continue such behaviour until the cover layer is removed again, at which point the same cells again begin to grow like tumour cells.

Monovalent Agglutinin for Blocking Surface Sites

Concanavalin A (Con A), a phytagglutinin or lectin, isolated[7] from Jack Bean meal (Calbiochem) was used in these studies, and was shown to react specifically with carbohydrates and preferentially to agglutinate tumour cells[8]. We decided to use Con A rather than wheat germ agglutinin because agglutination brought about by wheat germ agglutinin[9] could be overcome by serum glycoproteins and serum[10], thereby prohibiting its use in growth medium that requires serum.

To cover the agglutinin site and at the same time to avoid the criticism that any growth control which we observed was simply the result of the immobilization of two neighbouring cells by the normal agglutination process, we tried to split or degrade the agglutinin molecule into pieces which had only one binding site. First we tried papain which was earlier used to split γ-globulin, then pronase, both without success. Then we found that chymotrypsin treatment resulted in such a split agglutinin which stopped tumour cell growth at confluency, and data similar to those in Fig. 1 were obtained with chymotrypsin. A better procedure involving trypsin was independently developed by M. S. Steinberg and I. A. Gepner (in preparation). A modification of that method was used for most of the experiments described here. 1 mg Con A was dissolved in 1 ml. phosphate buffer (0·2 M, *p*H 7·0) and treated with 0·1 per cent trypsin (Difco) for 5 h at 37° C. Enzymatic digestion of Con A was stopped by the addition of 0·5–1·0 per cent soybean inhibitor (Sigma). Two pieces of evidence suggest that the trypsin did break Con A and that the monovalent pieces were attached to the agglutinin receptor site. Table 1 shows the agglutination with polyoma virus of transformed mouse fibroblasts (Py3T3) before and after preincubation with trypsinized Con A. The procedure used for the agglutination assay was as follows. Mouse fibroblasts (3T3) and Py3T3 cells were harvested by rinsing the culture dishes twice with saline at 37° C and then suspending the cells with an EDTA solution at 37° C as described earlier[3]. The agglutination tests were performed in the well of a porcelain spot plate and standardized to 10 min of mixing on a rocking platform with a constant temperature plate at 22° C. The agglutinations were scored in terms of half-maximal agglutination concentrations, that is, that concentration of agglutinin necessary to agglutinate 75 per cent of the cells. It can be seen that preincubation of the Py3T3

Table 1. AGGLUTINATION OF 3T3 AND Py3T3 CELLS BEFORE AND AFTER PREINCUBATION WITH TRYPSINIZED CON A

Cell type	Additions	Intact Con A necessary for half-maximal agglutination (μg/ml.)	Cell type	Additions	Intact Con A necessary for half-maximal agglutination (μg/ml.)
3T3	—	>1,500	Py3T3	250 μg/ml. trypsinized Con A preincubated with 5×10^{-3} M α-methyl-mannoside; added to cells and incubated for 20 min, washed and tested	250
Py3T3	—	250			
Py3T3	250 μg/ml. trypsinized Con A preincubated with cells for 20 min	>1,500	Py3T3	250 μg/ml. trypsinized Con A preincubated with cells for 20 min, washed and tested	>1,500
Py3T3	Trypsin + soybean inhibitor	250			
Py3T3	Bovine serum albumin (250 μg/ml.)	250	Py3T3	Cells preincubated with 5×10^{-3} M α-methyl-mannoside, washed and tested	250

All agglutinations were carried out according to the procedure described in the paper and are scored as concentration of Con A necessary for half-maximal agglutination.

cells with trypsinized Con A radically increases the amount of agglutinin necessary to bring about half-maximal agglutination. The remainder of the table suggests specificity of the agglutinin for a chemically defined site on the cell surface. Analytical ultracentrifugation with trypsinized Con A resolves only one peak that is moving slightly slower than the untrypsinized Con A, suggesting that the Con A was reduced in size by trypsinization.

Using this "split" agglutinin to cover the receptor sites on the cell surface, we have been able to bring about contact inhibition of growth in cultures of Py3T3 cells which normally do not exhibit contact inhibition of growth or low saturation density. Whether other properties of these transformed cells have also returned to normal after this treatment is being investigated.

We used the cell lines 3T3 and Py3T3, obtained from Dr H. Green. All experimental cell lines were grown in 60 mm Falcon tissue culture dishes with Dulbecco's modified Eagle medium with 10 per cent calf serum or 15 per cent foetal calf serum. All cultures were seeded at low densities and then allowed to grow to the required density, at which time the desired concentration of trypsinized Con A was added. This was done by removing the old medium and replacing it with fresh medium or conditioned medium in which the desired concentration of trypsinized Con A was dissolved. By seeding the cells at one density and allowing them to grow to the desired density we hoped to exclude the possibility that the effect of trypsinized Con A was on the attachment of the cells to the plastic surface and had nothing to do with contact inhibition of growth. Cell counts were made every 24 h for 6 days with a haemocytometer. New medium with trypsinized Con A was added every 2 days to prevent the accumulation of catabolites and to supply the necessary metabolites. The *p*H was kept stable in an incubator with constant pCO_2.

Fig. 1 demonstrates the graded response of cell growth observed when varying quantities of trypsinized Con A were added to the culture medium, and indicates that the higher the concentration of monovalent agglutinin in the medium the more the growth behaviour of the transformed cells approaches that of the normal fibroblasts. This suggests a quantitative relationship between the covering of the agglutinin receptor layer and the degree to which contact inhibition of growth is expressed. The more surface sites that are closed with monovalent agglutinin the lower the resultant saturation density. Such a relationship has suggested itself from earlier work in which we demonstrated that more easily agglutinable cell lines showed a higher saturation density than lines which agglutinated less at the same concentration of agglutinin[3]. Thus there seems to be a reasonable quantitative relationship between the number of sites opened and the saturation density of the particular cell line. The ultimate proof for such a correlation will require a measurement of the exact number of sites per unit area that are opened with respect to those that are covered.

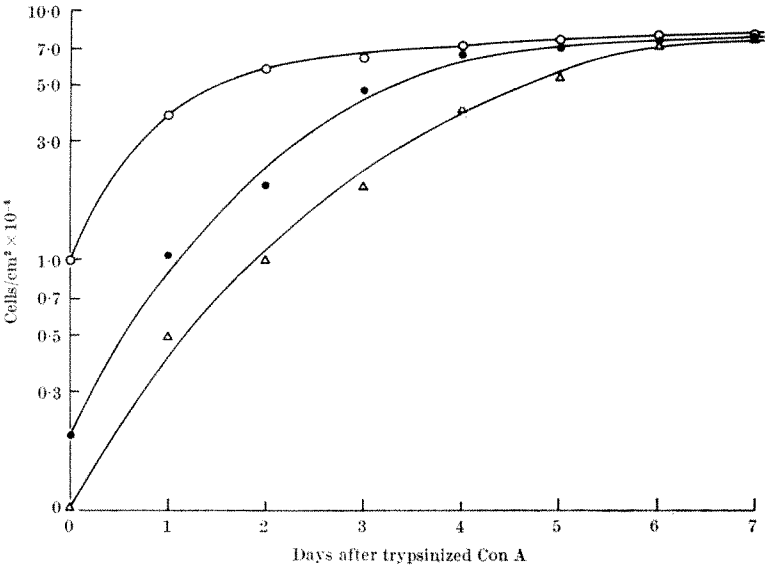

Fig. 2. Effect of 50 μg trypsinized Con A on the growth of Py3T3 cells seeded at different densities. ○—○, Py3T3 cells seeded at 1×10^4 cells per cm² + 50 μg trypsinized Con A; ●—●, Py3T3 cells seeded at 2×10^4 cells per cm² + 50 μg trypsinized Con A; △—△, Py3T3 cells seeded at 1×10^3 cells per cm² + 50 μg trypsinized Con A.

The addition of monovalent agglutinin to Py3T3 cells does not interfere with growth *per se*, for Py3T3 cells grow normally for 24–48 h before reaching confluency (Fig. 1). Further, monovalent agglutinin does not interfere with the growth of 3T3 cells at the concentration where Py3T3 overgrowth is clearly inhibited, suggesting that we are not observing merely a toxic effect of trypsinized Con A on the growth of Py3T3 cells. The addition of soybean inhibitor or of soybean inhibitor and trypsin had no effect on the growth of 3T3 or Py3T3 cells in a control experiment.

Although no toxic effects could be found with monovalent agglutinin, native, bivalent agglutinin led to the death of both 3T3 and Py3T3 cells. This toxicity might be the result of two different effects. Adjacent cells could be irreversibly bound to each other, or single cells without neighbour cells could be immobilized by bivalent molecules folding back on themselves, thereby connecting adjacent sites of the same cell surface and reducing the membrane mobility and flexibility.

Fig. 2 demonstrates that trypsinized Con A does not simply decrease or prevent growth of transformed cells *per se* but rather plays a part in a density dependent phenomenon, similar to the contact inhibition of growth observed in normal cells. In this experiment, monovalent agglutinin was added to cells previously seeded at

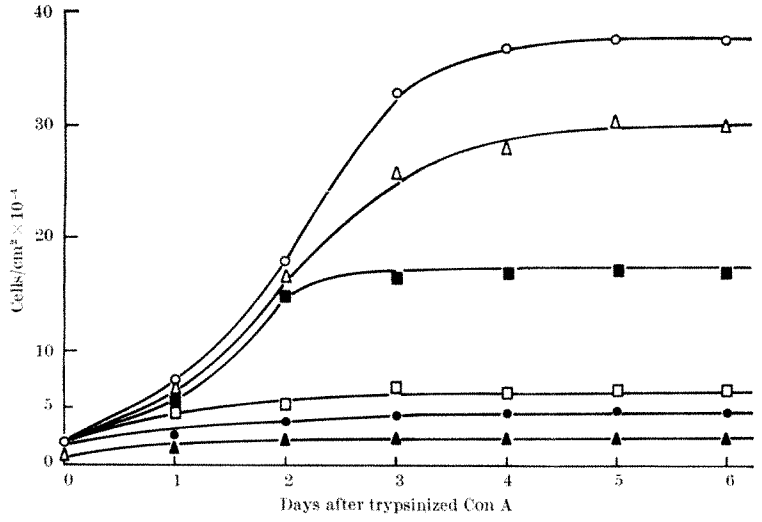

Fig. 1. Growth response of Py3T3 cells to varying concentrations of trypsinized Con A. ○—○, Py3T3, control; △—△, Py3T3 + 10 μg trypsinized Con A; ■—■, Py3T3 + 25 μg trypsinized Con A; □—□, Py3T3 + 50 μg trypsinized Con A; ●—●, Py3T3 + 74 μg trypsinized Con A; ▲—▲, 3T3, control.

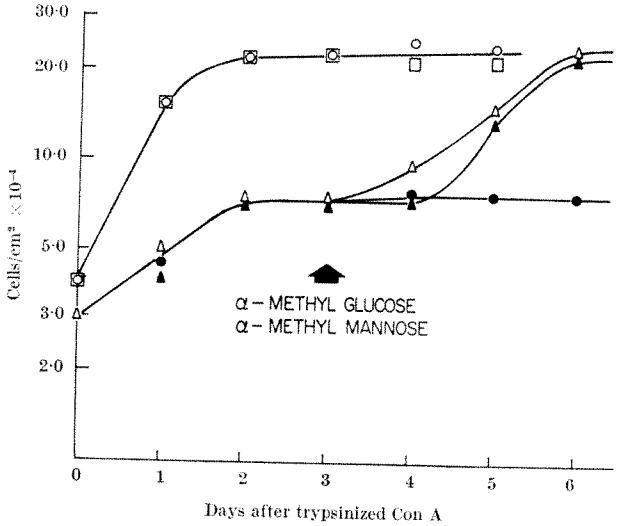

Fig. 3. Reversal of the effect of trypsinized Con A on the growth of Py3T3 cells. ○—○, Py3T3, control; □—□, Py3T3 cells + 50 μg trypsinized Con A incubated with 10^{-2} M α-methyl-glucoside for 12 h; △—△, Py3T3 cells + 50 μg trypsinized Con A + 10^{-2} M α-methyl-glucoside or 10^{-2} M α-methyl-mannoside added to the contact inhibited culture at day 3; ▲—▲, Py3T3 cells + 50 μg trypsinized Con A + 10^{-3} M α-methyl-glucoside of 10^{-2} M α-methyl-mannoside added to the contact inhibited culture at day 3; ●—●, Py3T3 cells + 50 μg trypsinized Con A.

different densities and the cells were allowed to grow. Cells seeded at the highest density stopped growing first, followed by the cells seeded at lower densities, suggesting that cell density and therefore cell to cell contact are significant in the restrictive growth control observed after covering the surface with monovalent agglutinin.

If the medium containing monovalent agglutinin is removed and replaced with fresh medium before the cultures reach confluency, the cells will grow past confluency and no growth control will be observed. If, however, new medium is added only after the cells have reached confluency, such cells will not overgrow the monolayer and the growth control exerted by the monovalent agglutinin will remain effective. This again suggests that although the attachment of the monovalent agglutinin to the cell surface is necessary to produce the growth control reported here, it is not sufficient to bring about growth inhibition but must be coupled with a particular cell density to be effective. This finding is again analogous to observations made for contact inhibition of growth in normal 3T3 cells.

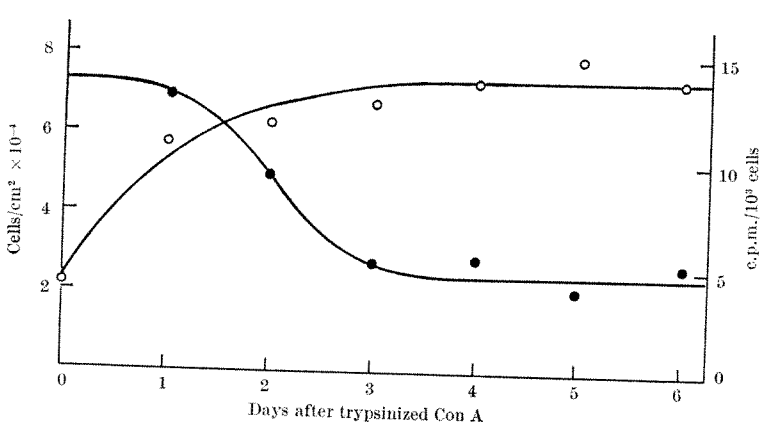

Fig. 4. ^{3}H-Thymidine uptake by Py3T3 cells grown with 50 μg trypsinized Con A. Cells were seeded at the desired density and each day a 2 h pulse of 1 μCi/ml. was added to the plate to be used the next day. After the pulse, the medium was replaced with conditioned medium + 50 μg trypsinized Con A. The next day the cell number and the radioactivity of ^{3}H-thymidine incorporated into DNA was determined. ○—○, Py3T3 cells + 50 μg trypsinized Con A; ●—●, ^{3}H-thymidine, c.p.m./10^3 cells per ml.

Evidence for Reversibility and Non-toxicity

To exclude the possibility that cessation of growth at confluency may just have been brought about by damage to the cell by the attachment of monovalent agglutinin to the cell surface, and to demonstrate that the attachment was site specific and that this site specificity accounted for the inhibition of growth, the experiment in Fig. 3 was performed. Transformed cells to which monovalent agglutinin was added together with either α-methyl-glucopyranoside or α-methyl-mannopyranoside (the hapten inhibitors of Con A) grew to the expected saturation density of untreated transformed cells. Moreover, if the cells were allowed to come to the density at which their growth was inhibited, and a hapten was then added, contact inhibition of growth was overcome, the cells resumed growth and eventually reached the cell density of the control culture. These results confirm the quantitative nature of the inhibition. The cell number of the culture released with 10^{-3} M hapten always lags behind the cell number of the culture released with 10^{-2} M hapten (Fig. 3) indicating that, the more sites that are reopened, the more rapid the release from contact inhibition of growth. Incomplete reversion with still lower concentrations of hapten is likely but this remains to be proved.

Time Dependence of the Effect of Concanavalin A

To determine the time dependence of the trypsinized Con A effect on growth, cells were allowed to grow to a density of 8×10^4 cells/cm², which exceeds the density to which trypsinized Con A treated cells normally grow. Trypsinized Con A (50 μg) was added and cell numbers were determined for the next 6 days. Somewhat less than one complete cell division could still be observed before the onset of complete inhibition of growth, suggesting that at such high cell densities all the cells are potentially sensitive to contact inhibition by monovalent agglutinin within one cell cycle but actual inhibition can only occur at a defined part of the cycle. By analogy with contact inhibition of growth in normal fibroblasts the stage in the cell cycle at which they stop is probably G_1. According to this model, any cell in G_1 will stop growth immediately while all other cells will do so only when they have reached G_1. Thus at this density the cell number of the culture should almost, but not quite, double. A slight discrepancy from exact doubling would be predicted because of all those cells that were in the sensitive part of G_1 when trypsinized Con A interrupted their further progress in the cell cycle. This prediction is substantiated in Fig. 4, and we hope to verify it in synchronous culture.

Release from growth inhibition seems to occur in much less time than the acquisition of growth inhibition. Such a short lag suggests that once the growth control induced by trypsinized Con A is released, the cells need considerably less than a full cycle to reinitiate growth.

Fig. 4 illustrates the pattern of ^{3}H-thymidine uptake into DNA by cells which have been exposed to monovalent agglutinin, and demonstrates that within 24 h after the onset of inhibition by trypsinized Con A the rate of DNA synthesis decreased rapidly, reaching a stable minimum at about the time that the cell number was maximum. This again suggests that certainly not more than one round of replication is necessary to induce growth inhibition once the cells have reached the proper density and that less than one round occurs before cessation of growth. Further, ^{3}H-thymidine uptake is still normal at least 24 h after addition of trypsinized Con A. If trypsinized Con A had blocked trans-

port in general by interfering with binding sites, pores or other mechanisms of membrane translocation, such an effect would have been expected to occur immediately or at least within 24 h. General transport[10,11] is therefore not the most likely basis for an explanation of the type of growth control involved in our experiments, but it cannot be ruled out as a secondary effect if only the transport of very specific components were altered.

A number of possible models for the role of the exposed agglutinin receptor layer in contact inhibition may be suggested. The components which cover the agglutinin receptor layer may affect the following important processes: its presence or absence may directly or indirectly change physicochemical surface properties like adhesiveness or membrane flexibility important for cell mobility and the division process; it may affect membrane turnover; the surface components may influence attachment or permeability for specific ions, general nutrients[13] or specific growth factors[14]; and they may be crucial for the propagation of messages relating to the control of cell division. Such messages could act at high cell density and close range between cells or could be exchanged intracellularly between the cell nucleus and the membrane as a means of coordinating events in the cell cycle and cell division. The validity of each of these hypotheses will be tested.

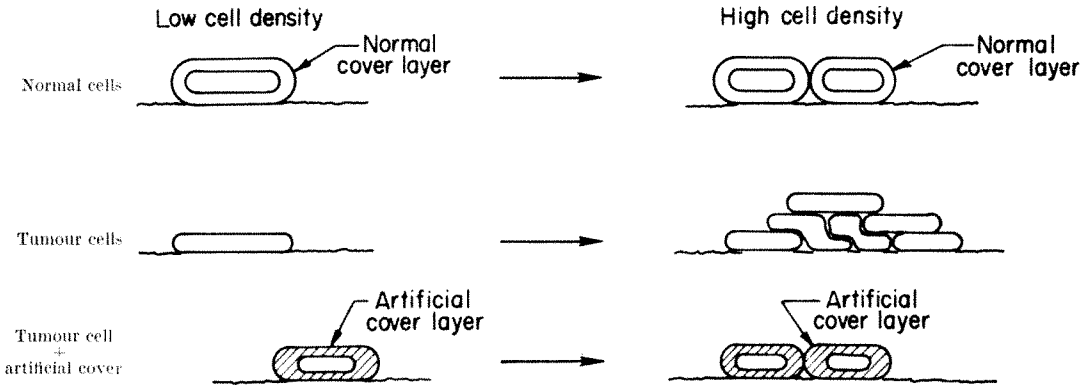

Fig. 5. Possible model for contact inhibition of growth.

Model for Contact Inhibition of Growth

Taken together with our earlier findings that exposure of the agglutinin receptor layer with trypsin can overcome contact inhibition of growth, these results demonstrate the importance of certain glycoproteins on the cell surface in the maintenance of growth control in the normal cell. The results reported here have the additional advantage of not producing the type of unspecific damage to the cell surface which trypsin must produce. Of course, we do not think that the concanavalin site is the only site that has to be covered to bring about contact inhibition of growth. Nor do we think that the wheat germ agglutinin site is the site which, if uncovered, brings about loss of contact inhibition even though we previously used it to monitor for escape from contact inhibition of growth[6]. With the evidence we now have on nine different agglutinins, most of which react with different sites exposed on tumour cells, we have suggested[6,13] and now reiterate that a whole subsurface layer is exposed in the course of transformation or brief proteolytic treatment. We propose that trypsinized Con A restores, in a functional way, a cover layer which is present in the normal cell.

Fig. 5 is an attempt to depict our conclusions in a very simplistic way; it should in no way be construed as a demonstration of a specific mechanism for contact inhibition of growth. The upper part shows a normal cell with a normal cover layer which is subject to contact inhibition of growth. On the surface of the transformed cell in the middle of the figure the agglutinin receptor sites are uncovered and growth control is lost. In the lower part the transformed surface is repaired with a substitute cover layer in the form of a monovalent agglutinin and in these circumstances the transformed cell has regained the type of growth control seen in normal cells.

Our findings allow two interpretations: loss of contact inhibition can be ascribed to the absence of the cover layer or exposure of the agglutinin receptor layer. Because the contact inhibited state can be restored by substituting the cover layer with a plant protein which is probably chemically different from the natural exterior components of mouse fibroblasts, we envisage more significance in the agglutinin receptor layer, although more work is necessary to decide between the two possibilities.

This work was supported by US Public Health Service grants, a training grant, and a grant from the American Cancer Society and the Anita G. Mestres Fund.

Note added in proof. Shoham *et al.* (*Nature*, **227**, 1244; 1970) have also come to the conclusion that native Con A kills transformed cells, a result not unexpected in view of the possible explanations offered in the text above. It should be stressed, however, that in order to avoid that killing effect and nevertheless cover the surface receptor sites we decided to split the molecule into monovalent pieces. Only this procedure allowed us to bring the transformed cells back into a state of normal growth control.

Three-dimensional Fourier Synthesis of Human Deoxyhaemoglobin at 3·5 Å Resolution

by
HILARY MUIRHEAD*
J. GREER†
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH

Electron density maps of human deoxyhaemoglobin at a resolution of 3·5 Å reveal new conformations of the C-terminal residues of the β chain and confirm their contribution to the alkaline Bohr effect. A preliminary comparison of this structure with that of horse oxyhaemoglobin shows that the main differences occur at the chain termini and at certain side chains in the $\alpha_1\beta_2$ interface.

MAMMALIAN haemoglobins undergo a reversible transition between two alternative structures. One of these is taken up when a ligand occupies the sixth coordination position at the iron atoms; the other when this position is empty. X-ray analysis of human deoxyhaemoglobin and horse deoxyhaemoglobin at 5·5 Å resolution had revealed large differences in quaternary structure between oxy and deoxyhaemoglobins[1,2]. It was hoped that the X-ray analysis at 3·5 Å resolution would identify the much smaller changes in tertiary structure which must precede the alteration in quaternary structure and also show whether the residues responsible for the alkaline Bohr effect had been correctly identified[3,4].

Much information about the mechanism of haem-haem interaction, oxygen affinity and the Bohr effect could be obtained from X-ray studies of abnormal human haemoglobins where these functions are impaired[5,6]. Some of these abnormal haemoglobins crystallize with the same space group and unit cell dimensions as normal human haemoglobin. One of us (J. G.) prepared difference Fourier maps[7] of several of these mutants at 5·5 Å resolution but found them difficult to interpret. This work was undertaken partly to determine phase angles to a resolution sufficiently high to allow the stereochemical differences between normal and mutant human haemoglobins to be clearly distinguished. One such comparison is described in a forthcoming article.

Table 1. HEAVY ATOM DERIVATIVES USED FOR ISOMORPHOUS REPLACEMENT

Derivative No.	Hg No.	Abbreviation	Substituent on S of cysteine No. 93β	112β	104α
1	1+2	PMB	$-HgC_6H_4COO^-$	—H	—H
2	1 to 6	MM	$-HgCH_3$	$-HgCH_3$	$-HgCH_3$
3	3+4	$HgAc_2$	$-CH_2-CONH_2$	$-Hg-OOC-CH_3$	—H

Experimental Procedures

Crystals of human deoxyhaemoglobin were grown in ammonium sulphate solution, buffered to *p*H 6·5 as described by Muirhead *et al.*[1]. The crystals belong to the monoclinic space group $P2_1$ with unit cell dimensions $a = 63{\cdot}2$ Å, $b = 83{\cdot}4$ Å, $c = 53{\cdot}8$ Å and $\beta = 99° 15'$. The unit cell contains two molecules so that the crystallographic asymmetric unit contains one complete molecule of molecular weight 64,000. The limiting sphere of radius 3·5 $Å^{-1}$ contains 6,900 independent reflexions. Human haemoglobin contains three pairs of sulphydryl groups which differ in reactivity[8,9]. Three heavy atom derivatives were used to determine phase angles by the multiple isomorphous replacement technique[10]: in one cysteines 93β were substituted with *p*-mercuribenzoate (PMB), in the second cysteines 93β, 112β and 104α with methyl mercury (MM), and in the third cysteines 112β with mercuric acetate ($HgAc_2$) (Table 1). The unit cell dimensions of crystals of all three derivatives were the same as those of the parent compound within experimental error.

A complete set of three-dimensional data between 6·0 and 3·5 Å resolution was measured for the native protein and for each of the three derivatives. The phases of all the reflexions to a resolution of 5·5 Å had already been determined from photographic measurements[1]. 11,600 X-ray diffraction intensities comprising 5,800 independent reflexions were measured for each data set on a Hilger and Watts four-circle diffractometer, which was fitted with helium-filled input and output collimators and connected on-line to a time-shared Ferranti Argus 312 computer, using CuKα radiation from a Philips sealed fine-focus X-ray tube run at 40 kV and 24 mA. Each reflexion was measured by an ordinate analysis procedure as described by Watson *et al.*[11]. The measured intensities were corrected for Lorentz, polarization and absorption factors[12] using a program written by T. H. Gossling.

Because of radiation damage only about 1,000 Bijvoet pairs of reflexions could be measured from a single crystal. Each data set contained measurements from five to eight different crystals and these measurements were scaled together using a least squares procedure. For a single crystal the agreement residual for the structure amplitudes of Bijvoet pairs of reflexions

$$\left(2{\cdot}0\frac{\Sigma(\|F_{hkl}-|F|_{h\bar{k}\bar{l}}|)}{\Sigma(|F|_{hkl}+|F|_{h\bar{k}\bar{l}})}\right)$$

varied between 0·03 and 0·07, the largest values being obtained for the crystals with six molecules of methyl mercury per molecule of haemoglobin, while when the different crystals in each set were scaled together the percentage standard deviation in F varied between 2·4 and 3·2. It is impossible to determine accurately the overall temperature factor of the crystals using data to a resolution of only 3·5 Å, but it seems to be less than the temperature factor for crystals of horse oxyhaemoglobin.

Approximate heavy atom coordinates were known already[1] but three-dimensional difference Patterson syntheses were calculated for all three derivatives to check their quality. The heavy atom parameters were refined using alternate cycles of phase determination and least squares refinement[1,13,14] on 1,800 selected reflexions, anomalous scattering being ignored. These reflexions were chosen from the medium-to-strong intensities so that there were equal numbers in equal ranges of $\sin^2\theta/\lambda^2$. The parameters derived from the last cycle of the refinement process are given in Table 2.

The centroid[15] phase angles of all 5,800 independent reflexions were calculated from the final heavy atom parameters. Fig. 1 shows the variations of the mean parent and calculated heavy atom structure amplitudes for the complete data sets, and of the accuracy of the phase determination as a function of resolution. The mean figure of merit, averaged over all reflexions, is 0·81 corresponding to a mean error in phase angle of 36°. For all three derivatives the root mean square lack of closure of the phase triangles, E, is significantly less than the root mean square calculated heavy atom structure amplitude, f_H, indicating that all three derivatives are providing accurate phase information at 3·5 Å resolution

The diffractometer data and the 5·5 Å resolution photographic data were scaled together using overlapping reflexions, and weighted averages of the phase angles were used in the Fourier calculations.

Electron Density Map

The "best"[15] Fourier synthesis was calculated in sections perpendicular to the a^* axis at intervals of $a/80$, $b/120$ and $c/80$ using a Fortran program written by R. A. Crowther. Sections of the Fourier perpendicular to the molecular dyad axis were calculated on a Cartesian coordinate system[1] at 1 Å intervals, using a skew planes program written by J. M. Baldwin. These sections were displayed in contour form on a computer controlled oscilloscope and recorded on 35 mm film[16]. The zero contour was at 0·15 e/Å^3 and the contour interval was 0·15 e/Å^3. The maximum density was 2·30 e/Å^3. They were enlarged by projection and copied on to 'Perspex' sheets to the scale 2 cm = 1 Å for subsequent interpretation and model building. The electron density map was sufficiently clear to construct a skeletal model of human deoxyhaemoglobin using a half silvered mirror to superimpose the model and the electron density map[17].

The absence of any ligand on the haem group in deoxyhaemoglobin as in deoxymyoglobin[18] is clearly seen by comparing the electron density on the distal side of the haem group in Fig. 2*a* with that of the β haem group in horse oxyhaemoglobin (Fig. 5 of ref. 19): a difference of one or two oxygen atoms can be detected. The only large differences in tertiary structure between oxy and deoxyhaemoglobins are those involving the termini of the polypeptide chains affecting the environment of the residues thought to be responsible for the alkaline Bohr effect[3].

Fig. 2*a* (sections −14 to −8 of the map) shows the carboxyl terminus and the surroundings of the haem group of the β-chain. Note that Tyr HC2(145)β is very clearly defined in contrast to the low density found for the phenolic group in the horse oxyhaemoglobin high resolution map[20]. The carboxyl group (labelled COO^-) and the terminal histidine side chain, His HC3(146)β, are also clearly visible; the latter bonding to the γ-carboxyl of Asp FG1(94)β in the same chain. The formation of this bond in deoxy as opposed to oxyhaemoglobin[20] was predicted and must be responsible for the contribution of the β-chains to the alkaline Bohr effect[3]. Unexpectedly, a salt bridge from the terminal carboxyl group to the ε-amino group of Lys C5(40)α stabilizes the conformation of the terminus and forms an $\alpha_1\beta_2$ (ref. 21) link which is absent in oxyhaemoglobin.

Fig. 2*b* (sections 8 to 15) shows salt bridges between the two α chains: one between the guanidinium group of the terminal Arg HC3(141)α_2 and Asp H9(126)α_1; the other bridges form part of a system of four polar groups involving Asp A4(6)α_1, Lys H10(127)α_1, the alpha amino group of Val NA1(1)α_1 and the alpha carboxyl group of Arg HC3(141)α_2. The array is such that Asp A4(6)α_1 can bond only to Lys H10(127)α_1. Lys H10(127)α_1 could bond to both Asp A4(6)α_1 and to the α-COO^- of Arg HC3(141)α_2. The α-NH_3^+ of Val NA1(1)α_1 is too far away to bond to Asp A4(6)α_1 but may be within the correct distance to form a salt bridge with the α-COO^- of Arg HC3(141)α_2. The system thus contains one salt bridge linking two polar groups within the same α-chain: Asp A4(6)–Lys H10(127); this is common to both oxy and deoxy structures. In addition there are salt bridges between the two α-chains which exist only in deoxyhaemoglobin: Asp H9(126)α_1–Arg HC3(141)α_2 and possibly NH_3^+ of Val NA1(1)α_1–COO^- Arg HC3(141)α_2. The tetramers will, of course, contain twice the number of bridges listed here, because of their dyad axis. These bridges would have to break if the tetramer were to dissociate into αβ dimers. As in the β-chain (Fig. 2*a*) the penultimate Tyr HC2(140)α is clearly defined in the deoxy structure.

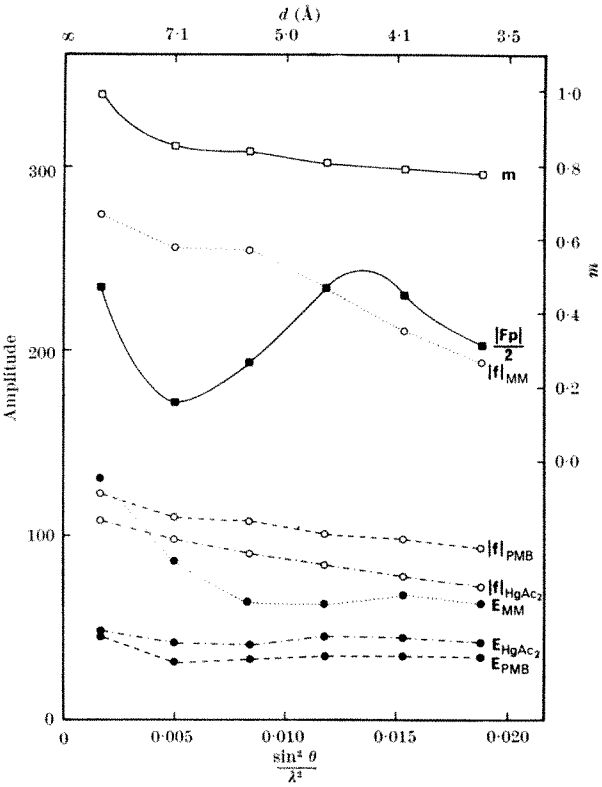
Table 2. FINAL HEAVY ATOM PARAMETERS AND *R*-FACTORS

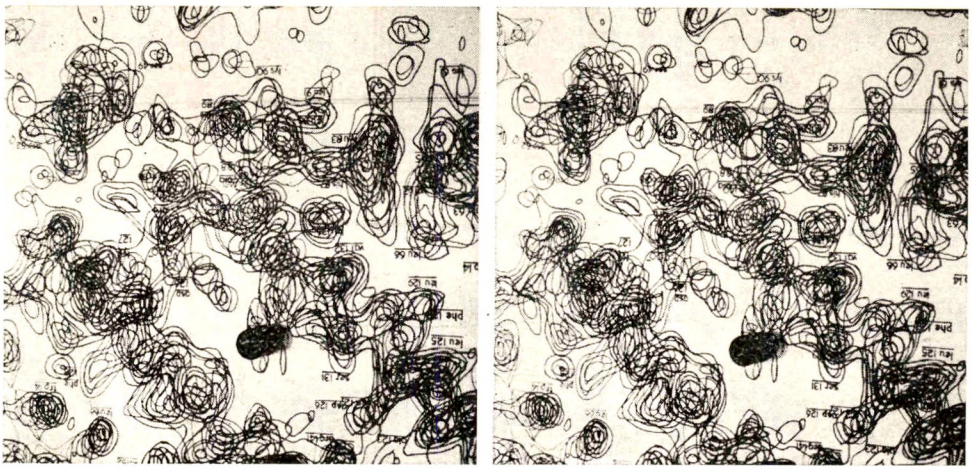
	Z	*z*	*y*	*x*	*B*	*R*
PMB						
Site 1	81	0·234	0·050	1·112	29	0·44
2	80	0·240	0·0	0·420	28	
MM						
Site 1	88	0·242	0·059	1·103	71	0·43
2	89	0·246	0·002	0·422	75	
3	66	0·023	0·181	0·744	11	
4	79	0·507	0·125	0·753	20	
5	86	0·086	0·167	0·844	25	
6	73	0·439	0·110	0·655	13	
$HgAc_2$						
Site 3	47	0·024	0·185	0·739	16	0·60
4	65	0·507	0·128	0·763	32	

Z is the occupancy; *x*, *y* and *z* fractional coordinates and *B* the isotropic temperature factor. All six sites lie in a single molecule. Sites 1 and 2, 3 and 4 and 5 and 6, respectively, are related by the non-crystallographic dyad axis.

$$R = \frac{\Sigma(\| F_H \|_{obs} - \| F_H \|_{calc} \|)}{\Sigma(\| F_H \|_{obs} - \| F_P \|_{obs} \|)}$$

The heavy atom parameters were refined using 1,800 selected reflexions. The *R* factors are based on all the measured reflexions.





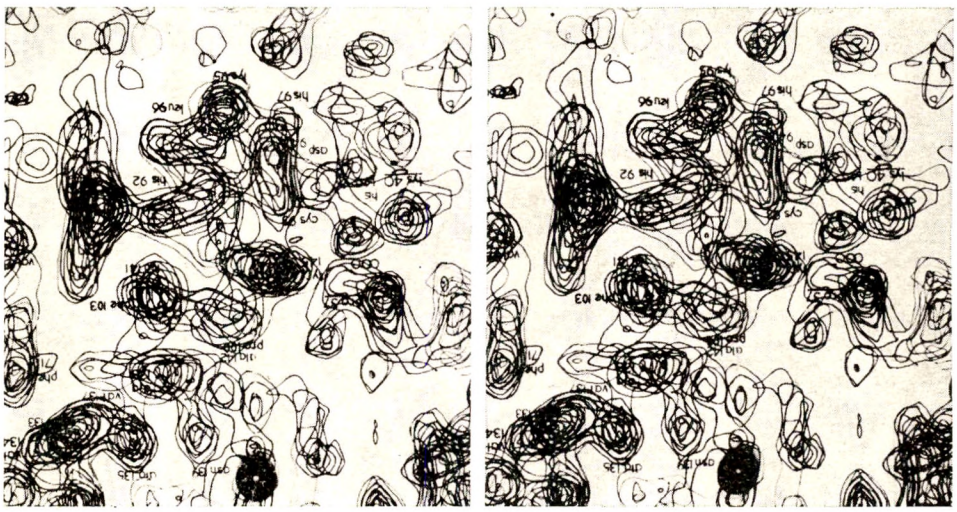


Fig. 1. Mean structure amplitudes of the native protein and of the heavy atoms, and accuracy of phase determination as a function of $\sin^2\theta/\lambda^2$. The meaning of the curves from the top downwards is as follows: *m* (ordinate at top right) is the average figure of merit of the phase angles[14]. $|F_P|$ is the average structure amplitude of the native protein. The three curves for the $|f|$ values (○) of the heavy atom derivatives refer to the average root mean squares of $|f_H|$. The *E* values (●) represent the root mean square lack of closure errors of the phase triangles for the three derivatives. – – –, PMB; · · ·, MM; — · — · —, $HgAc_2$.

The amino terminal group of each α-chain is involved in the alkaline Bohr effect[4]. The formation of a salt linkage between the amino and carboxyl termini of opposite α-chains in the deoxy form only has been predicted in order to explain this contribution to the Bohr effect[3]. It is not yet possible to confirm the existence of this salt linkage without refinement of the atomic coordinates. All other changes in tertiary structure are small and those which have been interpreted occur in the contacts between subunits.

The $\alpha_1\beta_1$ contact is almost identical in the oxy and deoxy molecules as expected from the comparison at 5·5 Å resolution[1,2]. The only significant change is linked to the stabilized conformation in deoxy of the carboxyl termini of the α-chains. In horse oxyhaemoglobin there is probably a hydrogen bond between Asp H9(126)α_1 and

a

b

Fig. 2. Stereoscopic figures of the 3·5 Å deoxyhaemoglobin electron density map. The sections are perpendicular to the molecular dyad axis and are spaced at 1 Å intervals. The centre of the black ring (top centre in both figures) marks the dyad axis. The zero contour is at 0·15 e/Å^3. The contour interval is 0·15 e/Å^3. Underlined residues form part of the α chains; plain ones part of the β chains. *a*, A superposition of sections −14 to −8 of the electron density map of human deoxyhaemoglobin. The scale is 2 mm to the Å. Part of the β haem group is seen edge on at the centre right attached to the proximal histidine (his 92). Tyr HC2(145)β (*Tyr* 145) is at the centre. Below and to the left is the salt linkage between His HC3(146)β and Asp FG1(94)β. The β-chain carboxyl terminus (COO^-) is bonded to Lys C5(40)α (*Lys* 40) as is shown at the centre left. *b*, Sections 8 to 15 of the electron density map showing one carboxyl terminus and part of the H helices of the α-chains. The scale is 1·5 mm to the Å. Part of the α haem group is seen edge on at the lower left attached to its proximal histidine (*His* 87). The two salt linkages are to the right of and below the molecular dyad; one between Lys H10(127)α_1 (*Lys* 127) and the terminal carboxyl of α_2 (COO^-), and the other between Asp H9(126)α_1 (*Asp* 126) and Arg HC3(141)α_2 (*Arg* 141). The phenolic group of Tyr HC2(140)α (*Tyr* 140) lies 12 Å below the dyad and half way between the labels *His* 87 and COO^-.

Tyr C1(35)β_1[20]. This aspartate is bonded to Arg HC3(141)α_2 in deoxyhaemoglobin; the tyrosine is lying in the $\alpha_1\beta_1$ interface and does not seem to form a hydrogen bond.

The largest relative movement between subunits occurs at the $\alpha_1\beta_2$ interface[1,2]. Remarkably, this large change in quaternary structure is accompanied by only very small changes in tertiary structure at the interface. Small adjustments in the Gα_1 helix and the Cβ_2 helix allow Pro G2(95)α_1 to remain in van der Waals contact with Trp C3(37)β_2 in spite of the relative movement of the two chains.

The flexibility of the side chain of Arg C6(40)β_2 allows it to maintain contact with Tyr C7(42)α_1 in both structures, although the detailed interaction may be different. The γ-hydroxyl of Thr C6(41)α forms a hydrogen bond to the main chain carbonyl of Thr C3(38)α in the same chain in deoxyhaemoglobin. In oxyhaemoglobin the proximity of Thr C6(41)α_1 to His FG4(97)β_2 suggested the possibility of a hydrogen bond between these residues[20]. A comparison of the electron density maps of horse oxy and human deoxyhaemoglobins indicates, however, that the threonine bonds back into its own α chain in the oxy structure as well.

As a result of these changes in tertiary and quaternary structures, there are four extra salt bridges between α_1 and α_2 in the deoxy structure. It therefore seems that the deoxyhaemoglobin tetramer would be less likely to dissociate into dimers than that of oxyhaemoglobin, as has been observed by Kellett, Midgarden and Schachman (private communication). There are also differences in the van der Waals contacts at the subunit interfaces, which are very small at the contacts $\alpha_1\beta_1$ and large at the contacts $\alpha_1\beta_2$. Without accurate atomic coordinates, however, it is impossible to predict whether the van der Waals contacts increase or decrease in stability.

The relationship between ligand bonding and the changes in tertiary and quaternary structures is still

obscure and these results do not suggest any mechanism for cooperativity. The identification of all the changes in tertiary structure as well as a complete description of the quaternary structure change will require a more detailed comparison of the oxy and deoxy structures. This may be possible on the basis of a Fourier synthesis of horse deoxyhaemoglobin at 2·8 Å resolution determined by Bolton (to be published).

Copies of the structure amplitudes and electron density maps are available on request.

We thank Dr M. F. Perutz for discussion, Miss Valerie Coulson for technical assistance and Mrs J. M. Baldwin, Dr R. A. Crowther and Mr T. H. Gossling for making computer programs available to us. For computing facilities we thank Professor F. Hoyle and the computer staff of the Institute of Theoretical Astronomy, Cambridge, and the manager and staff of the Computer Unit at the Rutherford High Energy Laboratory, Harwell. One of us (J. G.) thanks the US National Science Foundation for a fellowship.

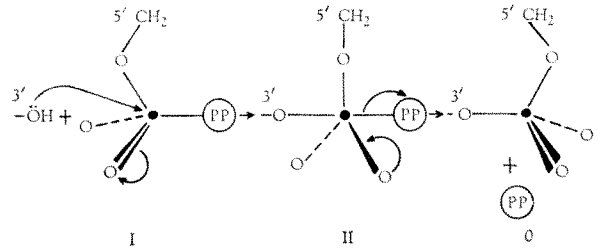
RNA Polymerase: Two-step Mechanism with Overlapping Steps

by
V. L. FLORENTIEV
V. I. IVANOV
Institute of Molecular Biology, Academy of Sciences of the USSR, Moscow



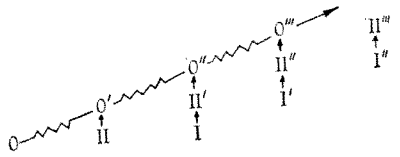
RNA transcription could take place by Watson–Crick base pairing between the growing RNA chain and the DNA template if the DNA unwinds locally after changing from its usual B form to the less stable A form.

RNA polymerase (EC 2.7.7.6) synthesizes a polyribonucleotide with the aid of a DNA template according to the following scheme.

The chain lengthening proceeds by linkage of the ribose 3′-hydroxyl to the 5′-phosphate group of an attacking nucleotide, the base sequence of the new polymer being determined by the base sequence of the DNA[1].

Findings concerning the general mechanism of hydrolysis of phosphate esters indicate that the splitting of the ester bond proceeds by way of an intermediate in which the five covalent bonds of the phosphorus atom are in a trigonal bipyramidal configuration[2]. The overall reaction of nucleotide addition may therefore be depicted by the following two-step scheme.

In this reaction, intermediate II is thermodynamically unstable, and its formation requires energy. But the next step, pyrophosphate liberation, proceeds with release of considerable free energy. It is tempting to suggest that RNA polymerase operates in such a way that these two stages are concerted, so that in the course of addition of a new nucleotide, formation on the thermodynamically unfavoured "pyramidal" triphosphate intermediate is coupled with the pyrophosphate release.



Here, we suggest a model for the molecular mechanism of RNA polymerase action based on the above hypothesis, assuming an overlap of steps in the process of sequential addition of two nucleotides (see ref. 3 for a more detailed review of the data). We will deal only with the polymerization mechanism proper (chain elongation) and not with other known functions of the enzyme, such as the recognition of an operon promoter and the breaking of the polynucleotide chain at the operon termination region.

The two types of atomic models that have been used in this study are spacefilling models ("Eugon", Hungary) and structural models of the Dreiding type. Models of the A form of DNA and of nucleotides conforming to the "Eugon" were manufactured for us by Yu. N. Symakin according to atomic coordinates from ref. 4.

Model for Operation of RNA Polymerase

By "state I" we designate the state of an adding nucleoside triphosphate on attachment to the active site of the RNA polymerase system before covalent binding to the 3′-hydroxyl of ribose. The state of a nucleotide in pyramidal configuration at the α-phosphate group will be designated "state II". A nucleotide completely incorporated into the RNA chain will be indicated by the symbol "0". Then, according to the above "overlap hypothesis",

the nucleotide pattern at the growing end of RNA would be

Conformation of the Template at the Growing Point

We shall assume that DNA transcription involves the Watson–Crick base pairing mechanism. This assumption seems to be the most reasonable one at present, although alternative schemes have been proposed in which a triple complex with non-uncoiled DNA is formed[5].

For the unwinding of DNA with the concomitant formation of a new hybrid A-like structure to be "economical", we think that the A form of template is more suitable than the B form. Indeed, the base pairs in the glycosidic groove (that which is faced by glycosidic bonds) of the A form are located near the periphery of the molecule, so that only a small displacement is required for a base to be found outside the parental helix. We can therefore also assume that the normally unstable A form of DNA helix is stabilized in a section of the template adjoining the active site of the system. The idea that RNA synthesis is connected with the B→A transition was emphasized in the studies of Hamilton[6] and Arnott *et al.*[7]. Thus RNA polymerase from *M. lysodeikticus* can operate with two-stranded polyribonucleotides which can exist only in the A conformation[8]. That one and the same enzyme may operate with such different template structures as the B form and A form is contradictory to the concept of enzyme specificity. Because it is impossible to induce the A→B transition in RNA double helices we are faced with the necessity to induce the B→A transition in DNA. Such a local B→A transition in the course of polymerase operation might be induced by exclusion of some water molecules from the DNA section bound to the polymerase protein. Removal of water provides, at the same time, appropriate conditions for the reaction of nucleotide polycondensation to occur.

Examination of three dimensional molecular models shows that there is no substantial steric hindrance to the unfolding of a base in one DNA strand from the glycosidic groove of A form DNA after disruption of hydrogen bonds linking it to the complementary base of the other strand (Fig. 1). This unfolding is caused by rotations in the sugar phosphate backbone. It can be demonstrated with atomic models that, when DNA bases are "extracted" in this way, the conformational change is restricted to one DNA strand only, while the conformation of the other strand remains practically unaltered. If the "extracted" part of the chain consists of two or three bases, a small disruption will be produced in the regular A structure (Fig. 1).

Structure of the Hybrid at the Growing Point

If our basic assumption of reaction step overlap is correct, two nucleotides are involved at a time. The adding nucleotide is in state I and the preceding nucleotide is in state II; both are base paired to the DNA. The minimum number of bases at the unfolded region of the template would be two.

A few experimental data are available which testify to the existence of "stacking" interaction between base pairs in the hybrid region[9,10]. Inspection of molecular models shows that a couple of the "extracted" bases, together with the complementary counterparts of the ascent RNA, can be fitted into a right handed helix similar to that of A form (Fig. 1). The spatial arrangement of the helices of DNA and of the hybrid portion seems to be far from random: the approximate axis of the hybrid helix is inclined to the DNA axis at an angle, the minimum magnitude of which is restricted by the necessity to provide room for the last two ribonucleotides; this angle is about 40°. It can be measured in space-filling atomic models as the angle of inclination between the average planes of the pentose rings (Fig. 1). If one postulates a requirement for the conservation of template regularity the regular hybrid must be short because of the divergence of the axes of the hybrid and the template. (If no such postulate is made, the hybridized portion may be long. Note that the term "helical axis" is not applicable in a strict sense to a hybrid of two base pairs, but the general conformation of such a hybrid is similar to that of a short piece of A structure.)

Thus at each step in the RNA polymerase operation a new base is "extracted" from the DNA template, and the deoxynucleotide, the complementary ribonucleotide of which has lost pyrophosphate, folds back into the DNA with restitution of the DNA hydrogen bonds. The helix axis of the hybrid moves in a helical way along the DNA, thereby implying a simultaneous shift of the enzyme.

To clarify our model for the molecular mechanism of the enzyme and the functions of the protein moiety of RNA polymerase, it is necessary to consider the question of binding points between the enzyme and the template and the detailed stereochemistry of the RNA chain elongation.

Binding between RNA Polymerase and Template

In the absence of the substrates, RNA polymerase is known to be bound with DNA rather weakly, so that an increase in ionic strength will lead to dissociation of the enzyme from the DNA[1]. During the synthesis of RNA, however, the bonding of the enzyme with DNA becomes sufficiently strong to form a non-dissociating complex[1]. In the model that we propose, this specific strong attachment, arising in the course of RNA synthesis, results from interaction between the negatively charged pyrophosphate groups of the two interacting ribonucleoside triphosphates (II and I) and the cationic sites of the polymerase subunits. The base moieties of these triphosphates from Watson-Crick pair with the DNA bases. Nucleotides I and II, together with nucleotide "0", form the transient hybrid region (the A form part of the hybrid

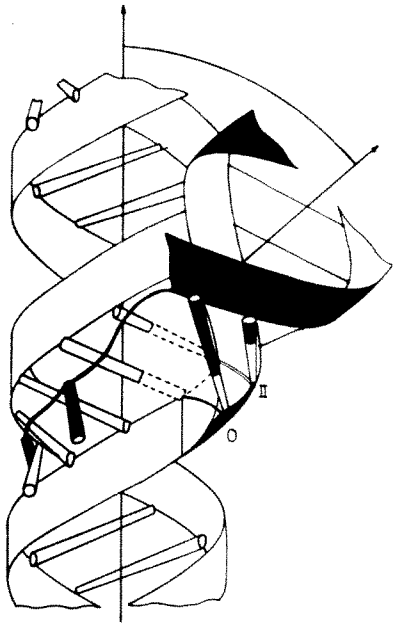


Fig. 1. Conformation of the template and structure of the hybrid at the growing point of the RNA chain. In the A form, the approximate planes of the sugar rings are represented by the ribbons. The A form hybrid really consists of two pairs but is extrapolated in order to demonstrate the interrelationship of the helices.

is formed by the 0 and II pairs). Because two ribonucleoside triphosphates function at any one time, our model explains the strong binding of the enzyme; besides its non-specific interaction with DNA (which is probably electrostatic), there are additional specific bonds during the synthesis. This proposition is attractive because, on release of pyrophosphate, firm attachment of the given binding site to DNA is abolished. It is also important to the consideration of a molecular mechanism for the polymerase movement.

Conformations of the Nucleotides and Enzyme Movement

By assuming an A type conformation for the hybrid region (0, II) the sugar-phosphate backbone can be depicted as in Fig. 2. One can see that the presence of a pyramidal phosphate does not lead to significant distortion of the A form backbone. The conformation of the pyrophosphate part in nucleotide II will be considered later. The deviation of the backbone structure from the A form will be smallest in the case of the apical bond cleaved in the pyrophosphate. Disposition on one line of the ribose-α-phosphate and α,β-phosphate bonds also follows from the stereochemistry of phosphate ester hydrolysis[2]. We have therefore defined the conformation of the sugar-monophosphate part of nucleotides 0 and II.

The non-covalently bound nucleoside triphosphate I has a very different position from that of a nucleotide in the A form. The phosphorus atom attacking the ribose 3′-hydroxyl should be no less than ~3·5 Å from the 3′-oxygen (the sum of their van der Waals radii). In the next step (I→II), the covalent bond formation, this distance will be reduced to 1·98 Å (this being the length of an apical bond in pyramidal phosphate[11]. Moreover, because the resulting (0′II′) situation is connected with the preceding (0 II) situation by helical symmetry operation (with the translation value of A form), the nucleotide I should be located above nucleotide II (with respect to the DNA axis) (Fig. 2). The restrictions stipulated by these requirements permit fairly precise localization in space of the atoms of nucleotide I (Fig. 2).

Essentially, the only conformations that remain unknown are those of the pyrophosphate groups of nucleotides I and II. With space-filling atomic models one can see that the pyrophosphate of the pyramidal intermediate (II) can be arranged in such a way that its terminal oxygen will be at a distance of a hydrogen bond from a ribose 3′-hydroxyl of this nucleotide (Fig. 3). If such a conformation is possible in nucleotide II, the attractive

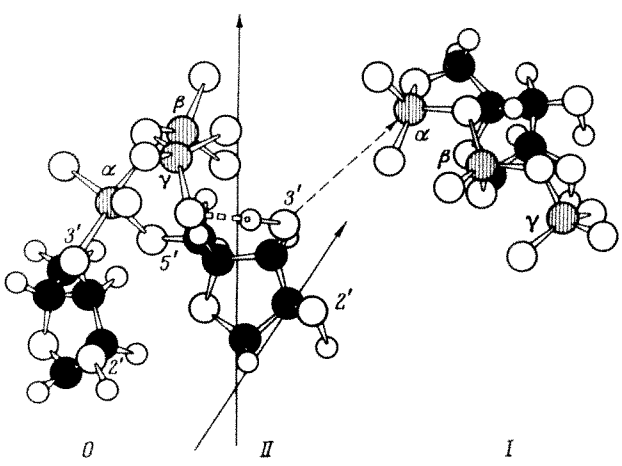

Fig. 2. Stereochemistry of the sugar-phosphate backbone at the growing end of RNA. Solid arrows show the direction of the axes of the DNA template and of the hybrid. Dotted arrow indicates the direction of nucleophilic attack. The binding points for the enzyme are the terminal pyrophosphate groups of nucleotides I and II. Note the pyramidal α-phosphate group and the hydrogen bond between the γ-phosphate and the 3′-hydroxy groups of nucleotide II.

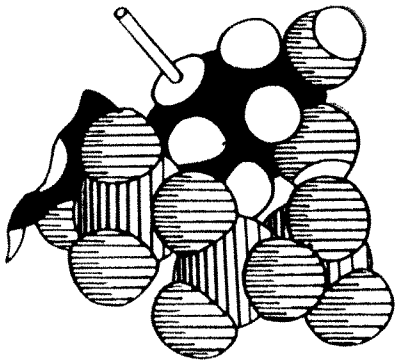

Fig. 3.

possibility arises that the pyrophosphate group acts as a catalyst for nucleophilic addition of the nucleotide I. Moreover, the basicity of the pyrophosphate would steadily increase in the course of formation of the transition state, thereby promoting proton removal from 3′-hydroxy group. This is the condition for the reaction to occur effectively. The mechanism also provides for synchronization of the steps I→II′ and II→0′, and suggests a molecular basis for the coupling of the exergonic step of pyrophosphate release with the endergonic step of pyramidal phosphate formation.

The last structural aspect to be examined is the conformation of the pyrophosphate group in nucleotide I. If we assume that the binding sites of the enzyme for successive nucleotides are on one level with respect to the DNA axis, then, because nucleotide I is situated above nucleotide II in the helical system, its pyrophosphate group must be pulled down relative to the ribose ring (Fig. 2, right). Only at the next step (I→II′) will this pyrophosphate group attain the hydrogen bonded conformation characteristic of state II. We now have all the prerequisites for a description of the movement of RNA polymerase along the DNA molecule.

At the moment when the next deoxynucleotide folds out from the DNA template, the thermal energy of the movement would probably be sufficient for a neighbouring nucleotide to assume the required position. (It is known that several terminal base pairs of a two-stranded DNA molecule are unwound at physiological temperatures[12].) If an appropriately situated binding site on the polymerase holds a complementary ribonucleoside triphosphate, the DNA base extracted will be fixed in the new position to form a hybrid pair (state I). We thus obtain an A type conformation constituted by the nucleotide pairs 0 and II, and the hybridized nucleotide I, which at that step does not form part of the A structure. To achieve a new A type conformation (II′ 0′) from the pairs (II and I), pair II must be displaced to the right and upwards (Fig. 4). When this shift reaches the extent when a ribose 3′-hydroxyl is at a distance equal to the sum of van der Waals radii from the P atom of the α-phosphate group in the ribonucleoside triphosphate I, nucleophilic addition will occur with the formation of the intermediary pyramidal phosphate. This is coupled with pyrophosphate release from the preceding nucleotide: I→II′; II→0′. In the course of pyramidal phosphate formation and of the preceding displacement of a nucleotide II, the pyrophosphate group of the latter will also be shifted; this shift, as can be seen from Figs. 2 and 4, must have a component along the DNA axis. Because the pyrophosphate group is attached to an enzyme subunit, it is shifted upwards by the translation value for the A form (2·56 Å). Inspection of atomic models shows that the sugar-phosphate backbone has the mobility required to make such a displacement possible. Precisely the required amount of displacement is achieved automatically, because the resulting conformation follows from the previous one by a helical

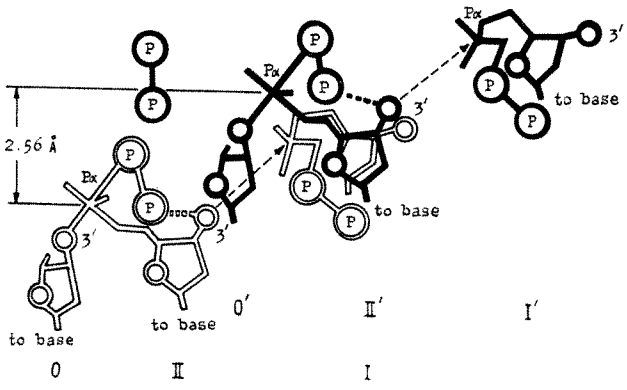

Fig. 4. Repetitive steps during the RNA synthesis. "White" (0, II, I) and "black" (0′, II′, I′) are the situations at the successive stages of the RNA polymerase operation. I⟶II′, II⟶0′ are the simultaneous reaction stages. The ribose 2′-hydroxyls are omitted.

symmetry operation. Displacement of the polymerase subunit entrains the adjacent one and thereby the whole enzyme macromolecule. Because the pyrophosphate conformation at the right hand binding site (Fig. 2, state I) is stretched downwards, the displacement of the enzyme will lift the pyrophosphate group to the position where the γ-phosphate group will be "locked" by the hydrogen bond to a ribose 3′-OH group (I→II′) (Fig. 4). It is important that the pair I itself remains motionless in the course of the transition I→II′. While a nucleotide II moves and is converted to state 0′, its pyrophosphate group is being released; its strong binding to the respective enzyme subunit is abolished, and the DNA base is folded back into the template with liberation of a new RNA link from the hybrid.

So far, the Mg^{2+} (or Mn^{2+}) ions, which are essential components of the system, have not been involved in the model. In reactions involving phosphates these ions are regarded as quenchers of the negative charges at the oxygen atoms in ionized phosphate groups. This neutralization is necessary for the reactions to occur[13]. In our model, the negative charges of the terminal pyrophosphate group of a nucleoside triphosphate are neutralized by attachment to protein. But the α-phosphate group is not bound to the protein, and the divalent metal ions might be involved in its neutralization.

Quaternary Structure of RNA Polymerase

RNA polymerase is known to have a complex structure, being composed of different types of polypeptides (σ, α, β) which perform different functions[14]. We consider only those subunits which are involved in propagation of synthesis (β ?). One of the features of our model is the simultaneous operation of two protomers (or binding sites) connected with the nucleotides in states I and II. It was not possible to devise a simple mechanism for RNA synthesis using only the two "acting" protomers. This difficulty is abolished, however, if the "acting" part of the polymerase consists of several identical protomers (binding sites) in a circular arrangement around the DNA. Then these protomers may replace each other sequentially at each state of the enzyme operation. Clearly the number of binding sites involved will determine the degree of rotation of the polymerase ring around the DNA.

Conclusion

In an earlier report[15] concerning a molecular model for the action of a transaminase, we concluded that the main distinction between enzymatic reactions and reactions in the corresponding model systems lies in the enzyme's capacity to provide appropriate conditions for each stage of a multistep process. These conditions, which are usually alternating ones, are provided by structural rearrangements at a preceding stage of the catalytic process. The model considered here shows that repetitive sequential reactions of one and the same type can be achieved very effectively by coupling the exergonic and endergonic steps between two successive reaction cycles. One may speculate that some "non-template" enzymes composed of identical protomers may also have "overlap mechanisms".

We thank Professor A. E. Braunstein, Drs M. Ya. Karpeisky and R. Sh. Beabealashvily for valuable suggestions.

A Suggested Mechanism for DNA Transcription

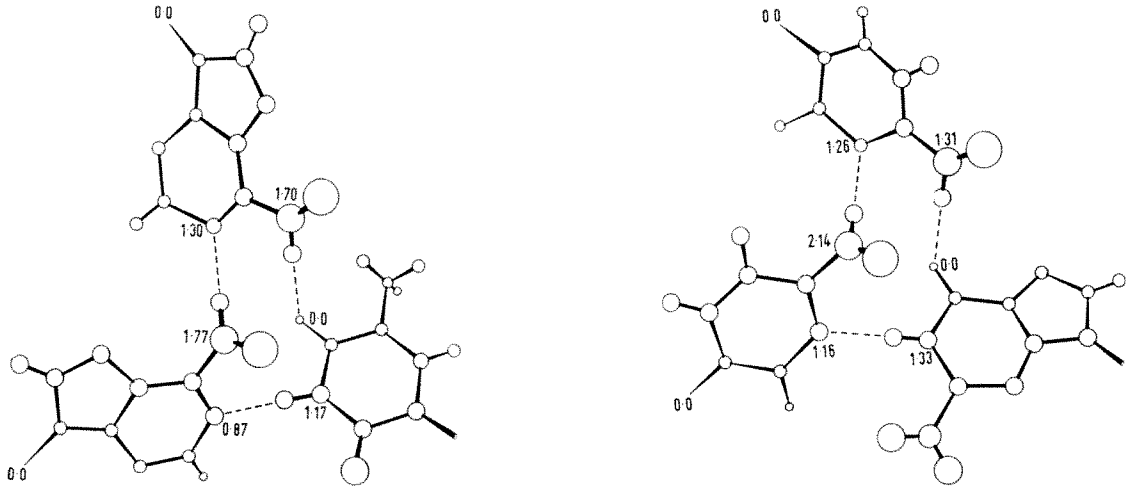
by

P. A. RILEY

Department of Biochemical Pathology, University College Hospital Medical School, London WC1E 6JJ

RNA transcription could take place without unwinding the DNA double helix if the RNA chain grows in the wide groove of the DNA by a specific stereochemical interaction between the ribonucleotides and the base pairs of the DNA.

THERE is good evidence that DNA replication is semi-conservative and involves separation of the two strands which then act as templates for the synthesis of new complementary strands[1–4]. Alternatively DNA could act as a template by remaining in its native double stranded state with the paired bases acting as the template for an RNA base inserted in the major groove. This would result in asymmetric transcription from a double stranded DNA template—a condition which is known to exist[5–8]. The possible involvement of a triple stranded intermediate in transcription has been suggested in a general way by Watson[9] and in detail by Stent[9] and Zubay[10,11]. Stent's model[9] involves the growth of a third polynucleotide chain within the major groove of the DNA double helix, leading to a three chain helical structure, but the base triplets involved are unsatisfactory because the hydrogen bonds are strained, an improbable tautomeric shift in the position of the hydrogen from N1 to the oxygen on C6 of guanine is



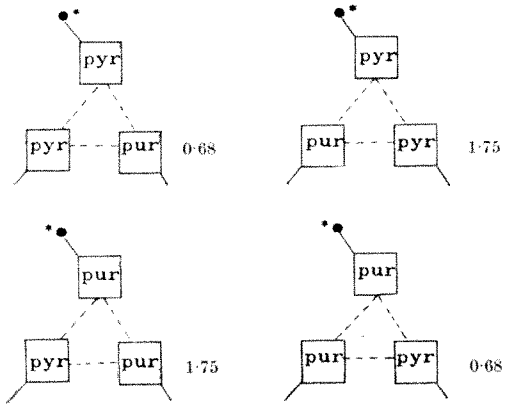


Fig. 1. Schematic view of base triplets for purine and pyrimidine copying with the inserted N_{base}–C_{sugar} bond facing left into the major groove. The triplets shown are (*a*) adenine–thymine–adenine, and (*b*) cytosine–guanine–cytosine. The displacements out of the plane of the paper marked in Å are those measured on the model and not necessarily optimal. The amino groups are rotated by about 40° to the plane of the ring. Hydrogen bonds are shown by dotted lines.

involved, and there is evidence which implicates base complementarity involving hydrogen bonding groups of the Watson–Crick type[12–15]. Base triplets of this kind have been suggested by Zubay but the model lacks template specificity[10,11].

The Watson–Crick model of DNA[16] provides a molecular basis for genetic continuity by virtue of a complementary template, the specificity of which is implicit in two fundamental parameters. The first of these is strain-free hydrogen bonding between the purine and pyrimidine bases, and the second is a limitation of the overall size of the base pairs. Here we suggest a model of transcription based on nucleotide triplets with Watson–Crick hydrogen bond donor and acceptor groups and optimum hydrogen bonding between the bases.

If a third base is to be inserted into the major groove of DNA, the hydrogen bond donor and acceptor groups which will be involved in forming the base triplet will be those attached to C4 of pyrimidine and C6 of purine. The position of these groups differs according to the disposition of the purine and pyrimidine combining in the molecule. As a result of this there is a size limitation on the inserted base. In planar terms this is shown by the distances between the average position and the actual position of the C′1 of the inserted nucleotide when hydrogen bond lengths of 3 Å are assumed (Table 1). If the base triplets are limited to those which deviate by less than 1 Å from the average position there are two possible dispositions of the bases—those shown in Fig. 1 and their mirror image But a planar arrangement of the bases is unsatisfactory because there is a large deviation from linearity by the hydrogen bonds.

Table 1. DEVIATION FROM AVERAGE POSITION IN VARIOUS TRIPLETS (Å)

The average position is indicated by the asterisk.

Table 2. TEMPLATE SPECIFICITY OF BASE TRIPLETS

DNA base pairs	RNA base: N_{base}–C_{sugar} bond facing left	RNA base: N_{base}–C_{sugar} bond facing right
A–T	A	U
G–C	G	C
T–A	U	A
C–G	C	G

The arrows show the direction of sugar-phosphate strand (C′3⟶C′5).

To satisfy the conditions for strong hydrogen bonding the base pairs of the DNA have to be rotated about the symmetrical hydrogen bond between the N3 of the pyrimidine and N1 of the corresponding purine on an axis perpendicular to the helix axis to an angle of approximately 40° to each other. This allows a third base to be inserted from the major groove side and to form strong hydrogen bonds through the carboxyl and amino groups on the DNA base pair. If the hydrogen bond donor and acceptor group limitations are applied to these base triplet configurations the template specificity is such that the inserted base is a copy of the base in the strand of the DNA in which the sugar phosphate chain runs in the same direction as that in the strand which is being synthesized (Table 2). This is ensured by the bonding angles which are such that the tilt of the inserted base is the same as the tilt of the base in the strand being copied and which requires the sugar to be in the C′3-endo conformation. This is the observed conformation of the sugar ring in all forms of RNA studied[17].

The distortion of the DNA which is envisaged involves alteration in the conformation of the sugar–phosphate backbone including a change from the C′2-endo position of the native B-DNA in which the bases are coplanar, to the C′3-endo position. This type of conformational distortion can be reversibly obtained *in vitro* by alterations of the relative humidity[18–21]. This alteration in the conformation of the sugar results in a tilting of the nucleotide base. Because the sugar-phosphate backbones run antiparallel, the effect could be in the opposite direction for the paired base (Fig. 2). This would cause rotation of the bases. Some increase in the distance between base pairs would

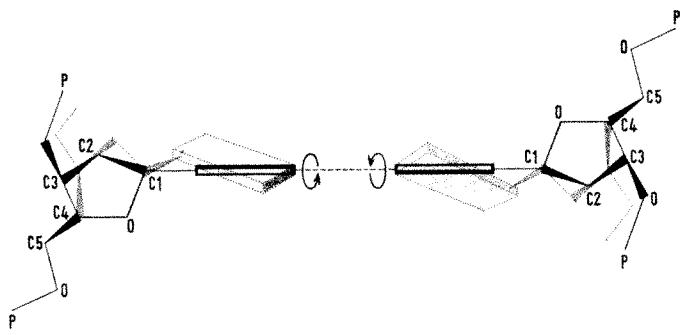

Fig. 2. Diagram illustrating the relative rotation of the DNA bases resulting from the distortion of the two sugar-phosphate strands.

accompany such a distortion, together with alterations in the bond rotations in the phosphate moiety of the backbone. This type of conformational distortion could be produced by RNA polymerase. A consideration of the atomic displacements involved shows that the effect would be localized and the base triplet transient, probably existing at one point only at any time. The RNA chain would be displaced from the major groove by the recovery of the DNA from the distortion as the enzyme proceeds.

Examination of models shows that an abrupt transition from coplanar to rotated base conformation is not possible and therefore a wavelike perturbation of DNA is likely to occur whereby progressive increments of base tilting occur from the front of the wave to the fully distorted maximum and then diminishing in its wake (Fig. 3). This conception of polymerase activity may offer an explanation for the inhibitory effects of certain dyes and drugs which by interaction with DNA prevent the transcription of RNA. For example, because the principal feature of the proposed model is the rotation of the DNA bases to an angle of about 40° relative to each other during transcription, it follows that agents which restrict or interfere with this rotation will be inhibitory. Thus the mechanism of action of intercalating agents, such as acridines[22], is readily explained: their interposition between the DNA bases precludes rotation and prevents the transcription of a segment of the genome. That the inhibitory effect of actinomycin D is a result of its binding to DNA was proposed by Hamilton *et al.*[23]. In our model, it would impede the rotation of the guanine residue relative to the sugar-phosphate backbone. Moreover, it is a feature of this proposed transcriptional mechanism that gene expression can be restricted by attaching material through covalent bonds to the backbone of each of the DNA strands. By preventing the distortion of the deoxyribose sugar a segment of DNA may be prevented from being transcribed without affecting the ability of the strands of the molecule to act as templates for replication. There is evidence that in physiological conditions RNA synthesis begins at certain specific initiation sites on the DNA[24,25] and therefore by preventing initiation at these sites certain portions of the genome could be made inaccessible to transcription.

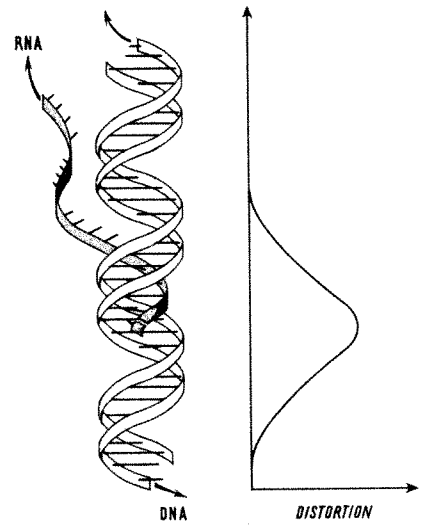

Fig. 3. Synthesis of a strand of RNA on a DNA template as a transient triplet helical structure. In the diagram the distortion of the DNA double helix represents a 5 per cent rotation per base pair.

The process of initiation requires the attachment of sigma factor[26]. This does not seem to be an essential component of the polymerizing enzyme, but it is instrumental in priming the DNA at the initiating site[27]. In our model, the sigma factor could produce the necessary initial distortion in the DNA for it to act as a template for RNA synthesis, and it may be that a section of the initiation site is therefore not transcribed. The initial distortion would be an energy requiring reaction consistent with the kinetic data of Walter *et al.*[28]. The requirements for base rotation are less rigorous for a purine template than for a pyrimidine template and it would be anticipated that purines would predominate at the 5′ terminus of the transcribed RNA. This has been shown to be the case both *in vivo* and *in vitro*[29–31]. It follows that the initiation of RNA transcription would be favoured by a purine rich region in one strand. This would also determine which strand is copied and thus the direction in which RNA synthesis takes place. This is in agreement with the finding of deoxycytosine clusters asymmetrically distributed between the two strands of DNA isolated from a variety of organisms and which have been proposed as the initiation sites[32].

It is difficult, using the triplet model of transcription, to provide a satisfactory mechanism for RNA synthesis on a single stranded DNA template[33]. Because no distortion of the DNA is involved, it is possible that the descending strand could fit into the enzyme site normally occupied by the distorted ascending strand and thus act as a template for the synthesis (in the opposite direction) of RNA with the complementary base sequence. It follows that there would be loss of selectivity in initiation for there is no limitation of attachment sites for the polymerase.

A feature of the transcriptional mechanism proposed in this report is the sensitivity of the polymerase to small regions of denaturation of the DNA duplex, for if RNA synthesis is to proceed, it is an indispensable requirement that the DNA is in the base-paired state. It would therefore be expected that RNA synthesis can be reversibly inhibited by lowering the ionic strength, whereas the reverse might be predicted for the alternative local melting model. The results of Fuchs *et al.*[34] agree with the prediction of the triplet model although they interpret their findings in terms of an effect on "strand exchange" in a model of transcription by local unwinding. Unfortunately, other relevant evidence, such as the resistance of the nascent RNA to ribonuclease digestion[35,36], can as easily be explained in terms of either model. Possibly X-ray diffraction studies of the enzyme–DNA complex are the only satisfactory means of distinguishing between them.

I thank Dr W. Fuller for advice and model building facilities, Dr T. F. Slater for discussion, Mr B. M. Lewin for comment and the Beit Memorial Trustees and the Wellcome Trustees for research fellowships.

Subunit Structure of Qβ Replicase

by
M. KONDO
R. GALLERANI
C. WEISSMANN

Institut für Molekularbiologie
der Universität Zürich

Qβ replicase comprises four different polypeptides, only one of which is coded for by the phage genome.

THERE is currently considerable interest in the structure of the RNA of phage Qβ and its relationship to the virus-specified proteins[1–3]. The Qβ phage particle comprises two minor proteins (A_1 and A_2 (ref. 4; unpublished results of Farron and C. W.)), besides the coat protein. Labelling experiments on actinomycin-inhibited *Escherichia coli* infected with Qβ revealed a fourth phage specified protein, tentatively identified as a Qβ replicase subunit[4]. We have examined highly purified Qβ replicase preparations and have found them to contain four polypeptides of different electrophoretic mobility, only one of which, with a molecular weight of about 69,000, is Qβ specific. The functional and structural relationship of the three host-specific polypeptides to the Qβ replicase molecule is unclear. Because the molecular weight of Qβ replicase is 130,000 or greater, the enzyme must consist of more than one subunit. We estimate that the four polypeptides thought to be specified by the Qβ genome, A_1, A_2, coat and replicase β subunits, comprise about 1,500 amino-acids; on the other hand, the number of nucleotides available for coding in Qβ RNA corresponds to not more than 1,150 codons[2].

Qβ replicase was purified by a slightly modified version of the method of Eoyang and August[5] (see Table 1) to a specific activity of 7,000 units/mg, the highest value reported so far. It was dependent on host-specific factor for activity with Qβ RNA as template[6]. The sedimentation coefficient of the enzyme was determined by preparative zonal sedimentation through a sucrose gradient using human haemoglobin ($s_{20,w} = 4{\cdot}31$)[7], rabbit muscle aldolase ($s_{20,w} = 7{\cdot}35$)[8,9] and beef liver catalase as reference proteins ($s_{20,w} = 11{\cdot}1$)[10]. The $s_{20,w}$ value of Qβ replicase was interpolated to be 6·7 from the calibration curve shown in Fig. 1. Assuming the relationship between sedimentation coefficient and molecular weight to be the same for replicase as for an average globular protein, an approximate molecular weight of 130,000 can be estimated. There was no significant effect on the relative sedimentation rate by varying the ammonium sulphate concentration between 0·02 and 0·8 M although, at low ionic strength (0·01 M Tris, 0·005 M Mg^{2+}), aggregation occurs[11].

Highly purified Qβ replicase was dissociated with sodium dodecyl sulphate (SDS) and mercaptoethanol and analysed by polyacrylamide gel electrophoresis in the presence of 0·1 per cent SDS. Four bands labelled α, β, γ and δ were found in amounts that varied from one preparation to another. The β band was usually the strongest component (Figs. 2 and 3). Similar results were obtained at higher concentrations of SDS and in the presence of 0·5 M urea. To determine which of the polypeptides was specified by the virus we did the following experiment. Two batches of *E. coli* labelled with ^{35}S

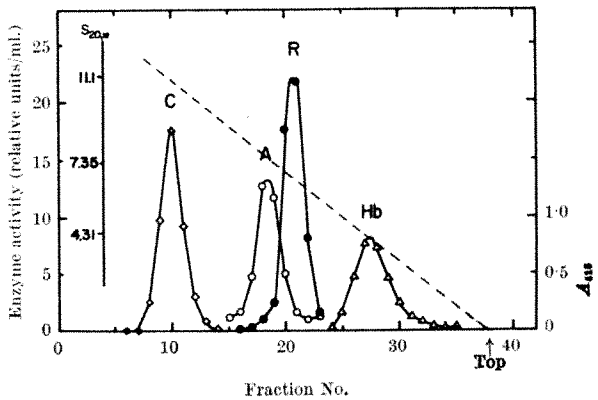

Fig. 1. Determination of the sedimentation coefficient of Qβ replicase. Qβ replicase (specific activity, 4,800 units/mg, about 150 units), rabbit muscle aldolase (about 200 μg, Boehringer) and beef liver catalase (about 300 μg, Boehringer) were mixed and dialysed against a buffer containing 50 mM Tris (*p*H 7·8), 5 mM $MgCl_2$, 1 mM EDTA, 5 mM β-mercaptoethanol and 0·1 M ammonium sulphate for 2 h. Human haemoglobin (about 200 μg) was added to the mixture which was centrifuged through a 5–23 per cent sucrose gradient in the same buffer as that used for dialysis, at 40,000 r.p.m. and 4° C for 24 h in the Spinco 'SW 41' rotor. Qβ replicase (R, ●) activity was assayed as usual[5]; the value 10 on the ordinate equals 5 replicase units. Catalase (C, ◇) was assayed according to the method of Beers and Sizer[15]; the value 10 on the ordinate corresponds to 50 catalase units. Aldolase (A, ○) was assayed according to Jagannathan *et al.*[19]; the value 10 on the ordinate corresponds to 5 aldolase units. Haemoglobin (Hb, △) was measured spectrophotometrically at 415 nm.

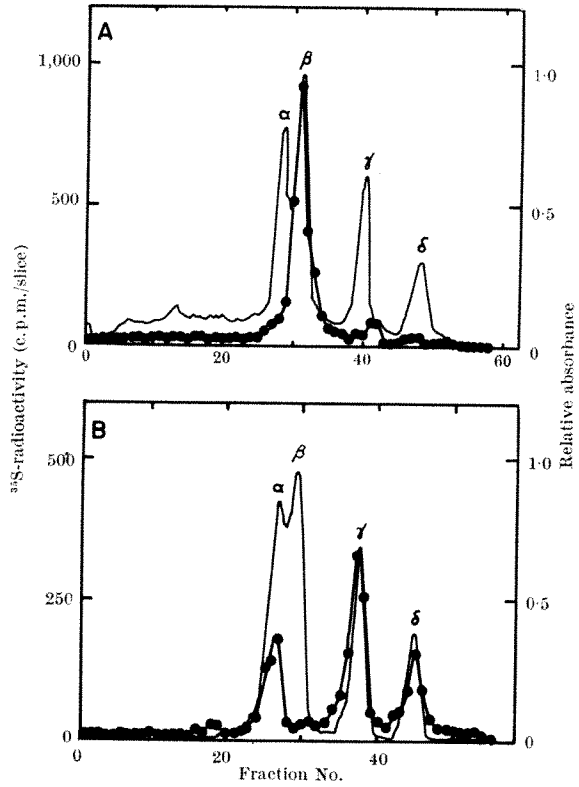

Fig. 2. Analysis of ^{35}S-labelled polypeptides of Qβ replicase preparations by gel electrophoresis. ^{35}S-labelled Qβ replicase (step 5, about 500 units) was incubated for 2 h at 37° C in a buffer containing 50 mM Tris (pH 7·8), 5 mM $MgCl_2$, 1 mM EDTA, 2·0 per cent β-mercaptoethanol, 0·22 per cent SDS and 3·3 per cent sucrose. The samples (about 75 μl.) were mixed with 5 μl. of bromphenol blue (0·25 per cent) in 30 per cent sucrose, layered on 10 per cent polyacrylamide gels[13,17] (7 × 100 mm) and run at 8 mA per tube for 6 h. The gels were stained with 0·25 per cent Coomassie brilliant blue in 50 per cent methanol–7 per cent acetic acid overnight, destained with the same solvent and scanned with the Joyce–Loebl 'Chromoscan' at 620 nm. After soaking in 0·1 per cent SDS for several hours, the gels were frozen and cut into 1 mm slices. The slices were digested with H_2O_2 and alcoholic hyamine hydroxide and counted in Bray's solution[20]. The general methods and buffers have been described[13,17]. *A*, Qβ replicase purified from a mixture of ^{35}S-labelled Qβ-infected cells (1 g) and unlabelled Qβ-infected cells (100 g); 6·6 μg (9,600 c.p.m. of ^{35}S) of the step 5 preparation was applied to the gel. *B*, Qβ replicase purified from a mixture of ^{35}S-labelled uninfected cells (1 g) and unlabelled Qβ infected cells (100 g); 88 μg (4,800 c.p.m. of ^{35}S of the step 5 preparation was used.

were prepared, one uninfected and labelled with ^{35}S throughout log phase growth, the other labelled with ^{35}S after infection with Qβ. About 1 g of each preparation was mixed with 100 g of Qβ-infected *E. coli* and Qβ replicase was purified as usual. Table 1 shows that after the final purification step (zonal centrifugation) the ratio of ^{35}S to enzymatic activity was ten times lower when the radioactive proteins were from non-infected rather than from infected cells. After dissociation with SDS and mercaptoethanol both preparations were subjected to polyacrylamide gel electrophoresis. The gels were stained and scanned to locate the four bands; the gels were then sectioned and the radioactivities were determined. The distribution of (unlabelled) protein among the four bands was similar in both preparations (Fig. 2), but in the sample containing ^{35}S-labelled protein from infected cells virtually all radioactivity was in band β, whereas in the sample containing ^{35}S-labelled proteins from uninfected cells bands α, γ and δ but not β were labelled. Thus β corresponds to the virus-specified polypeptide. The same conclusion has been reached independently by R. Kamen (personal communication and following article[12]).

The molecular weight of the virus-specified replicase subunit was determined in an SDS-containing polyacrylamide gel system[13,14], by comparing its mobility with that of aldolase, catalase, bovine serum albumin and phosphorylase a (all dissociated in mercaptoethanol and sodium dodecyl sulphate) side by side in split gels or gel slabs as well as by co-electrophoresis. Fig. 3 shows that the mobility of the β band is slightly less than that of bovine serum albumin (68,000)[15]. The mobility of the reference proteins was plotted against log molecular weight[13,14] and the molecular weight of the β band was interpolated to be 69,000. The values for the α, γ and δ

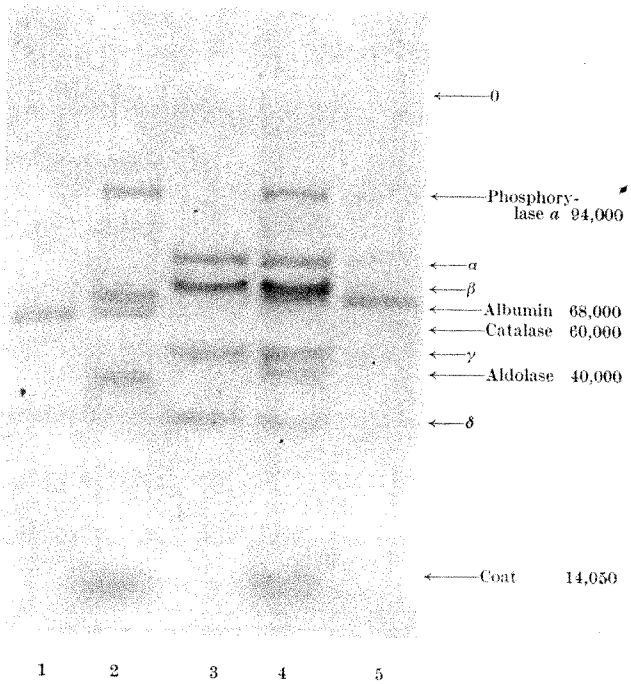

Fig. 3. Polyacrylamide gel electrophoresis of Qβ replicase and reference proteins. The conditions for electrophoresis are described in the legend to Table 2. 1, Catalase; 2, phosphorylase a, bovine serum albumin, catalase, aldolase, Qβ coat protein; 3, Qβ replicase; 4, Qβ replicase, phosphorylase a, bovine serum albumin, aldolase, Qβ coat protein. 15 μg of Qβ replicase, 8 μg Qβ coat protein and 4 μg each of the other reference proteins were run in one lane.

Table 1. PURIFICATION OF Qβ REPLICASE FROM ^{35}S-LABELLED *E. coli*

Step	Replicase activity (units) A	Replicase activity (units) B	^{35}S Radioactivity (c.p.m.) A	^{35}S Radioactivity (c.p.m.) B	Specific activity (units/mg) A	Specific activity (units/mg) B	^{35}S Radioactivity/replicase activity (c.p.m./units) A	^{35}S Radioactivity/replicase activity (c.p.m./units) B

* Normalized to an initial value of 1,000 c.p.m./unit.

(*A*) Starting material was a mixture of 100 g of unlabelled, Qβ-infected *E. coli* Q13 and 1 g of Qβ-infected *E. coli* Q13 labelled with ^{35}S (7×10^8 c.p.m.) after infection. For the labelled preparation, cells were grown in 1 l. of medium containing 0·5 g NaCl, 3·0 g KCl, 1·1 g NH_4Cl, 0·2 g $MgCl_2 \cdot 6H_2O$, 12·1 g Tris, 0·023 g KH_2PO_4, 0·294 g $CaCl_2 \cdot 2H_2O$, 50 μg $FeSO_4 \cdot 7H_2O$, 0·01 g sodium citrate, 1·6 g casamino-acids, 10 g glycerin, 10 mg thiamine, 160 μmoles $(NH_4)_2SO_4$. When the cell number reached $1·6 \times 10^8$ cells/ml., the bacteria were harvested, suspended in 1 l. of the above medium lacking sulphate and glycerin. After 20 min at 37° C 10 g of glycerin and 20 mCi of ^{35}S-SO_4^{-2} were added to give a final SO_4^{2-} concentration of 5 μM. After 10 min, Qβ was added at a multiplicity of infection of 10. The infected cells were harvested after 40 min at 37° C. (*B*) Starting material was a mixture of 100 g Qβ-infected *E. coli* Q13 and 1 g of uninfected *E. coli* Q13 labelled with ^{35}S (10^9 c.p.m.). The cells were grown in the medium described above except that ^{35}S-SO_4^{2-} (80 μM, 0·25 mCi/μmole) was present throughout growth; the cells were harvested in log phase (3×10^8 cells/ml.). Qβ replicase was purified as described by Eoyang and August[5], except that (*a*) elution from the DEAE-cellulose column was with an NaCl gradient (0·1 to 0·3 M), (*b*) chromatography on 0·5 M 'Biogel' was substituted for that on 'Sephadex G-200', and (*c*) zonal centrifugation was carried out as described by Feix *et al.*[11].

Table 2. MOLECULAR WEIGHTS OF POLYPEPTIDE FROM Qβ REPLICASE PREPARATIONS AND Qβ PARTICLES

(1) Polypeptides from Qβ replicase preparations	Mol. wt.	(2) Polypeptides from Qβ particles	Mol. wt.
α	74,000	A_1	38,000
β	69,000	A_2	44,000
γ	47,000	Qβ coat	14,050*
δ	33,000		

* From the amino-acid composition given by Konigsberg *et al.*[16]. Molecular weights were estimated by the general procedure of Shapiro *et al.*[13] and Weber and Osborn[14]. All proteins were incubated for 2 h at 37° C with 0·1 per cent mercaptoethanol and 0·1 per cent SDS before electrophoresis. Samples were either run side by side with a mixture of reference proteins in split gels (0·7×12 cm tubes filled with 3 ml. of gel for 6 h at 10 mA/gel) or in adjacent slots in gel slabs (6×13 cm, 4 mm thickness, 12 h at 30–35 mA), or co-electrophoresis from the same slot of a gel slab flanked by unmixed samples (see Fig. 3). Buffers and gels were prepared according to Viñuela *et al.*[17]. All gels contained 10 per cent acrylamide and 0·27 per cent *bis*-acrylamide; gel slabs contained 0·5 M urea in addition. The same relative mobilities were found whether or not urea was present. The molecular weights were obtained from a plot of log (molecular weight of the reference proteins) against distance travelled.

The values in column 1 were obtained from eleven independent experiments; those in column 2 from two. The standard error of the mean was less than 5 per cent. The reference proteins[14] were phosphorylase *a* (94,000), bovine serum albumin (68,000)[18], beef liver catalase (60,000), rabbit muscle aldolase (40,000) and Qβ coat protein (14,050)[16].

bands are given in Table 2. None of the components occurring in Qβ replicase preparations has the same mobility as any of the subunits of DNA-dependent RNA polymerase. It is not immediately evident which, if any, of the subunits besides β constitute the native enzyme. Two observations are of interest in this connexion. First, a Qβ replicase preparation derived from a mixture of labelled uninfected and unlabelled infected cells contains radioactivity in the α, γ and δ bands. This means that the labelled polypeptides either exchange with the putative subunits of replicase, or that they are present in the preparation as independent protein molecules. Because Qβ replicase prepared from a mixture of a small amount of *E. coli* labelled with ^{35}S after infection and a large excess of infected unlabelled cells contains more than ten times more radioactivity in the β than in all the other bands, it seems that synthesis of α, γ and δ is strongly depressed after infection. Second, if a Qβ replicase preparation is incubated with Qβ RNA and the resulting 30S binding complex[11] is isolated, only the α and β polypeptides are recovered. This may mean either that α and β are associated as subunits of one protein, or that they constitute two different proteins both of which have the capacity to bind to Qβ RNA. If all four polypeptides are part of a structural unit, it is necessary to account for the fact that their added molecular weights (223,000) greatly exceed the value of 130,000 estimated from the sedimentation properties of the enzyme. Such an apparent discrepancy could arise if the enzyme were highly asymmetric or if it were in an association–dissociation equilibrium with its subunits. The latter possibility would also account for the finding that the four polypeptides occur in non-stoichiometric and variable amounts within the sharply sedimenting enzyme band.

Assuming an average molecular weight of 110 for an amino-acid, the added molecular weights of the polypeptides thought to be specified by the Qβ genome correspond to 1,500 amino-acids (Table 2). Qβ RNA comprises 3,500 nucleotides of which not more than about 3,400 are used for coding[2,3]; it can therefore specify only 1,150 amino-acids. Beyond assuming errors in the molecular weight determinations of the RNA or the polypeptides the discrepancy could be explained in several ways. First, only one of the A proteins is virus-specified while the other is derived from the host. Neither the data of Garwes *et al.*[4] nor labelling experiments done in our laboratory encourage this view, but it cannot be ruled out. Second, the virus preparations consist of a mixture of two kinds of particles, containing different A proteins. Third, the smaller of the A proteins is derived from the larger by proteolytic cleavage. Comparison of the fingerprints of A_1 and A_2 may provide the answer.

We thank Dr R. Kamen and Dr H. Schachman for valuable discussions and Mr Eduard Peier and Mr Werner Römer for their technical assistance. This project is supported by grants from the Schweizerische Nationalfonds and the Jane Coffin Childs Fund.

Characterization of the Subunits of Qβ Replicase

by
ROBERT KAMEN*
The Biological Laboratories,
Harvard University,
Cambridge, Massachusetts 02138

The RNA replicating enzyme induced by RNA phage Qβ consists of a single phage specific and three host specific polypeptide chains. At least one of the host subunits is shown to be essential for enzymatic activity, and none are known subunits of *E. coli* DNA-dependent RNA polymerase.

In RNA bacteriophages a common RNA molecule is both the replicating genetic material and the messenger for protein synthesis. Because no RNA-dependent RNA polymerase is known to exist in bacteria, the RNA phage must induce a new enzyme for replication and, indeed, such a RNA polymerizing activity appears in cells shortly after infection[1–3]. The induction of the enzyme requires the protein produced by only one of the cistrons of the RNA phage[4–8].

Purified[9–13] RNA dependent RNA polymerase induced by phage Qβ (replicase) directs the replication of Qβ RNA *in vitro*. New infectious RNA molecules[14] are produced by copying of minus strands synthesized on the original phage RNA plus strand[15]. The phage enzyme is able to replicate its homologous RNA in a host cell full of

* Present address: Institut für Molekulärbiologie, Universität Zürich.

potentially competitive RNA species because of its extreme template specificity: the only natural RNA molecules it will use as templates are Qβ plus strands[16], Qβ minus strands[11,17,18] or a 6S RNA found in Qβ infected cells[19]. Because all RNA molecules initiated by Qβ replicase start with 5′-pppGpG . . .[17,18,20], it is not surprising that the enzyme will also synthesize RNA complementary to synthetic ribopolymers containing cytidylate[12,21] as in the polymerization of poly G on poly C templates. It will not, however, replicate the synthetic RNAs to generate copies of the original template. Extensively purified replicase requires two host factor proteins[17,21,22] called F_I and F_{II}, to copy Qβ plus strands, but these factors are not required for activity with the other templates. Although it has often been assumed that the replicase itself—defined as the enzyme which copies minus strands or poly C (but which requires F_I and F_{II} to copy plus strands)—is an oligomer of a single phage specific polypeptide chain, its subunit structure has not been elucidated. The fact that the enzyme sediments at about 7S (refs. 13, 21, 24), while there is room on the phage RNA for information specifying a protein molecular weight of only about 60,000 devoted to RNA replication, suggests that subunits are indeed present. Here I report that pure Qβ replicase contains four different polypeptide chains, only one of which is Qβ specific. The others pre-exist in the host cell.

I have developed a new isolation procedure (to be published) which yields enzyme more than 95 per cent pure. It involves use of the host factor independent synthesis of poly G on a poly C template as a routine assay. Total specificity for replicase was ensured by adding the antibiotic rifampicin[25] to inhibit the synthetic polymer activity of the host RNA polymerase. Rifampicin does not inhibit replicase[26,27] and I found no rifampicin resistant GMP incorporation in extracts of uninfected cells (unpublished results). Enzyme overproduction was obtained by using a Qβ coat amber mutant (amber 12, generously provided by Dr K. Horuichi) which makes three to five times the wild type level of replicase at late times after infection.

The procedure used is a modified combination of the Babinet[28] and Burgess[29] methods originally developed for the isolation of host DNA-dependent RNA polymerase. Infected cells are broken with glass beads; the resulting extract is mildly digested with deoxyribonuclease and fractionated by multi-stage liquid polymer phase partitioning, DEAE-cellulose and phosphocellulose column chromatography with a final zonal sedimentation in high salt glycerol gradients. The last step resolves host polymerase (12·3S) and replicase (7S). A small scale version of the procedure is described in the legend to Fig. 2. The final protein fraction sediments as a single 7S peak in high salt glycerol gradients (see Fig. 9), and has a specific activity (measured by the poly C assay) of approximately 500 nmoles GMP incorporated/mg protein/min at 30° C. No RNA polymerase, poly A synthetase, polynucleotide phosphorylase or nuclease activity can be detected. Although the poly C dependent activity is used throughout the purification, the enzyme obtained is active with Qβ RNA templates, provided host factors are added, and is active without host factors on denatured double stranded Qβ RNA as a source of minus strands.

Sodium dodecyl sulphate (SDS)–polyacrylamide gels[30,31] were used throughout the purification procedure to follow the size and number of individual polypeptides. The purest enzyme still contained four polypeptide chains (Fig. 1): their molecular weights, calculated by the method of Weber and Osborn[31], and by co-electrophoresis with close marker proteins (R. K., to be published) are 70,000, 65,000, 45,000 and 35,000 for bands "I–IV", respectively. None has the same molecular weight as any known subunit of host RNA polymerase[32]; the bands are distinct from the RNA polymerase β, β′, σ or α bands.

Efforts to develop alternative purification schemes or to fractionate further the final product just described have failed to produce active enzyme with fewer bands on an SDS gel. I therefore proceeded with experiment to test the hypothesis that all four polypeptides are subunits of Qβ replicase. (While this manuscript was in preparation I learned that Weissmann, Kondo and Gallerani had obtained the same four polypeptide chains using a slight modification of the method of Eoyang and August[13]; personal communication and preceding manuscript[24].)

One Phage and Three Host Polypeptide Chains

The RNA of phage Qβ can specify protein of molecular weight not exceeding about 150,000. The total molecular weight of the three structural proteins found in mature virions, and also synthesized in antibiotic inhibited infected cells (see Fig. 5), is approximately 90,000, leaving only about 60,000 for any protein(s) involved in RNA replication. Thus it is unlikely that more than one of the four replicase polypeptides could be phage specific. To determine the origin of the polypeptides, tracer amounts of ^{35}S-labelled uninfected cells were mixed with unlabelled, infected cells; an extract was made, and the replicase purified to determine whether any of the host radioactivity was associated with the purified enzyme. As a control, the same labelled cells were mixed with uninfected cells to verify that, in this case, no protein purified as did the replicase.

The phosphocellulose (PC) column elution profiles of the parallel infected and uninfected carrier cell purifications are shown in Fig. 2. Most of the protein from the previous DEAE-cellulose step flowed through the PC column, for the two oppositely charged resins were run at the same *p*H. The main peak of protein eluted by the NaCl gradient is slightly broader in the purification using infected carrier cells (Fig. 2*B*) and the Qβ replicase activity lies in the leading half of this peak. No rifamycin resistant GMP incorporation was detected in the protein eluted in

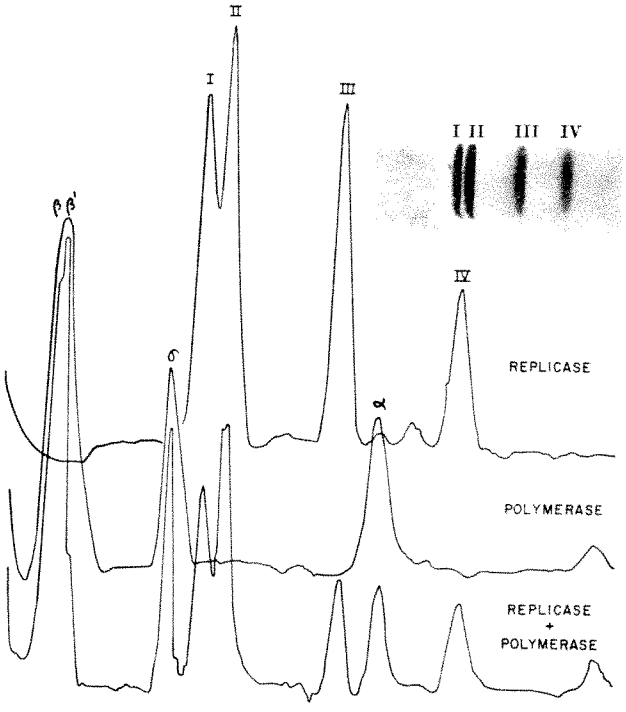

Fig. 1. SDS-polyacrylamide gels of Qβ replicase and *E. coli* RNA polymerase. The gels (10 per cent acrylamide, 0·27 per cent *bis*-acrylamide, 0·1 per cent SDS, 0·1 M sodium phosphate; *p*H 7·2) were prepared, run and stained with Coomassie brilliant blue, as described by Weber and Osborn[31]. The photograph shows highly purified Qβ replicase. The gel scans (done at 600 nm in a Gilford scanner) compare replicase and *E. coli* RNA polymerase, and show that the two enzymes share no common subunits.

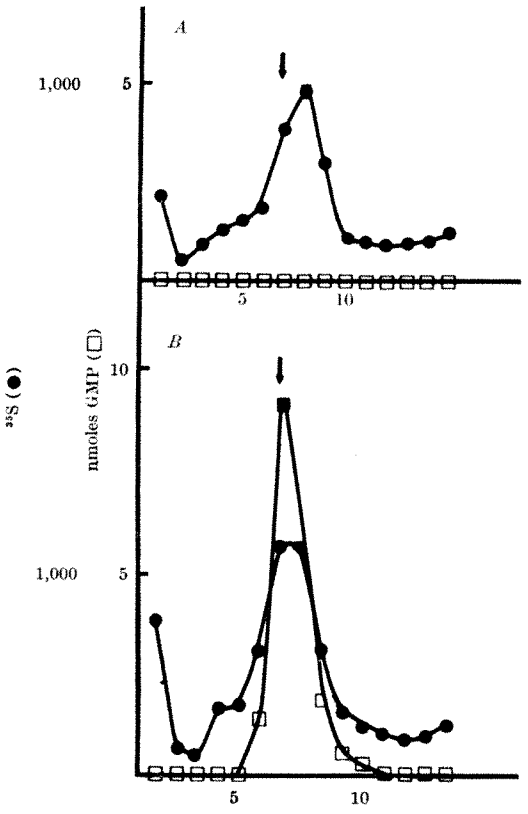

Fig. 2. Phosphocellulose elution profiles of protein from uninfected (*A*) and Qβ amber 12 infected (*B*) cells mixed with tracer amounts of uninfected ^{35}S-labelled cells. The steps used before the phosphocellulose chromatography were the following: a female strain, PR-13 (ref. 41) (RNase$_3^-$, PNPase$_3^-$) was labelled by growth in $^{35}SO_4^{2-}$ medium (TA medium—see Fig. 5—modified by decreasing the $MgSO_4$ to 2×10^{-4} M, adding carrier-free $^{35}SO_4$ at 10 mCi/100 ml., and omitting cysteine and methionine) and 0·8 mCi mixed with either 5 g of unlabelled Qβ amber 12 infected cells or with 5 g of unlabelled PR-13. The two cell mixtures were purified for replicase in the same way although activity was only detected in the infected cell mixture. All steps were at 0–4° C. The cells were ground in alumina, and the resulting cell pastes were taken up in 10 ml. of standard buffer plus Mg^{2+}: 0·05 M Tris-HCl (*p*H 7·5 at 25° C), 0·001 M EDTA, 0·1 mM dithiothreitol, 20 per cent glycerol, 0·005 M magnesium acetate, and clarified by low speed centrifugation. To minimize protease action, 0·5 ml. of a saturated ethanolic solution of phenylmethylsulphonyl fluoride was added to the extracts. The extracts were then fractionated by multi-stage liquid polymer phase partitioning. One-third weight of a standard buffer plus Mg^{2+} solution containing 6·4 per cent Dextran 'T500' (Pharmacia) and 25·6 per cent polyethylene glycol 6,000 ('Carbowax 6,000', Union Carbide) was added, and the phase system produced was stirred for 30 min. The phases were then separated by brief low speed centrifugation, and the top phases discarded. To the bottom phases, an equal volume of 6·9 per cent 'Carbowax 6,000' in 2·0 M NaCl standard buffer plus Mg^{2+} was added, and the phases were separated after stirring for 30 min. The top phases were removed and saved, and the bottom phases extracted twice more as just described. The pooled 2·0 M NaCl phases were then dialysed against standard buffer (no Mg^{2+}) overnight. The resulting dialysates (about 65 ml.) had conductivities of 2·5 mΩ^{-1}. Absorption on DEAE–cellulose was achieved batchwise without removal of the polyethylene glycol or concentration, by the direct addition of a slurry of Whatman 'DE-52' (equilibrated with standard buffer). About 10 ml. of resin was added to each dialysate, and after one hour of slow mixing, the 'DE-52' was removed by slow speed sedimentation. It was washed twice with 25 ml. of standard buffer, twice with 25 ml. of 0·12 M NaCl in standard buffer, and finally three times with 0·2 M NaCl in standard buffer. The pooled 0·2 M washes were diluted two-fold with standard buffer, and applied slowly to 2 ml. Whatman 'P-11' phosphocellulose columns which had been extensively equilibrated with standard buffer. To ensure that the two parallel purifications were as identical as possible, the PC columns were eluted from a common multi-outlet gradient maker (Buchler) using the same peristaltic pump as well as a single timed fraction collector. The profile of protein eluted by an NaCl gradient (0·12–0·5 M NaCl, total volume 40 ml.) is illustrated. ●, ^{35}S protein; □, replicase activity. Activity was measured in the standard poly C dependent assay, which contained 0·05 M Tris-HCl (*p*H 7·5) at 25° C, 0·010 M magnesium acetate, 0·001 M EDTA, 0·1 mM DTT, 0·001 M phosphoenolpyruvate, 5 μg/ml. pyruvate kinase, 2·5 mg/ml. rifampicin, 0·1 mM polycytidylic acid, and 0·2 mM GTP (specific activity 1–2,000 ^{14}C c.p.m. per nmole), in 10 per cent glycerol, at a final volume of 0·2 ml. Reactions were incubated for 10 min at 30° C, stopped with the addition of 3 ml. 5 per cent trichloroacetic acid (TCA), 1·0 M NaCl, and 0·01 M sodium pyrophosphate; the RNA precipitates were collected on 0·65 μm membrane filters, washed six times with 3 ml. of the TCA–salt solution, and once with 95 per cent ethanol. After drying, the filters were counted in 3 ml. of toluene–'Omnifluor' scintillation fluid.

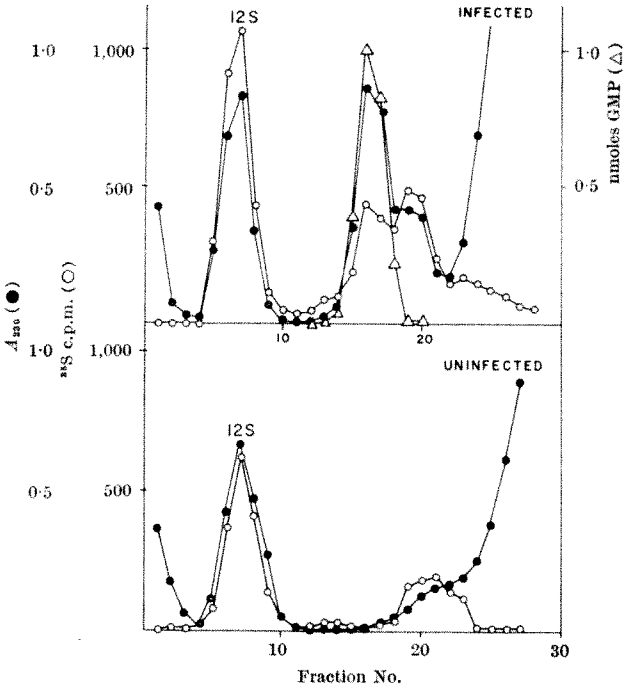

Fig. 3. High salt glycerol gradients of the phosphocellulose fractions purified from Qβ amber 12 infected cells or uninfected cells mixed with ^{35}S-labelled female cells. The labelled protein fractions indicated by the arrows in Fig. 2 were mixed with egg white lysozyme carrier and concentrated by dialysis against standard buffer containing saturated $(NH_4)_2SO_4$. The precipitates were dissolved in standard buffer plus 5 mM magnesium acetate and 0·2 M $(NH_4)_2SO_4$, dialysed to lower the glycerol concentration to 5 per cent, and loaded on 11·5 ml. glycerol gradients (10–30 per cent glycerol in standard buffer plus Mg^{2+} and 0·2 M $(NH_4)_2SO_4$). The gradients were centrifuged at 41,000 r.p.m. in an International 'SB283' swinging bucket rotor at 12° C for 23 h. Replicase activity (△) was measured with the standard poly C assay, but ^{3}H-GTP (7,500 c.p.m./nmole) replaced ^{14}C radioactivity so that the ^{35}S-protein (○) could be determined in the same TCA precipitates. The absorbance (●) at the top of the gradients is the carrier lysozyme. No replicase activity was found in the gradient from uninfected cells. Sedimentation was from right to left.

the uninfected carrier cell purification (Fig. 2*A*), nor at earlier stages in the purification. This confirms that the activity is totally phage specific.

The PC fractions indicated by the arrows in Fig. 2, corresponding to the leading half of the protein peaks eluted from the two columns, were concentrated separately (after adding lysozyme as carrier) and then run on high salt glycerol gradients. The two resulting gradients (Fig. 3) are similar, except for a 7S peak of absorbance and ^{35}S only present on the gradient with the infected carrier cell. Qβ replicase activity is coincident with this 7S peak. The other principal peak, at about 12S, common to both gradients, is host DNA-dependent RNA polymerase. The co-sedimentation of ^{35}S-labelled (and therefore host specified) protein with the 7S replicase activity, plus the absence of ^{35}S or absorbance in the 7S region of the control "blank" purification, leads to two important conclusions. First, the 7S replicase is about 95 per cent pure, because little or no protein is found in this position in the "blank" purification, and second, the pure replicase must contain at least one host polypeptide because it is ^{35}S labelled. The ratio of absorbance (derived almost entirely from the carrier cells) to ^{35}S is higher in the 7S replicase peak than it is in the 12S peak on the same gradients. Thus one or more of the replicase subunits is not radioactive and must be phage specific.

The ^{35}S labelled replicase, obtained from the gradients shown in Fig. 3, was analysed by SDS–acrylamide gel electrophoresis to resolve its constituent polypeptide chains. The gel was stained for protein with Coomassie brilliant blue, and then examined for ^{35}S by autoradiography using the procedure described by Fairbanks, Levinthal and Reeder[33]. Fig. 4 shows the stained gel

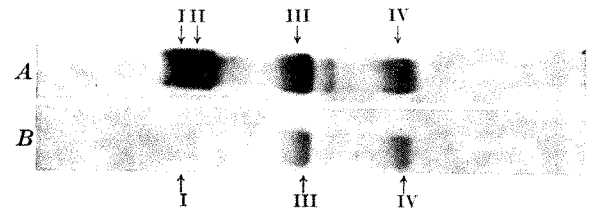

Fig. 4. SDS gels of ^{35}S-labelled Qβ replicase. The radioactive enzyme obtained from the gradient shown in Fig. 3 was analysed by electrophoresis on a 10 per cent SDS–polyacrylamide gel. After running and staining for protein in the usual manner[31], the gel was sliced longitudinally and the slices dried down on a sheet of filter paper under vacuum[34]. A photograph of a dried gel slice is shown in *A*. There are four stained bands, corresponding to subunits I–IV in Fig. 1. The other minor bands are only detectable here because the gel has been very heavily loaded and the photograph overexposed during printing to maximize contrast. They constitute less than 5 per cent of the total protein. The autoradiogram of the dried gel (*B*) shows that subunits I, III and IV are radioactive, and therefore host specific. Subunit II contains no detectable ^{35}S.

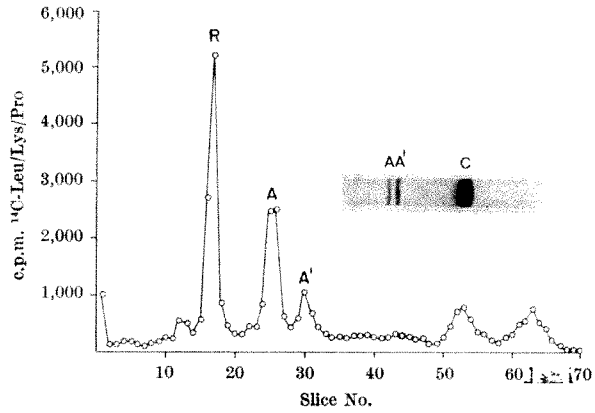

Fig. 5. SDS-acrylamide gel of rifampicin inhibited cells infected with Qβ coat amber 12. *E. coli* F11 (ref. 42, an actinomycin and rifampicin sensitive derivative of Q13) grown in TA medium* minus leucine, lysine and proline was used (1 ml.) to infect 75 ml. of fresh medium in a 500 ml. flask. The cells were grown at 37° C, to a density of 1×10^8 cells/ml., and then infected with **Qβ** amber 12 (at a multiplicity of infection of 10 with 0·06 per cent revertants). 25 min later, rifampicin was added to 33 μg/ml. After allowing 20 min for complete inhibition of host protein synthesis (verified in preliminary control experiments), 2 μCi each of ^{14}C-leucine, ^{14}C-lysine and ^{14}C-proline (specific activities 280, 309 and 205 μCi/μmole) were added and the culture was incubated for a further 45 min. This labelling period corresponds to the time of maximal replicase synthesis in amber 12 infected cells. At 90 min after infection, the cells were chilled, harvested and resuspended in 0·5 ml. of 0·1 M sodium phosphate buffer (*p*H 7·2). After heating to 100° C, SDS and mercaptoethanol were added to 0·5 per cent and 1 per cent respectively, and the cells were disrupted by boiling for a further 20 min. The sample was then dialysed against 0·1 M sodium phosphate–0·1 per cent SDS–1 per cent mercaptoethanol and 10 per cent sucrose at room temperature overnight. The dialysate, which contained 73,000 c.p.m./5 μl. (counted in NEN 'Aquasol') was used directly for SDS gel electrophoresis without further treatment. The gel was frozen after electrophoresis, and sectioned into 1 mm slices with a razor blade gel slicer. The radioactivity was eluted by soaking the slices overnight in 0·4 ml. of 0·1 per cent SDS, and counted after addition of 3 ml. NEN 'Aquasol' liquid scintillation fluid. The gel profile shows two major protein peaks, R (molecular weight 60,000–70,000) and A (molecular weight 40,000–45,000). The inset is a photograph of a similar SDS gel run on unlabelled Qβ virus particles dissociated by heating in SDS. The mobility of labelled peak A is the same as that of the largest viral protein; that of R is considerably slower than any of the structural proteins.

* TA medium contains (per l.) 10 g NaCl, 1 g NH_4Cl, 0·25 ml. 2×10^{-2} M $FeCl_3$, 2·5 ml. 0·2 M K_2HPO_4, 1·0 ml. 1 M $MgSO_4$, and 11·5 g TES buffer adjusted to *p*H 7·5 with 1 M NaOH and autoclaved. Then, 100 ml. quantities are completed with separately sterilized solutions of 20 per cent dextrose (2·5 ml.), 1 per cent methionine (1·0 ml.), 1 per cent tyrosine (1·0 ml.), 5 per cent yeast extract (0·05 ml.), 1 M $CaCl_2$ (0·25 ml.), and a mixture of amino-acids in proportion to leucine as they are found in *E. coli*, omitting only those to be used for labelling. The methionine, tyrosine and yeast extract are necessary for growth of strain F11 (tyr$^-$met$^-$, unknown growth factor requiring).

and its autoradiographic image. The same four stained bands seen in Fig. 1 are apparent, although the quantity of protein applied to the gel makes it difficult to resolve bands I and II after slicing and drying for autoradiography. Bands I, III and IV contain ^{35}S, but band II does not. Thus the 70,000, 45,000 and 35,000 molecular weight polypeptides are host specific, whereas only the 65,000 subunit can be phage specific. The fact that the three polypeptides are not purified in the absence of the phage specific subunit argues that they are subunits of the replicase. Moreover, because the source of the ^{35}S-labelled host polypeptides found with the replicase in this experiment was a separate batch of uninfected cells, they must actively exchange during purification or, alternatively, the phage specific protein must be present in large excess in extracts of Qβ amber 12 infected cells.

Subunit II is the Product of the Replicase Cistron

To demonstrate that the phage specific subunit II is the product of the Qβ replicase cistron, I have prepared labelled marker proteins from Qβ amber twelve infected cells the host protein synthesis of which was inhibited by rifamycin. Previous studies on other RNA phages, using either actinomycin[34–36] or rifamycin[37] to inhibit host protein synthesis, have resolved three phage specific proteins on SDS–acrylamide gels. By using amber mutants[36,38], the proteins have been assigned unequivocally to the three known RNA phage cistrons: coat, maturation protein and synthetase (replicase). The largest of the proteins (60,000 molecular weight for phage MS2 (ref. 36)) is the product of the replicase cistron. In a study of the proteins specified by wild type Qβ Garwes *et al.*[39] have reported that four, rather than three, polypeptides are found on SDS gels. Three of these proteins (which I shall call A, A′ and coat) are found in mature Qβ virions. These results have been confirmed in this laboratory (unpublished observations of R. K. and M. Osborn). Whether the second minor virion protein (A′) is in fact the product of a new phage cistron, not present in the other RNA phages studied, is not yet clear. The fourth and largest of the Qβ proteins was assigned to the replicase cistron because it is the only one not found in virions. Although Garwes *et al.*[39] reported the molecular weight of this protein as 49,000, recalculation from the data they presented, using the MS2 proteins they provided as internal markers for molecular weight calibration, indicates that 64,000 would be a better estimate of its size.

Fig. 5 shows the pattern of phage specific proteins synthesized in a Qβ amber 12 infected su$^-$ host labelled

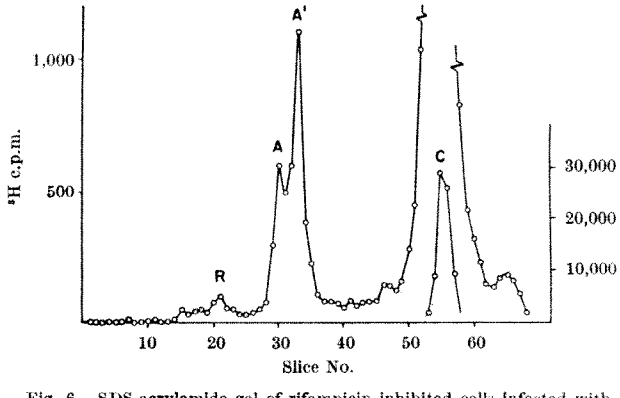

Fig. 6. SDS-acrylamide gel of rifampicin inhibited cells infected with wild type Qβ. 25 ml. of strain F11 in TA medium was grown to 1×10^8 cells/ml. Two 10 ml. aliquots were spun down, and each was resuspended in 1 ml. of fresh medium. One aliquot was infected with wild type Qβ at a multiplicity of infection of 10. After 5 min incubation at 37° C, the cells were diluted with 9 ml. of TA containing 25 μg/ml. rifampicin. They were then incubated until 22 min after infection at which time 10 μCi of ^{3}H-proline (specific activity 26·8 Ci/mmole) was added. At 32 min the cells were chilled and centrifuged. The cell pellet was taken up in 0·1 M Tris (*p*H 7·9), containing lysozyme (100 g/ml.), deoxyribonuclease (10 g/ml.) and ribonuclease (50 g/ml.) and incubated for 10 min at 37° C. SDS (0·5 per cent) and mercaptoethanol (1 per cent) were then added and the extracts heated to 100° C for 10 min. The extracts were then dialysed overnight against 0·1 M sodium phosphate (*p*H 7·2), containing 0·1 per cent SDS, 0·14 M mercaptoethanol, and 10 per cent sucrose. (In long term labelling experiments—see Fig. 5—the enzymatic digestion step was omitted.) The infected cell culture incorporated 25 per cent of the added proline during the labelling period; the uninfected control incorporated less than 0·25 per cent of the label. A gel run on the extract from uninfected cells (not shown) had no visible protein peaks and less than 100 c.p.m. in each slice. The three peaks apparent on the gel from wild type infected cells correspond to the three proteins found in virus particles (see inset to Fig. 5): coat, A and A′. Little if any protein R was labelled in the 22–32 min pulse used.

during the period of replicase overproduction (45–90 min after infection). Two principal protein peaks, called R and A for the larger and smaller respectively, are obtained. No coat protein appears, for the phage contains an amber mutation in this cistron. Peak A has the same SDS gel mobility as the largest of the proteins found in virus particles (see inset in Fig. 5), corresponding to a molecular weight of 41,000, and is probably the Qβ maturation protein. The larger molecular weight protein, R, is identified as the product of the replicase cistron by the following criteria: it is the only Qβ specific protein found in infected cells but not in virions. In wild type infections, in which replicase protein synthesis ceases between 20 and 30 min after infection[1–3,10,13], very little protein with the mobility of peak R is labelled in a 10 min pulse beginning at 22 min (Fig. 6). In cells infected with coat amber 12, maximum synthesis of replicase occurs between 40 and 90 min after infection (to be published). R is the principal phage specific protein made during this period (Fig. 5). It is therefore likely to be the product of the Qβ replicase cistron.

To use the replicase polypeptide labelled in rifamycin inhibited cells as a marker for identification of the phage specific component of purified enzyme, it was necessary to prepare ^{3}H-labelled enzyme sufficiently pure to distinguish its subunits on an SDS gel. Enzyme was therefore purified from a small quantity of wild type Qβ infected cells labelled immediately after phage infection with ^{3}H-proline. As a further control, the cells used had been previously labelled with ^{14}C-proline to identify protein components synthesized before Qβ infection. Fig. 7 illustrates an SDS gel of this double labelled, partially purified enzyme. Peaks with the mobilities of subunits I, II, III and IV are seen, as well as several contaminants. As expected from the ^{35}S experiment, host specific subunits I, III and IV contain ^{14}C as well as ^{3}H-proline, while subunit II contains only ^{3}H-proline. This confirms that subunit II is induced after Qβ infection.

In the gel shown in Fig. 8, ^{14}C-labelled proteins synthesized in rifamycin inhibited cells infected with coat amber twelve are co-electrophoresed with the ^{3}H-labelled purified enzyme. Peak R, identified above as the Qβ replicase gene product, co-electrophoresed with the phage specific component of the enzyme, subunit II. (Note that enzyme subunit III, which is host specific, did not migrate with

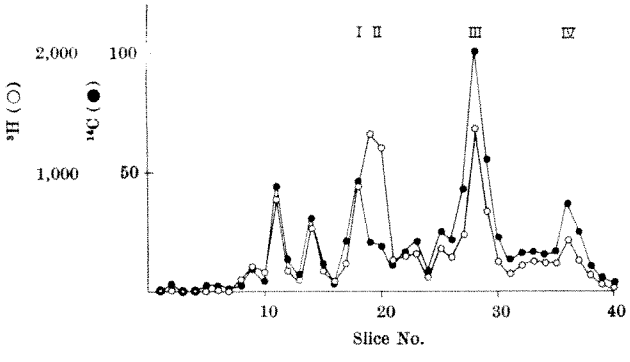

Fig. 7. SDS-acrylamide gel of double labelled Qβ replicase. The ^{14}C curve shows the distribution of protein synthesized before infection. The ^{3}H curve shows protein made after Qβ infection. *E. coli* Q13 (100 ml.) was grown in TA medium (minus proline) at 37° C to a density of about $0{\cdot}5 \times 10^8$ cells/ml. ^{14}C-proline (20 μCi, specific activity 206 μCi/μmole) was then added, and incubation was continued at 37° C. The proline was fully incorporated in 20 min. Two hours after ^{14}C-proline addition, the culture was infected with wild type Qβ (multiplicity of infection of 10) and labelled with ^{3}H-proline (1 mCi, specific activity 26·8 Ci/mmole). 35 min after phage infection the cells were chilled and harvested. After mixing with 2 g of unlabelled Qβ amber 12 infected cells, the replicase activity was purified by a procedure similar to that described in the legend to Fig. 2. Because wild type phage rather than replicase overproducing amber mutant were used, the final enzyme is only about 75 per cent as pure as that shown in Fig. 1. It should also be noted that the proportion of bands I, II, III and IV is different from that previously shown. This is the frequent result of efforts to purify enzyme on a very small scale; it probably arises from partial dissociation of the enzyme complex during purification, and is correlated with a decrease in the final specific activity.

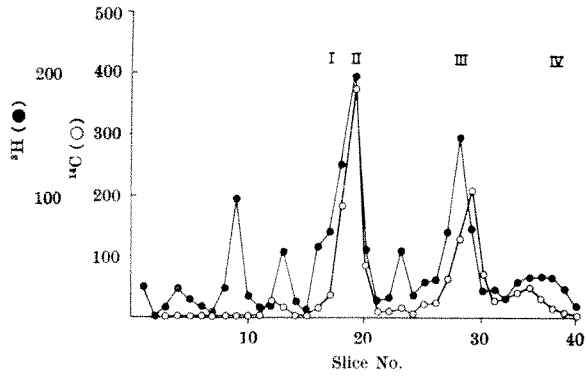

Fig. 8. Co-electrophoresis of ^{14}C-labelled proteins from rifampicin inhibited cells infected with Qβ coat amber 12 and ^{3}H-labelled partially purified Qβ replicase. An aliquot of the ^{14}C-labelled amber 12 proteins (see Fig. 6) was mixed with ^{3}H-proline labelled replicase (see Fig. 7) and run on a 10 per cent SDS gel. Slicing and counting were done as described in Fig. 6. Replicase subunit II co-electrophoresed with the product of the Qβ replicase action (R), but subunit III did not co-electrophorese with Qβ A protein.

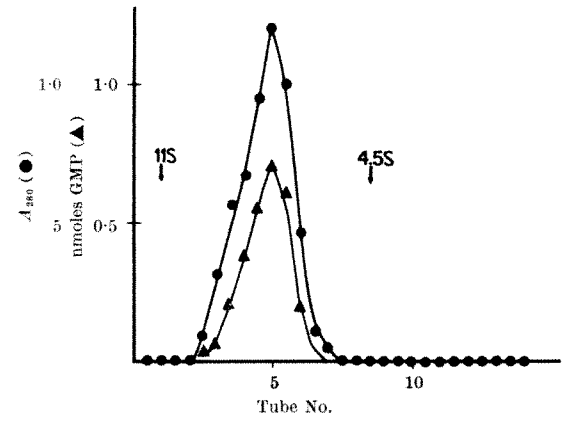

Fig. 9. High salt glycerol gradient of purified Qβ replicase. Approximately 3 mg of purified Qβ replicase (in 0·05 M Tris-HCl (*p*H 7·5 at 25° C)—0·005 M magnesium acetate—0·001 M EDTA—0·5 mM dithiothreitol—0·2 M $(NH_4)_2SO_4$—5 per cent glycerol) was centrifuged on an 11·0 ml. gradient (10–30 per cent glycerol, same buffer) at 40,000 r.p.m. in an International 'B-60' centrifuge, using the 'SB-283' rotor, for 33 h at 5° C. Replicase activity was determined with the standard poly C assay (see Fig. 2) and is plotted as nmole GMP incorporated per 10 min. Haemoglobin and catalase, run in a parallel tube, were used as sedimentation coefficient markers.

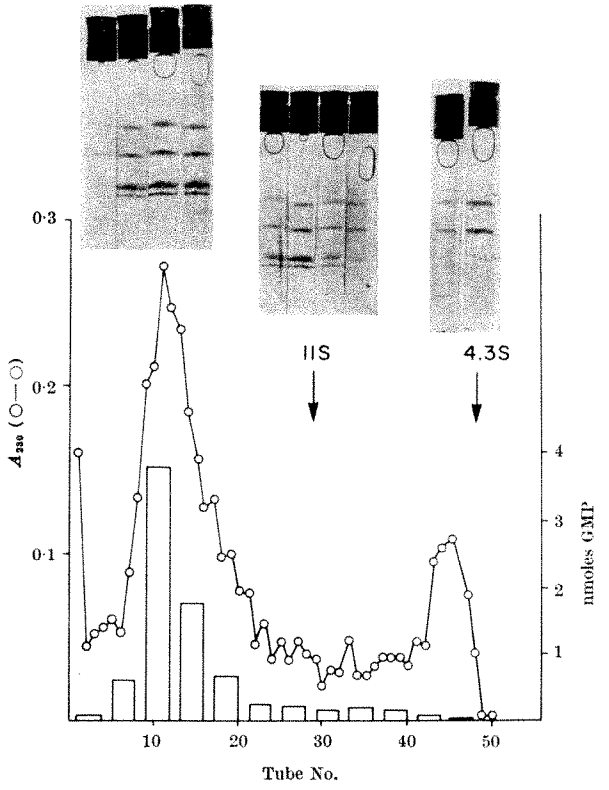
the same mobility as the 41,000 molecular weight viral A protein.) I therefore conclude that subunit II, as well as being the only replicase subunit synthesized exclusively after phage infection, is identical in molecular weight to the product of the phage replicase cistron.

Dissociation and Reconstitution of Qβ Replicase

To show that all the host subunits are essential it would be necessary to dissociate the enzyme complex into its four components, and to demonstrate that each subunit must be added to reconstitute enzyme activity. Although this has not yet been achieved, I have fractionated the enzyme into two inactive smaller components, one containing subunits I and II, the other subunits III and IV, and reconstituted activity by mixing the separated components.

The purified enzyme sediments as a single peak on high salt (0·2 M $(NH_4)_2SO_4$) glycerol gradients (Fig. 9) at about 7S. With no added salt, the protein and activity run as an 18S aggregate, with a significant amount trailing to 7S, and a minor peak of inactive material appearing at 4–5S (Fig. 10). SDS gels run on fractions across such "no salt" gradients showed all four polypeptides throughout the activity region, but only bands III and IV in the 4–5S region. Thus the four polypeptides co-sediment in large aggregates at very low salt. The appearance of a small amount of subunits III and IV running slower than



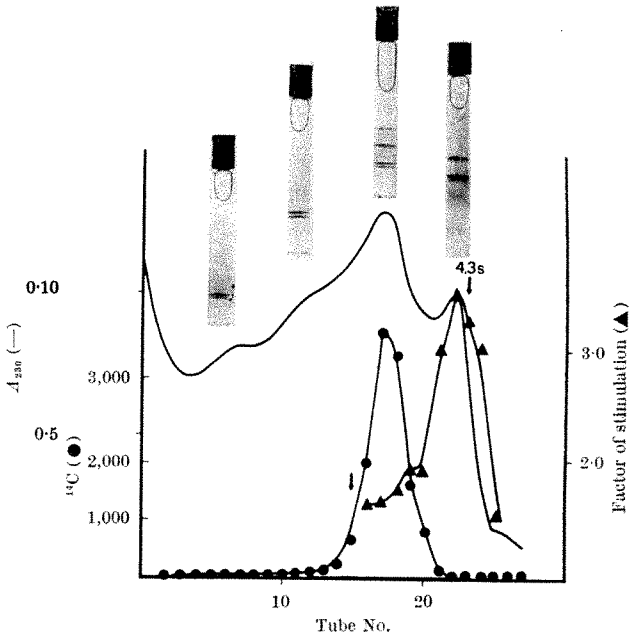


Fig. 10. Low salt glycerol gradient of purified Qβ replicase. Purified replicase (2·2 mg/ml.) was dialysed against 0·01 M Tris (*p*H 7·5), 0·001 M magnesium acetate, 0·0002 M EDTA, 0·1 mM dithiothreitol, 5 per cent glycerol and then 200 μl. was loaded on an 11 ml. 10–30 per cent glycerol gradient in the same buffer. The gradient was centrifuged for 15 h at 4° C in the 'SB-283' rotor of an International 'B-60' centrifuge. Haemoglobin and catalase were run in a parallel gradient as markers. Replicase activity was determined on 5 μl. aliquots from each of three consecutive gradient fractions, using the standard poly C assay, except that incubation was for 30 min at 37° C. SDS-acrylamide gels were run on 100 μl. aliquots of the gradient fractions.

7S suggested that the binding of this pair of subunits might be weak enough to permit more complete resolution in slightly altered conditions. The enzyme was therefore dialysed against low salt (0·01 M Tris-HCl, *p*H 7·5), and then run on separate glycerol gradients with varying $(NH_4)_2SO_4$ concentrations between 0·2 and 0·01 M. As the salt in the gradients decreased from 0·05 to 0·01 M the 7S protein peak shifted to 8–10S, with the simultaneous appearance of a leading shoulder extending to more than 20S, and a trailing peak at 4–5S. The pattern obtained at 0·01 M $(NH_4)_2SO_4$ is shown in Fig. 11. In each case, activity was found exclusively associated with the 8–10S peak. The activity recovered decreased proportionately with the fraction of protein sedimenting in this position. SDS gels run on fractions across such gradients (Fig. 11) demonstrated that the leading shoulder contained subunits I and II, the activity region I, II, III and IV, and the 4–5S peak subunits III and IV. In some experiments, in which very high concentrations of Cleland's reagent (8 mM) were used, a small amount of subunit I, but no II, was also found sedimenting with the 4–5S inactive proteins.

Protein from the leading edge of the activity peak on a 0·01 M $(NH_4)_2SO_4$ gradient, which is composed of subunit I and phage specific subunit II, but little subunit III or IV, was mixed with aliquots of protein from the more slowly sedimenting region of the same gradient. As shown in Fig. 11, protein from the 4–5S region, which is a mixture of host specific subunits III and IV, stimulated activity as much as three times, although it is inactive when assayed separately. In repeated experiments, using enzyme from several separate preparations, between two and seven-fold stimulations were observed. Fig. 12 shows the kinetics of reconstitution at three different temperatures. The reconstitution occurs rather slowly with activity still increasing after more than 3 h at 37° C. This increase in GMP incorporation indicates that active enzyme is being continually generated, for the time required after initiation to finish a product chain (150–200 nucleotides) in the poly C assay is less than 5 min at 37° C and re-initiation does not occur in the assay conditions used. Reconstitution is also temperature dependent; it is more efficient at 37° C than at 30° C, but the net recovered activity decreased markedly at 42° C. The temperature

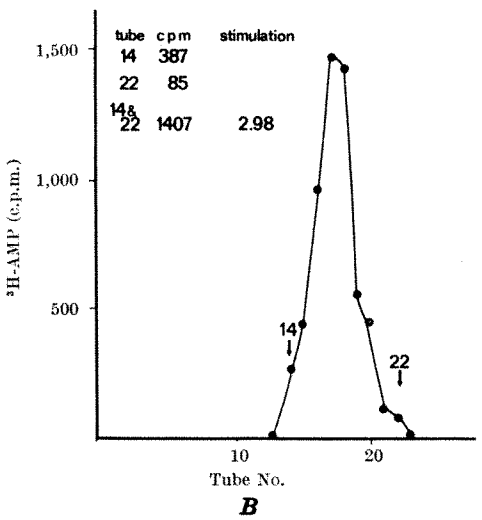

Fig. 11. *A*, Subunit separation gradient. Approximately 1·7 mg of purified replicase in 0·75 ml. was dialysed against 0·01 M Tris-HCl (*p*H 7·5)–0·001 M magnesium acetate–0·0002 M EDTA–0·1 mM dithiothreitol–5 per cent glycerol for 3 h and then loaded on an 11 ml. 10–30 per cent glycerol gradient in the same buffer plus 0·01 M $(NH_4)_2SO_4$. The gradient was centrifuged for 12 h at 41,000 r.p.m., 10° C. Haemoglobin run in a parallel tube served as a sedimentation marker. Replicase activity (of 5 μl. aliquots) was determined in the standard poly C assay, incubating for 30 min at 37° C. Tube 15 (5 μl., 678 c.p.m. assayed alone) was then mixed with 5 μl. from each of tubes 16–26 and re-assayed at 37° C for 30 min. ▲, The factor of stimulation (observed incorporation divided by the sum of the incorporation seen in separate assays). In *B*, the gradient was assayed using denatured double stranded Qβ RNA as template, and ^{3}H-ATP (13,800 c.p.m./mole) as radioactive substrate. The standard reaction mixture, in this case, was modified by the elimination of poly C and the addition of ATP, CTP and UTP to 0·2 mM. The data in the table shown in *B* are the results of a single point reconstitution assay in which aliquots of tubes 14 and 22 were assayed separately and together with the denatured double stranded RNA template.

requirement, combined with the apparent instability of the separated components at slightly higher temperature, probably accounts for the limitation of the net recovery of activity to about 30 per cent of that expected on a protein basis. The extent of reconstitution is only slightly enhanced by increasing the salt concentration (either $(NH_4)_2SO_4$ or KCl), or by using 8 mM dithiothreitol throughout dissociation and reconstitution. High molecular weight aggregates of subunits I and II (>14S) cannot be reproducibly stimulated. This may reflect the denaturation of the subunits in the complete absence of the two low molecular weight polypeptides or, more simply, the difficulty of disaggregating the highly multimerized material. The observed effects are not limited to the poly C activity of the replicase. With denatured double stranded Qβ RNA (a convenient source of minus strands) as template, the same activity profile and extent of reconstitution in mixing experiments was observed (Fig. 11).

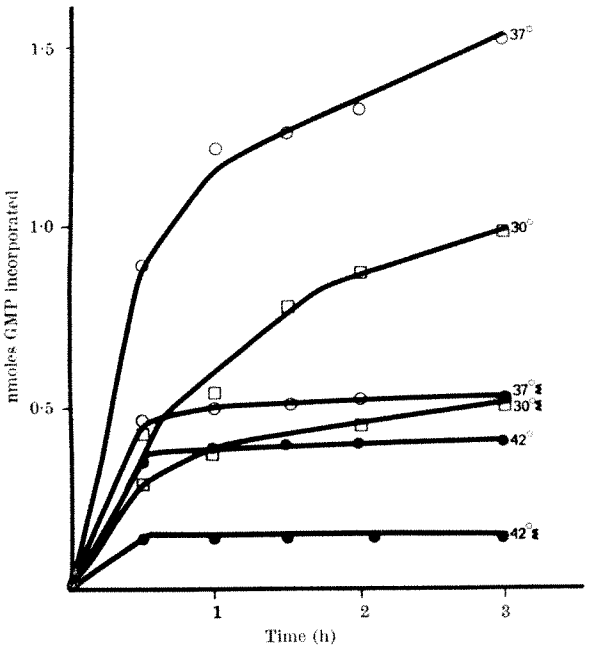

Fig. 12. Kinetics of activity reconstitution. Two fractions of replicase proteins were used. One contained subunit I, subunit II and approximately ten-fold reduced amounts of subunits III and IV. The other was pure subunits III and IV. The fractions were assayed separately and together as a function of time at 30° C, 37° C and 42° C. The curves labelled 30° CΣ, 37° CΣ and 42° CΣ are the sums of the separate assays at the three temperatures, while the curves labelled 30° C, 37° C, and 42° C are the actual observed incorporations with the mixed fractions.

The co-aggregation of all four polypeptides in the absence of salt indicates that there is some physical interaction between them. The aggregation and partial dissociation at low $(NH_4)_2SO_4$ suggest that host subunit I binds tightly to Qβ specific subunit II, while subunits III and IV, either separately or in combination, bind less tightly at this salt concentration and are therefore partially left behind at 4–5S. The stimulation of activity observed when host specific subunits III and IV are added to enzyme deficient in them shows that at least one of these subunits is required as well as the phage specific subunit. Proof of the involvement of the remaining two subunits awaits further physical and functional studies of the enzyme.

The chemical roles of the host subunits in the replicase reaction are not yet known. One or more of the host subunits could be involved in initiation, and may, like the polymerase sigma factor, dissociate from the rest of the enzyme after the initiation event[40]. Another may be involved in specific chain termination. Indeed, the phage specified subunit may serve primarily as a specificity determinant, with the locus of the active site for phosphodiester bond formation residing on one or more of the host subunits. Although none of the subunits is identical to a known component of the DNA-dependent RNA polymerase, it is quite possible that replicase uses some as yet unidentified part of the host's transcriptional machinery. The known relationships between phage and cellular RNA synthesis may be the result of a competition between replicase and RNA polymerase for a common protein factor.

I thank Professor James Watson for his support and direction, Professors Walter Gilbert and Klaus Weber for aid and guidance, Mr Alan Maxim for technical assistance and Drs Robert Schleif, Andrew Travers and Jeffrey Roberts for discussion. The work was done during the tenure of a predoctoral fellowship of the National Science Foundation.

Dissociation of Ribosomes on Polypeptide Chain Termination and Origin of Single Ribosomes

by
RAYMOND KAEMPFER
Biological Laboratories,
Harvard University,
Cambridge, Massachusetts 02138

After polypeptide chain termination, ribosomes are released from polysomes in the form of ribosomal subunits. Single ribosomes, which differ from ribosomes found in polysomes, are formed by association of the released subunits.

In bacteria[1,2] and yeast[3] there is a continual exchange of the two ribosomal subunits between the translating ribosomes and a pool of free subunits. This cyclic process seems to involve the dissociation of ribosomes after each round of translation of messenger RNA[4] and the association of subunits from the pool during initiation of protein synthesis[5,6]. The precise point at which the ribosomes dissociate is not known; in particular we do not know if ribosomes, on completing one or more polypeptide chains, are released from messenger RNA in an undissociated form or as ribosomal subunits.

Single ribosomes accumulate at the expense of polysomes in bacteria and in eukaryotic cells in conditions that decrease the overall rate of protein synthesis. Results of various studies on these ribosomes have been interpreted as evidence that following completion of polypeptide synthesis, ribosomes are first released from polysomes in the form of stable, undissociated single ribosomes and are only subsequently converted to subunits[7-9].

Here we show that on completion of polypeptide synthesis, *Escherichia coli* ribosomes are released from polysomes in the form of ribosomal subunits. These join a pool of subunits which, in sub-optimal conditions for protein synthesis, reassociate readily to form single ribosomes. This class of ribosomes is distinct from ribosomes found in polysomes.

Ribosome Dissociation follows Translation

When an extract containing polysomes from cells grown in heavy isotopes (^{13}C, ^{15}N, ^{2}H) is added to an approximately thousand-fold excess of polysomes extracted from cells grown in light isotope medium (^{12}C, ^{14}N, H) and the mixture is incubated in conditions permitting protein synthesis, rapid ribosomal subunit exchange occurs; this is shown by conversion of fully heavy ribosomes to ribosomes of hybrid density[4,10] that contain one heavy and one light ribosomal subunit[1]. The simplest explanation of this finding is that at or shortly after termination of polypeptide synthesis, ribosomes dissociate into 30S and 50S subunits which enter a pool of free subunits. Because of the predominance of light particles in the pool, heavy subunits recombine mostly with light subunits to form new ribosomes of hybrid density.

This scheme predicts that if reformation of ribosomes, but not the completion of nascent polypeptide chains, is prevented free subunits should accumulate at the expense of ribosomes in polysomes. This was tested by diluting the polysomes and free subunits of the heavy and light extracts a hundred times while keeping the concentration of the supernatant components constant by addition of S-100 extract from light cells. The rationale of this procedure is to attain subunit concentrations that limit the rate of reformation of ribosomes during protein synthesis. Fig. 1 shows that whereas only few free subunits are present in the original heavy polysome extract (*a*), incubation for up to 5 min results in a progressive accumulation of free subunits (*b*, *c*). A slight shoulder of hybrid ribosomes is present in Fig. 1*c*, and further incubation shows that of the ribosomes remaining after 15 min (*d*) approximately half were reformed to yield hybrids. To prevent such residual hybrid formation, the polysome extracts were diluted a further ten times (total dilution, thousand-fold). In these conditions large amounts of heavy and light ribosomal subunits accumulate (Fig. 1*e*) and there is no evidence for hybrids among the remaining ribosomes, which presumably have not yet finished a complete round of translation. The accumulation of subunits is completely blocked by sparsomycin (Fig. 1*f*). A zero time control sample of this incubation yielded the same profile as that in Fig. 1*a*. The results of this experiment show that ribosome dissociation follows translation, but they do not exclude the possibility that a single ribosome stage intervenes between the polysomes and the free subunit pool. If single ribosomes are formed on termination of polypeptide synthesis, however, they must dissociate without much delay.

Single Ribosomes arise from Subunits

A 1 : 10^3 mixture of isotopically heavy and light *E. coli* polysome extracts was incubated as described in Fig. 1, except that the extracts were diluted only twenty times with respect to polysomes and ribosomal subunits. At

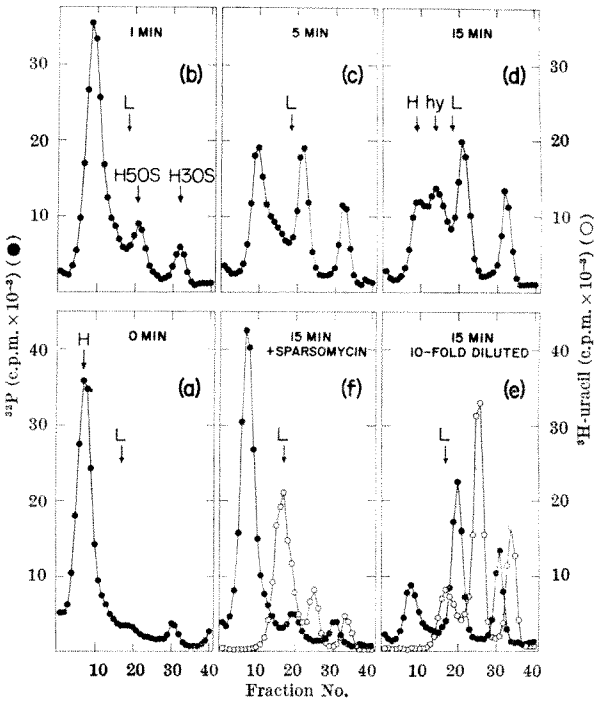

Fig. 1. Accumulation of ribosomal subunits in dilute polysome extracts. *E. coli* D10 (ribonuclease I⁻) was grown in heavy isotope medium[1] with $^{32}PO_4$ or in light isotope medium (0·5 per cent bactotryptone and 0·25 per cent NaCl) with ^{3}H-uracil. When the cultures reached a titre of approximately 10^8 cells/ml., polysome extracts were prepared by neutral detergent lysis at 0° C (refs. 4, 11). The reaction mixture (0·25 ml.) was 0·0067 M magnesium acetate, 0·06 M NH_4Cl, 0·1 mg/ml. *E. coli* tRNA, 0·0002 M ATP, 0·0002 M GTP, 0·005 M PEP, 20 μg/ml. pyruvate kinase, 4×10^{-5} M for each of eighteen amino-acids, 0·005 M β-mercaptoethanol, 0·05 M Tris-HCl (*p*H 7·8). It contained 25 μl. S-100 extract prepared from *E. coli* D10 and 20 μl. (*a*–*d*) or 2 μl. (*e*, *f*) of each polysome extract. The reaction was carried out at 37° C and terminated by rapidly cooling the mixture to 0° C. Eight μg each of ribonuclease and deoxyribonuclease were added in the cold. Sparsomycin (10^{-4} M) was present in sample *f*. The extracts were analysed on 12·5 ml. isokinetic sucrose gradients[1] (12·5 to 19·6 per cent sucrose in 0·01 M Tris-HCl (*p*H 7·4), 0·01 M magnesium acetate, 0·06 M KCl, 100 μg/ml. gelatin). They were centrifuged for 3·8 h at 41,000 r.p.m. ^{3}H-Labelled light ribosomal particles were present in gradients *a*–*d* but for simplicity their profiles are not shown. Instead, an arrow (L) indicates the position of light ribosomes in each gradient[10].

the time of mixing, the extracts contained few ribosomes sedimenting near 70S (Fig. 2*a*). Twenty minutes later, single ribosomes (Fig. 2*c*, region II) had accumulated at the expense of polysomes. The incubation mixture contained 0·06 M NH_4^+ as the dominant monovalent cation. Whether the extracts were centrifuged in sucrose gradients containing 0·06 M K^+ (Fig. 2*a*, *c*) or 0·06 M Na^+ (Fig. 2*b*, *d*), identical profiles were obtained.

Single ribosomes that accumulate *in vivo* and *in vitro* in a variety of sub-optimal conditions for protein synthesis could represent ribosomes released from polysomes on chain termination that are unable to dissociate into subunits. If so, single ribosomes generated from heavy polysomes in extracts containing excess light polysomes should be fully heavy.

The density of the single ribosomes was measured by sedimentation velocity analysis in isokinetic sucrose gradients in which heavy ribosomes and subunits sediment approximately 20 per cent faster than their light counterparts[1]. The density distribution of ribosomes obtained from region I in the gradient shown in Fig. 2*c* serves as a control. This region is expected to contain small polysomes remaining after 20 min of incubation, presumably because their ribosomes have not yet terminated polypeptide synthesis. If correct, this region should contain only fully heavy and fully light ribosomes. Fig. 3*a* shows that these are indeed the dominant species, while almost no hybrid ribosomes are present, an indication that little, if any, successful reinitiation of protein synthesis by newly formed ribosomes occurred in this experiment.

The density distribution of the single ribosome peak (Fig. 2*c*, region II) is shown in Fig. 3*b*. This distribution contrasts sharply with that of region I: almost all label originally present in heavy polysomes is found in ribosomes of hybrid density, sedimenting in a position between fully heavy and fully light species. This demonstrates that the single ribosomes observed in Fig. 2*c* are not derived directly from polysomes, but have arisen by the association of ribosomal subunits.

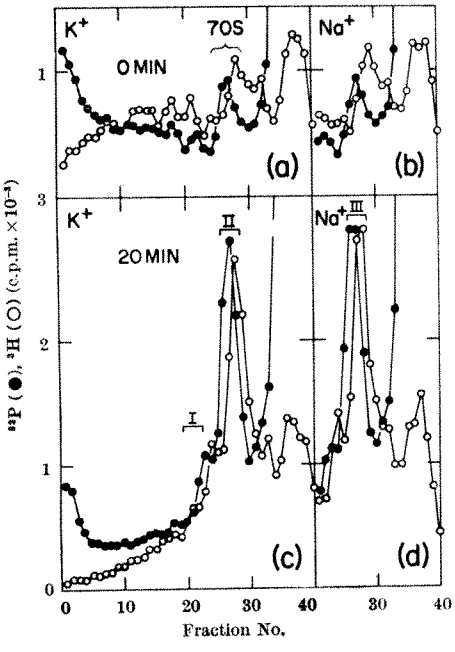

Fig. 2. Accumulation of single ribosomes during cell-free protein synthesis. A mixture of ^{32}P-labelled heavy and ^{3}H-labelled light polysome extracts was incubated as in Fig. 1*a*–*d* except that the concentration of polysomes was raised five-fold. After incubation for 0 min (*a*, *b*) or 20 min (*c*, *d*), the samples, cooled to 0° C, received sparsomycin (10^{-4} M) and deoxyribonuclease (8 μg/ml.) and were centrifuged for 0·6 h at 50,000 r.p.m. in 4 ml. sucrose gradients (see legend to Fig. 1). In gradients *b* and *d*, 0·06 M NaCl replaced KCl. Portions of 15 μl. were analysed for radioactivity.

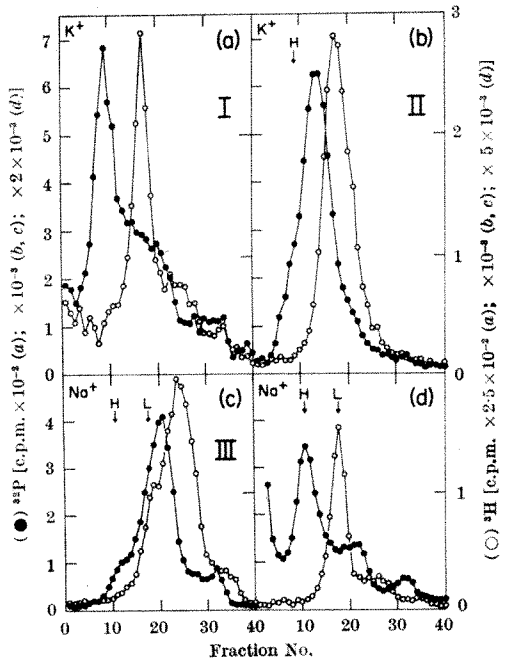

Fig. 3. Density distribution of single ribosomes and the effect of Na^+ ions. Sedimentation velocity analysis of material in regions I, II and III (Fig. 2) in isokinetic sucrose gradients (see legend to Fig. 1) containing 0·06 M KCl (*a*, *b*) or NaCl (*c*). Before centrifugation, the material of region I was incubated with 3 μg/ml. ribonuclease at 0° C. Gradient *d* (NaCl) contains heavy and light cell extracts mixed in the presence of 8 μg/ml. ribonuclease and deoxyribonuclease and kept at 0° C. Centrifugation was for 3·8 h at 41,000 r.p.m. Gradient *a* was centrifuged in a separate rotor. The expected position of heavy (H) ribosomes is shown by an arrow in *b*; arrows in *c* refer to positions of heavy and light ribosomes in *d*.

Formation of Ribosomes is not Freely Reversible

The accumulation of subunits during protein synthesis by diluted polysomes (Fig. 1) and the hybrid nature of single ribosomes (Figs. 2 and 3) are readily explained if ribosomal subunits are released from polysomes on polypeptide chain termination and subsequently recombine to form single ribosomes. The data could also be interpreted, however, in terms of a model in which single ribosomes are first released from polysomes but then equilibrated rapidly with a pool of free subunits. To explain the accumulation of ribosomal subunits, but not ribosomes in dilute polysome extracts (Fig. 1), the latter model requires that in such a system single ribosomes dissociate irreversibly.

To test this, ^{32}P-labelled light single ribosomes isolated from a sucrose gradient such as that of Fig. 2*c* and ^{3}H-labelled polysome extract were incubated with S-100 in conditions that convert most polysomes to ribosomal subunits, as in Fig. 1*e*. Although extensive accumulation of ^{3}H-labelled subunits occurred (Fig. 4, open circles), there was little, if any, dissociation of ^{32}P-labelled single ribosomes (filled circles) compared with the unincubated control (△ — △). The concentration of single ribosomes was approximately one-fifteenth of that of all ^{3}H-labelled ribosomal particles (polysomal and non-polysomal) in Fig. 4, and one-fifth of that of all ribosomal particles present in the experiment of Fig. 1*e*. The Mg^{2+} ion concentrations were identical in all experiments reported here: they were 7 mM during incubation and 10 mM during sucrose gradient centrifugation.

This experiment demonstrates the essential stability of single ribosomes in conditions of protein synthesis leading to the conversion of polysomal ribosomes to subunits, and shows that the formation of single ribosomes is not freely reversible.

Properties of Single Ribosomes

Single ribosomes sediment slower than monosomes obtained by ribonuclease digestion of a polysome extract

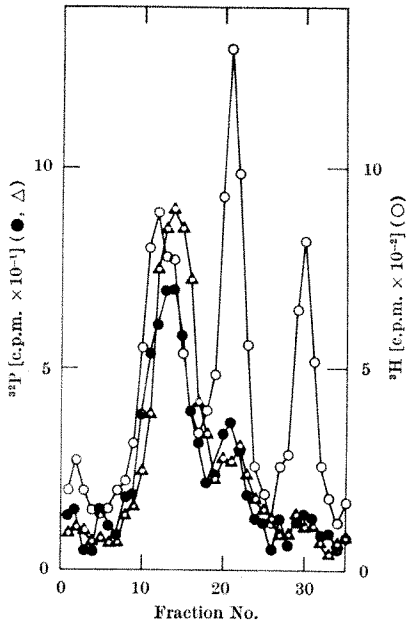

Fig. 4. Stability of single ribosomes in dilute polysome extracts. ^{32}P-labelled single ribosomes (●) isolated from light cells as in Fig. 2*c* (region II) were incubated with ^{3}H-labelled polysome extract (○) as in Fig. 1*e*, except that the concentration of ^{3}H-labelled polysomes was approximately three times higher and no ribonuclease was added after incubation. The sample was centrifuged as in Fig. 3*a* for 4·1 h. A sedimentation profile of unincubated single ribosomes (△), centrifuged in parallel, is superimposed.

(Fig. 5*a*). If the monosome peak is taken as 70S, the sedimentation coefficient of single ribosomes in this figure is 65S. Other experiments gave values varying from 64–66S. The leading edge of the single ribosome peak in Fig. 5*a* most likely contains contaminating monosomes.

Single ribosomes, unlike polysomes, are dissociated by ribonuclease into subunits. ^{32}P-labelled single ribosomes were mixed with ^{3}H-labelled polysome extract and incubated in the presence of 5 μg/ml. ribonuclease for 15 min at 37° C. While this treatment reduced polysomes to monosomes but no further, single ribosomes dissociated almost entirely into 30S and 50S subunits (Fig. 5*b*). The ^{32}P-labelled material sedimenting with the main ^{3}H peak presumably reflects the presence of some monosomes in the single ribosome preparation. Likewise, some of the ^{3}H-labelled subunits may be derived from single ribosomes. Incubation at 22° C rather than 37° C gave identical results but little or no dissociation by ribonuclease occurred at 0° C.

While the yield of single ribosomes is identical during short centrifugation (0·6 h) in K^+ or Na^+ gradients (Fig. 2), the material in region III (Fig. 2*d*) is dissociated during prolonged centrifugation (3·8 h) in an Na^+ environment (Fig. 3*c*). In these conditions, single ribosomes from region II (Fig. 2*c*) yielded the same pattern (not shown) as those from region III. By contrast, a ribonuclease digest of heavy and light polysome extracts sedimented mostly as ribosomes, not subunits, in Na^+ (Fig. 3*d*). This clearly shows that the presence of Na^+ ions leads to the gradual dissociation of single ribosomes, but not of ribosomes found in polysomes.

The extensive ribosomal subunit exchange occurring during protein synthesis in concentrated cell extracts[4] is not merely because of formation of single ribosomes. Most newly formed ribosomes are not dissociated by ribonuclease or by Cs^+ ions, which behave like Na^+ ions with respect to single ribosomes[14].

Single Ribosomes and the Ribosome Cycle

The results presented show that on completion of polypeptide synthesis, ribosomes are released from polysomes in the form of ribosomal subunits. Possibly, the dissociation of ribosomes is not concomitant with their release but occurs immediately after this event. Undissociated intermediates, however, if they exist, must be so short-lived that their presence would not be detectable by the techniques used here. It is also shown that stable single ribosomes, which accumulate in sub-optimal conditions for protein synthesis, arise from the pool of ribosomal subunits released from polysomes. Under conditions conducive to this process, the formation of single ribosomes is not freely reversible.

The nature of single ribosomes is not understood, but they can be distinguished from ribosomes found in polysomes by their properties just described. Others[15,16] have shown that single ribosomes require a higher Mg^{2+} ion concentration to prevent their dissociation than do polysomal ribosomes.

The absence of single ribosomes in gradients containing 0·06 M Na^+ was first shown by Phillips, Hotham-Iglewski and Franklin[14], who suggested that single ribosomes are artefacts created in the presence of K^+ or NH_4^+ ions, but not Na^+. This interpretation was based on the claim that single ribosomes present in cell lysates containing 0·06 M K^+ are stable when centrifuged in Na^+ sucrose gradients[14]. In fact, however, about half of the material sedimenting in the 70S region dissociated in these conditions (ref. 14, Fig. 6*a*). The 70S region analysed came from polysome distributions of early log phase cells (comparable with Fig. 2*a*) which contain few ribosomes sedimenting near 70S. Much of this material probably represents monosomes engaged in protein synthesis, and they are therefore stable in Na^+-sucrose gradients (see also Fig. 3*d*). The remainder represents Na^+ sensitive single ribosomes. Indeed, almost all ribosomes sedimenting near 70S in Na^+ sucrose gradient are active in protein synthesis[17]. Our conclusion that Na^+ but not K^+ causes the specific dissociation of single ribosomes has also been reached by Beller and Davis (personal communication). Mammalian single ribosomes have a specific salt sensitivity as well[18].

In growing *E. coli*, the concentrations of K^+, ranging from 210 to 250 mM, are four to five times higher than those of Na^+, and in late log phase, when increasing levels of single ribosomes are found in cell extracts, K^+ remains greatly in excess of Na^+[19]. Ionic conditions *in vivo* therefore favour the stability of single ribosomes, but these conditions alone cannot account for single ribosome formation.

Incubation with ribonuclease causes selective dissociation of single ribosomes in conditions when polysomal

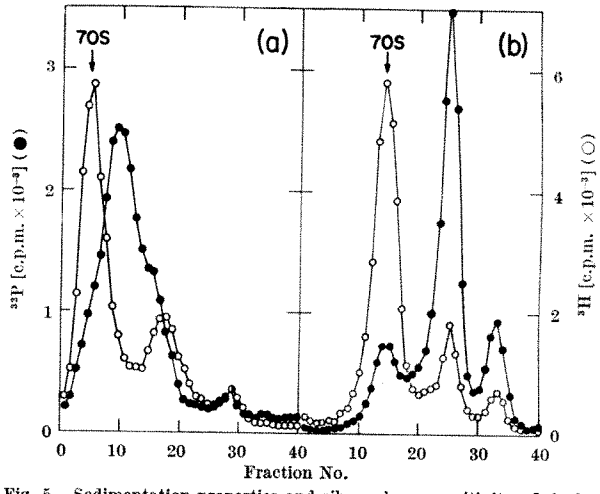

Fig. 5. Sedimentation properties and ribonuclease sensitivity of single ribosomes. *a*, ^{32}P-labelled single ribosomes from light cells, isolated as in Fig. 2*c*, were sedimented as in Fig. 3*a* for 4·7 h. ^{3}H-Labelled polysome extract was incubated for 15 min with 5 μg/ml. ribonuclease at 37° C and centrifuged in parallel. Peak positions did not vary more than one fraction in multiple parallel gradients. *b*, ^{32}P-labelled single ribosomes were incubated for 15 min with ^{3}H-labelled light polysome extract in the presence of 5 μg/ml. ribonuclease at 37° C, and centrifuged as in Fig. 3*a* for 4·0 h.

ribosomes or initiation monosomes bound to phage RNA[12] remain intact. Apparently, the two subunits in a single ribosome are held together by RNA, but because monosomes obtained after ribonuclease digestion of polysomes contain a protected fragment of messenger RNA[12,13], our results suggest that either such a fragment is exposed in single ribosomes, or it is absent altogether. The latter interpretation is also supported by data showing that in polysome profiles of log phase cells labelled for 10 s with ^{32}P, the specific radioactivity of the 70S region in Na^+ sucrose gradients exceeds that in K^+ gradients at least by a factor of two[20]. The suggestion that single ribosomes are artefactual monosomes[21], defective initiation complexes carrying messenger RNA, is not supported by these facts. Moreover, the defect in such complexes would have to be easily reversible, for single ribosomes accumulated in bacterial[22] or mammalian[23,24] cells can rapidly re-enter polysomes in conditions favouring a higher rate of protein synthesis. The relationship between single ribosomes and artificial 60S ribosomes containing poly U[31] remains to be established.

There is no evidence to suggest that single ribosomes are obligatory intermediates in the ribosome cycle. Indeed, in mammalian cells single ribosomes are not in equilibrium with subunits or polysomal ribosomes[23,25,26]. Similar data are not available for bacteria. In these cells, control of the rates of ribosome synthesis and cell division may preclude the accumulation of significant amounts of single ribosomes during steady growth.

The results presented suggest the following sequence in the ribosome cycle. On polypeptide chain termination, ribosomes dissociate into subunits. During rapid protein synthesis, freshly released subunits are immediately recycled into polysomes. When protein synthesis slows down, increasing numbers of subunits accumulate after their release from polysomes; these reassociate into single ribosomes which do not participate in protein synthesis. In conditions requiring a higher rate of protein synthesis, this storage pool of synthetically inactive ribosomes is mobilized and returned to subunits, possibly through the action of one or more factors[27–29].

According to this view, single ribosomes constitute side-track products of the ribosome cycle which are bypassed by ribosomes and subunits active in protein synthesis. Consequently, during low rates of protein synthesis, when the return of single ribosomes to the active ribosomal pool is not favoured, subunits newly released from polysomes would be expected to recycle preferentially. Such preferential recycling seems to occur in a reticulocyte cell-free system[30].

It is possible that in order to initiate a new round of protein synthesis, one or both species of subunits are modified after their release from polysomes. The modification may entail removal of C-terminal tRNA from the 50S subunit. When such tRNA is not removed, 50S subunits may reassociate with 30S subunits to yield single ribosomes stabilized by a tRNA molecule. Accordingly, ribonuclease would act to destroy the integrity of this tRNA and thus cause the specific dissociation of single ribosomes observed *in vitro*.

I thank Miss Nadia Mykolajewycz for technical assistance, Drs A. A. Travers and E. P. Geiduschek for comments, and Dr M. Meselson for use of his facilities. The work was supported in part by an institutional grant from Harvard University.

Two New Fossil Primates from the Lower Miocene of Kenya

by
PETER ANDREWS*
National Museum Centre
for Prehistory and Palaeontology,
PO Box 30239, Nairobi

Relationships of Miocene Hominoidea are re-evaluated in the light of two new fossil pongids from the early Miocene of Rusinga and Songhor, one an undetermined species of *Proconsul* possibly ancestral to orang-utans and the other an undetermined species of *Aegyptopithecus*.

THE Lower Miocene pongids of East Africa have long been recognized as the most likely ancestral group to modern pongids[1]. They were living at a time very close to the divergence of the hominid and pongid lineages, when the prototypes of the two families must still have been very similar[2,3]. In order to understand more clearly the relationships of these Miocene hominoids all of the specimens housed at the Centre for Prehistory and Palaeontology in Nairobi are being re-examined in the light of modern zoological knowledge of population variation and speciation. The size of the collection of primate material in Nairobi has more than doubled since 1951 through the efforts of Dr L. S. B. Leakey and his colleagues. Two of the new specimens are described here as being particularly relevant to the discussion of Lower Miocene primate radiation, a discussion stimulated by the preliminary work of Simons and Pilbeam[4]. A large scale revision of the Miocene Pongidae of Kenya

* Present address: Duckworth Laboratory of Physical Anthropology, Downing Street, Cambridge.

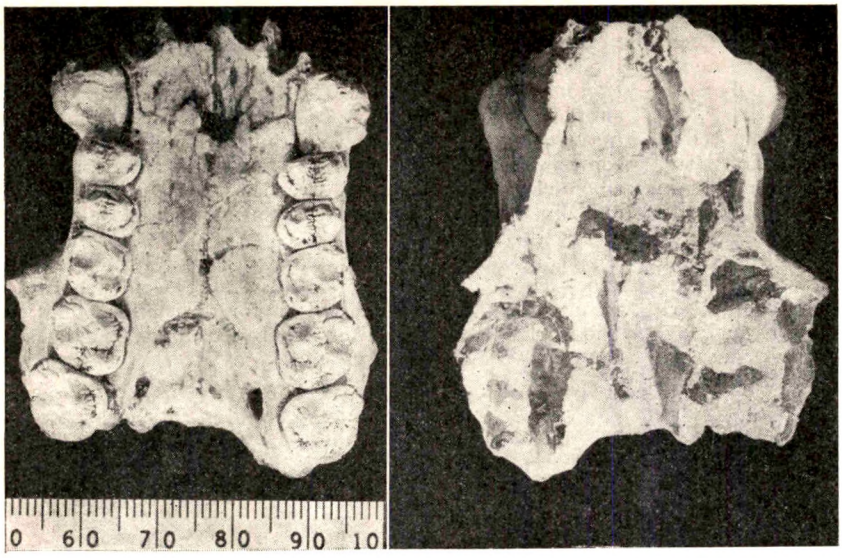

Fig. 1. Songhor palate, *KNM-SO* 700. Palatal view on the left and superior view on the right. Natural size.

is in progress, and until the new diagnoses can be more strictly defined the original taxonomic divisions of Le Gros Clark and Leakey[1] will be retained.

The two specimens consist of a palate with all the teeth except for the incisors (*KNM-SO* 700); and a symphysis and left body of the mandible of a much smaller primate with all the incisors and the left canine to first molar (*KNM-RU* 900). The first was recovered by members of Dr L. S. B. Leakey's team in 1966 from the calcified tuff underlying the red beds at Songhor in Western Kenya. This site has been dated as younger than $19{\cdot}7 \pm 0{\cdot}5$ m.y. (ref. 5). The second was recovered in 1956 from site *R*2 on Rusinga Island in Lake Victoria. The principal deposits on Rusinga Island have now been determined to represent one horizon which has been given a preliminary date of about 18 m.y. (ref. 6). The Songhor specimen has previously been figured[2], but neither specimen has yet been described.

Specimen *KNM-SO* 700

The specimen consists of the bony palate and the alveolar processes of the maxilla. All the teeth except for the incisors are preserved. The tips of both canines are broken off, and it is probable that the canines are not quite fully erupted. The third molars are fully erupted but only slightly worn, which suggests a subadult age for this individual. The floor and inferior lateral walls of the nasal cavity are present back to the palatine bone. The floor of the maxillary sinus is present on both sides, but the medial and lateral walls are broken down except for a few remnants. The medial palatine, incisive and transverse palatine sutures can be clearly seen (see Fig. 1).

The premaxilla is relatively large, extending all the way up the anterior margin of the nasal cavity. The size of the nasal cavity is similar to that of *Proconsul africanus* Hopwood 1933 (ref. 7), as is the bony palate, which is, however, relatively longer in *KNM-SO* 700. In contrast to this is the evidence for shortening of the face in the Songhor specimen: the anterior position of the greater palatine foramen, the prominent ridge for attachment of the soft palate, and the short alveolar tuberosities. The floor of the maxillary sinus is relatively greatly expanded. In the dentition, the canines are large blade-like teeth with a pronounced distal flange. The premolars are more molariform than usual in *Proconsul*, the talon and large lingual cingulum being indications of this. The fourth premolar is unusual in being longer than the third, a condition only found, in pongids, in some specimens of gorilla. The molars are elongated, carrying on the trend seen in the premolars. They increase in length and size from first to third. The trigon is relatively expanded, the hypocone large on all the molars, and the lingual cingulum is massively developed. There is no protoconule, and the occlusal ridges are poorly developed. Measurements of the dentition are given in Table 1.

The taxonomic position of the Songhor palate is not yet clear, and further work is necessary before it can be assigned with any confidence to a species. Its closest affinities are with *Proconsul africanus*, both by size and morphology, and some specimens which are similar to it have actually been described as this species[1,8]. It is possible that these specimens will turn out to be variants of *Proconsul africanus*, but the differences are not completely in line with the variation seen within one species of pongid. Rather, the differences parallel to a remarkable extent those between *Pan troglodytes* and *Pongo pygmaeus*. In the dentition, the blade-like canines with a prominent mesial groove and the molariform premolars are much closer to the orang-utan than to the chimpanzee, while *Poconsul africanus* is closer to the latter. The molar proportions are like those of some orang-utans, with the increase in length and area from the first to the third molar; and on the occlusal surface the low ridges and increase in wrinkling are also like the condition in the orang-utan. *Proconsul africanus* is closer to the chimpanzee in these features. The shortening of the face in the orang-utan is carried out to a greater extent: the alveolar tuberosities are very small relative to the length of the tooth row, the ridge for attachment of the soft palate is very prominent, and the greater palatine foramina are located anteriorly. In the African great apes all these features are developed in a way that is linked

Table 1. MEASUREMENTS OF DENTITION OF *KNM-SO* 700

Index B/L × 100	113·0	85·5

with facial lengthening rather than with shortening, and as far as they can be seen the same is true for the three species of *Proconsul*. The evidence for the expansion of the maxillary sinus also compares with the greatly enlarged sinus of the orang-utan[9] whereas the smaller sinus in the published *Proconsul* specimens is more like that of the chimpanzee and gorilla.

The resemblances to the orang-utan shown by specimen *KNM-SO* 700 are interesting in that they provide the first record in the Lower Miocene of Kenya of a possible member of the orang-utan lineage. Possible ancestors to the chimpanzee and gorilla have already been recognized in the Lower Miocene[3] and it is very probable that ancestral orang-utans were also living at this time. Three of the distinctive functional complexes of the orang-utan can be recognized in the Songhor palate; these are: (1) the lengthening and molarization of the cheek teeth; (2) the shortening of the face (in spite of lengthening of the teeth); and (3) the expansion of the maxillary sinus (in spite of the shortening of the face).

These features are to a certain extent functionally independent, although their significance in the present day orang-utan is not known for certain; and being functionally independent it is less likely that the resemblances shown have resulted from a parallel functional development in the Kenya specimen and in the orang-utan. Parallelism is still a strong possibility, however, and only the discovery of more complete Miocene and Pliocene material will show which explanation is the correct one. Phylogenetic considerations apart, the choice of naming this specimen will be left open at this stage to await the description of further material and the results of the statistical analysis now in preparation. Specimen *KNM-SO* 700 is therefore referred to *Proconsul* species *indet.*

Specimen *KNM-RU* 900

This specimen consists of the symphysis and left body of the mandible as far as the first molar. The right lateral incisor to the left first molar are intact, but the crowns of the canine to first molar have been slightly displaced posteriorly over each other. The incisor row has also been slightly displaced, the right side having been shifted anteriorly. The mandible seems to have been subjected to anteromedial pressure during fossilization to produce these distortions, and this has also produced a fracture on the medial aspect of the body of the mandible beneath the third premolar and has slightly crushed the cortex posterior to this. The symphysis has been eroded in the region of the genial fossa, but apart from this it is intact and the contour undistorted. The erosion continues posteriorly to below the roots of the fourth premolar. The alveolus is broken buccally, exposing parts of the roots of all the teeth, and the surface of the rest of the mandible has been fissured and cracked by weathering (see Fig. 2).

Specimen *KNM-RU* 900 is characterized by its very deep narrow symphysis. The breadth/depth index is very low, with a value of 42·3. The mental region is compressed from side to side so that the incisor alveolus is short. It is also curved, the roots of the central incisors being placed anterior to those of the lateral incisors. The anterior border of the symphysis is steep and it curves gently from the alveolar border to near the inferior, at which point it curves abruptly posteriorly. The exact conformation of the inferior part of the symphysis cannot be determined, but from the curve of the bone on either side of the crushing it would seem that the region of the genial fossa was indented strongly. Inferior to this the symphysis is prolonged posteriorly into an inferior transverse torus, and this constitutes the most posterior part of the symphysis. The body of the mandible is also relatively deep and narrow like the symphysis, but becomes much shallower posteriorly.

The dentition of specimen *KNM-RU* 900 is about the same general size as *Limnopithecus legetet* Hopwood 1933 (ref. 7), and the first molar is like that of this species. The third premolar is more like that of *Limnopithecus macinnesi*[1], but the fourth premolar and lower canine are unlike those of either species. The fourth premolar is very short mesio-distally, so that it is broader than long. This condition is seen in *Proconsul* but not in *Limnopithecus*. The canine has a high slender crown that is more reminiscent of the lower canines of cercopithecoid monkeys than of pongids. It has a considerable degree of distal curvature and an elongated mesial ridge. Measurements of the dentition are given in Table 2.

Fig. 2. Rusinga mandible, *KNM-RU* 900. Top left, buccal view; bottom left, lingual view; right, occlusal view. Natural size.

Before creating a new genus for a new specimen it is axiomatic that it should be compared with previously described taxa and assigned to one of them if the degree of similarity warrants it; and because it is not like any other of the Kenya Miocene specimens, it must be compared with taxa from other localities and from other periods. To find the closest similarity in terms of overall morphology it is necessary to go back to the Oligocene of Egypt, to *Aegyptopithecus zeuxis* Simons 1965 (ref. 10). This has a deep narrow symphysis, a "simian shelf", and a nearly vertical ascending ramus, all of which are very similar to the condition seen in the Kenya specimen. The size of the symphysis is less in *Aegyptopithecus zeuxis*, but the shape, as shown by the thickness/depth index of 40·7 is similar. The contour of the posterior slope of the symphysis is very similar, the most posterior part being at the inferior border. The dimensions of the body of the mandible[10] are slightly less than the corresponding values for *KNM-RU* 900, but again the indices are similar. Similarly the size and morphology of the fourth premolar and first molar are also like those of *Aegyptopithecus zeuxis*. Specimen *KNM-RU* 900 is provisionally assigned to the genus *Aegyptopithecus* to indicate its affinities, but no species name can be given until more work is done both on extending the diagnosis of *Aegyptopithecus* and on describing the whole complex of East African forms.

The upper dentition belonging with the mandible *KNM-RU* 900 is not known, but the upper dentition of *Limnopithecus macinnesi* is known in great detail, and it is of interest that there are only slight differences between it and *Aegyptopithecus zeuxis*. It is therefore possible that the upper dentition belonging with the

mandible of *Aegyptopithecus* species is similar in appearance to that of *Limnopithecus macinnesi* and cannot be distinguished from it at present.

The relationships of the Egyptian Oligocene and the Kenyan Miocene hominoids, and hence their phylogenetic affinities, are not yet clear. Simons has suggested[10] that *Aegyptopithecus zeuxis* has its closest affinity with *Proconsul* on the basis of their similar mandibular molar proportions, but the same proportions are seen also in *Limnopithecus legetet*. The differences he mentions between *Aegyptopithecus zeuxis* and *Limnopithecus* in the lower dentition are valid for *Limnopithecus macinnesi* but not at all for *Limnopithecus legetet*, which differs from *Limnopithecus macinnesi* (apart from being much smaller) in having third molars relatively longer than the first and second, more distinct buccal cingula on the lower molars, relatively reduced molar and premolar trigonids, and less distinct trigonid and talonid ridges. In these features *KNM-RU* 900 is closer to *Limnopithecus legetet*. The differences between both *Limnopithecus* species and *Aegyptopithecus zeuxis* are to be found chiefly in the morphology of the mandible and fourth premolar, and it is here that *KNM-RU* 900 differs from *Limnopithecus* and resembles *Aegyptopithecus*. It seems likely therefore, in view of the close similarities between *Aegyptopithecus zeuxis*, *Aegyptopithecus* species (*KNM-RU* 900), and *Limnopithecus legetet*, that all these taxa belong to the same phylogenetic lineage.

I thank Dr L. S. B. Leakey for permission to describe these specimens and for his financial help. I am also grateful for the helpful comments of Dr Leakey and for those of W. W. Bishop, R. J. Clarke, K. J. Joysey, D. R. Pilbeam, J. A. Van Couvering and A. C. Walker.

Galactic Soft X-rays and the Alignment of Interstellar Grains

by

N. C. WICKRAMASINGHE

Institute of Theoretical Astronomy, Cambridge

An excess flux of soft X-rays in the galactic disk could result in the alignment of interstellar grains which is required to explain the observations of interstellar polarization.

It is widely believed that the observed polarization of starlight is caused by nonspherical dust grains which are systematically aligned, the sense of this alignment being such that the long axes of the grains are lined up preferentially perpendicular to the galactic plane. The theoretical problem of explaining grain alignment has been discussed for nearly two decades but no entirely satisfactory solution has yet been reached. The most widely discussed alignment theory invokes the process of magnetic relaxation within dust grains which are spinning in the magnetic field of the galaxy[1]. Although this process could produce the correct sense of alignment of grains a high value of the magnetic field strength, greater than 10^{-5} G, seems to be required to produce sufficient alignment of most plausible grain models[2]. This minimum field strength requirement is in considerable excess of recent estimates of $\sim 10^{-6}$ G for the mean magnetic field in normal interstellar clouds. Two other mechanisms, also capable of producing the correct sense of grain alignment, were recently discussed by Salpeter and myself[3] and by Harwit[4]. The former mechanism requires a rather high value of the flux of low energy cosmic rays—a flux that now appears unlikely in view of recent arguments by Fowler, Reeves and Silk[5]. The mechanism proposed by Harwit[4], involving the transfer of internal angular momentum of stellar photons to grains, would appear to be effective only for relatively small-sized particles of a size distribution. Strong alignment effects are restricted to particles with radii $a \lesssim 5 \times 10^{-6}$ cm. The observed wavelength dependence of interstellar polarization, on the other hand, requires the alignment of larger grains with radii $a \gtrsim 10^{-5}$ cm (refs. 6 and 7). The several processes which have so far been discussed may thus be inadequate to accomplish the necessary alignment of interstellar grains.

It will be argued in this article that a galactic X-ray component in the energy range $\sim 0{\cdot}2$–$0{\cdot}4$ keV could play an important part in the alignment of dust grains. The requirement is that the total flux of soft X-rays at low galactic latitudes includes a modest local excess over the flux from an isotropic background. Observations by Cooke, Griffiths and Pound[8] have indicated that such an excess exists in the energy range 1·4–18 keV. Although observations at lower energies are at present somewhat uncertain the possibility of an excess flux arising from unresolved weak sources (in at least some directions in the galactic plane) cannot be ruled out. The alignment mechanism discussed here would, in any case, be expected to dominate in regions sufficiently near to galactic X-ray sources.

We first explore the effects of an excess galactic X-ray flux (of a prescribed intensity) in relation to the alignment of grains. We then derive an estimate of the magnitude of this excess flux which is required in order to accomplish the desired grain alignment.

The alignment process envisaged here involves photoelectric encounters of X-rays with grains, followed by the complete ejection of the resulting photoelectrons. It will be shown that the momenta of emitted photoelectrons are predominantly perpendicular to the direction of propagation of the original photons for the case of highly elongated grains. The resulting torques on the grains will be shown to be largely in the plane of the galaxy. This process would clearly tend to line up the angular momentum vectors of grains parallel to the galactic plane. Consequently the long axes of grains may be aligned preferentially perpendicular to the galactic plane—in accord with the observations of interstellar polarization.

I restrict my discussion to grains composed of silicate material ($MgSiO_3$) because there are arguments to suggest

that such grains may be responsible for interstellar polarization[6]. (My final conclusions will not be sensitive to this assumption, however.) I begin by noting that X-ray energies in the range $\sim 0{\cdot}2$–$0{\cdot}4$ keV—which would be of chief importance to the present process—lie between the K and L_1 edges of each of the constituent atoms in silicate material[9]. The atomic cross-section for photoejection of L electrons by such X-rays may be calculated from formulae derived by Hall[10]. For X-rays with energy $E \gg h\nu_{L_1}$ where ν_{L_1} is the L-edge frequency, the photoejection cross-section of an atom of atomic number Z may be shown to be

$$\sigma_L \cong 6{\cdot}4 \times 10^{-23}(Z-4{\cdot}15)^5\,(E/\mathrm{keV})^{-3{\cdot}5}\ \mathrm{cm}^2 \qquad (1)$$

Summing the contributions due to Mg, Si and O determined by equation (1) the total photoejection cross-section of $MgSiO_3$ then turns out to be

$$\sigma_L(MgSiO_3) \cong 8 \times 10^{-18}\,(E/\mathrm{keV})^{-3{\cdot}5}\ \mathrm{cm}^2 \qquad (2)$$

The stopping distance, D, of a photon of energy E which is intercepted by a grain is determined by

$$\sigma_L \cdot (N_0\,\rho/A) \cdot D \approx 1 \qquad (3)$$

where N_0 stands for the Avogadro number $\sim 6 \times 10^{23}$ cm^{-3}, ρ is the density and A is the molecular weight of the grain material. Setting $\rho \cong 3{\cdot}3$ g cm^{-3}, $A \cong 100{\cdot}38$ for $MgSiO_3$, equations (2) and (3) give

$$D \cong 6{\cdot}3 \times 10^{-6}\,(E/\mathrm{keV})^{3{\cdot}5}\ \mathrm{cm} \qquad (4)$$

Photons of energy $E \cong 1$ keV traverse a distance close to 10^{-5} cm before being stopped, while photons of energy $E \simeq 0{\cdot}3$ keV are absorbed within a few atomic radii of the grain's surface.

The absorption of a photon of energy in the range $E \sim 0{\cdot}2$–$0{\cdot}4$ keV results in the ejection of an L-shell electron from the grain material. The initial energy of the photoelectron is $E-h\nu_L$, where $h\nu_L$ is its binding energy in the L shell. To a sufficiently good approximation we may assume $E-h\nu_L \approx E$. The electron momentum, for the range of photon energies considered here, is predominantly transverse to the photon propagation vector[11]. The initial angular distribution of this momentum about the electric vector of the X-ray is $\sim\cos^2\xi\,d\Omega$ where $d\Omega$ is an element of solid angle in a direction making an angle ξ with the electric vector.

A further condition has to be satisfied for X-ray absorption to result in the transference of the required torques to the grains. The ejected photoelectron must leave the entire grain without being significantly slowed down or stopped within the grain. The characteristic stopping distance, d, of the electron in material possessing a mean excitation potential I, density ρ, mean atomic number $\bar{Z}$, and mean atomic weight $\bar{A}$ is given by[12]

$$d \approx \frac{E^2}{4\pi e^4 (N_0\,\rho \bar{Z}/\bar{A})\,.\,\ln(E/2I)} \approx 7{\cdot}6 \times 10^{-6}(E/\mathrm{keV})\ \mathrm{cm} \qquad (5)$$

where we set $\bar{A}/\bar{Z} \cong 2$, $\rho \cong 3{\cdot}3$ g cm^{-3} and $\ln(E/2I) \cong 0{\cdot}5$.

The condition that the ejected photoelectron escapes from the grain with a high probability, with an energy close to its initial value, is that the photon absorption depth D is much less than the electron stopping distance d. From equations (4) and (5) this condition yields $E < 1$ keV. We confine our attention in the subsequent discussion to the energy range $E \sim 0{\cdot}2-0{\cdot}4$ keV which satisfies this requirement and also ensures the validity of equation (2). For such X-ray energies photoejection of L electrons from silicate grains occurs within a few atomic layers of the grain surfaces. X-rays with energy much below 0·2 keV are unlikely to be important except near sources, on account of the strong absorption properties of the interstellar gas at these energies.

Consider X-ray photons of energy E propagating in a direction $\mathbf{x}$ close to the galactic plane and incident on a grain. I assume a needle-shaped grain with thickness small compared with its length, similar to the models used to discuss the wavelength dependence of interstellar polarization[6]. The orientation of the grain axis may be described by spherical polar coordinates taken at the centre of mass G, with the direction $\theta = 0$ taken to be the direction of the X-ray source $\mathbf{x}$ and the plane $\varphi = 0$ being the plane through $\mathbf{x}$ which is perpendicular to the galactic plane. The direction $\mathbf{x}$ is also taken to be the x-axis, GX, and the normal to the galactic plane through G as GY in a right-handed set GX, GY, GZ of rectangular cartesian axes. Let an X-ray photon be absorbed at a point on the grain surface the position vector of which is $\mathbf{r}$. We first suppose that the momentum of the ejected photoelectron is confined entirely to the YZ plane and may be represented by the coordinates $\mathbf{p} = (0,\ p\cos\alpha,\ p\sin\alpha)$. The angular momentum imparted to the grain is given by the vector product $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ the components of which are

$$[L_x, L_y, L_z] = [rp\sin\theta\,(\cos\varphi\sin\alpha - \sin\varphi\cos\alpha),\ -rp\sin\alpha\cos\theta,\ rp\cos\alpha\cos\theta]$$

We may now evaluate the average values $\langle L_x^2\rangle$, $\langle L_y^2\rangle$, $\langle L_z^2\rangle$ assuming equal *a priori* probabilities for all grain orientations, allowing for a geometrical projection factor proportional to $\sin\theta$, and for all photoejection angles α. Thus we obtain

$$\frac{\langle L_x^2\rangle}{\langle L_y^2\rangle} = \frac{\iiint \sin^2\theta(\cos\varphi\sin\alpha - \sin\varphi\cos\alpha)^2 \cdot \sin^2\theta\,d\theta\,d\varphi\,d\alpha}{\iiint \sin^2\alpha\cos^2\theta \cdot \sin^2\theta\,d\theta\,d\varphi\,d\alpha}$$

where the integrations over θ, φ, α are respectively over the ranges $(0,\pi)$, $(0,2\pi)$, $(0,2\pi)$. Performing these integrals we get $\langle L_x^2\rangle/\langle L_y\rangle = 3$. A more realistic estimate of this ratio may be obtained by taking into account the actual angular distribution of photoelectrons about the electric vector of incident X-rays. For the case where this distribution function is of the form $\cos^2\xi\,d\Omega$ it may be shown by a similar analysis that $\langle L_x^2\rangle/\langle L_y^2\rangle = 12/7$. This result will be assumed in the following discussion.

For a single absorption event of an X-ray propagating in a direction close to the galactic plane the increase in the grain's angular momentum in the galactic plane is by an amount

$$|\Delta L| \approx [2(E-h\nu_L)m_e]^{1/2}\,a \simeq (2Em_e)^{1/2}\,a \qquad (6)$$

where a is the r.m.s. distance from a typical point on the grain surface to the centre of mass of the grain. The component of the grain's angular momentum in the direction of propagation of X-rays therefore grows, by a random walk process, at a rate given by

$$\frac{d}{dt}\langle L_x^2\rangle \cong 2Em_e a^2 A \times \text{flux of X-ray photons of energy } E \qquad (7)$$

where A is the average target area presented by the grain. If $\varphi(E)dE$ denotes the differential energy spectrum of galactic X-rays, equation (7) may be written as

$$\left.\begin{aligned} \frac{d}{dt}\langle L_x^2\rangle &\cong 2m_e\,a^2\,A \cdot I \\ I &= \int_{0{\cdot}2\ \mathrm{keV}}^{0{\cdot}4\ \mathrm{keV}} E\varphi(E)\,dE \end{aligned}\right\} \qquad (8)$$

For the case considered above, the rates of growth of $\langle L_y^2\rangle$ and $\langle L_z^2\rangle$ are related to $\langle L_x^2\rangle$ by

$$\frac{d}{dt}\langle L_y^2\rangle = \frac{d}{dt}\langle L_z^2\rangle = \frac{7}{12}\,\frac{d}{dt}\langle L_x^2\rangle \qquad (9)$$

To assess the likely importance of the present alignment mechanism let us consider a situation where it operates independently of other alignment processes. The main disaligning mechanism is taken to be the effect of gas collisions which causes the square of any angular momentum component (in any direction) to increase at a rate

$$\frac{\mathrm{d}}{\mathrm{d}t}(L_g^2) \cong (m_H v_{th} a)^2 n_H v_{th} A \qquad (10)$$

where v_{th} denotes the r.m.s. velocity of gas atoms. The parameter Q_J (defined by Purcell[2]) which signifies the extent of angular momentum alignment in a steady-state situation may now be computed. Using the definition of $Q_J[=\frac{1}{2}(3\langle\cos^2\beta\rangle-1)]$ together with equations (8–10), we obtain

$$Q_J = \frac{\langle L_x^2\rangle - \frac{1}{2}(\langle L_y^2\rangle + \langle L_z^2\rangle)}{\langle L_x^2 + L_y^2 + L_z^2\rangle + L_g^2} = \frac{5\langle L_x^2\rangle}{26\langle L_x^2\rangle + 12L_g^2} = \frac{5I}{26I + 12\varepsilon} \qquad (11)$$

with

$$\varepsilon = \frac{(m_H v_{th})^2 n_H v_{th}}{2m_e} \qquad (12)$$

where the last equality in equation (11) is obtained by cancelling a common damping time τ. Taking $v_{th} \cong 10^5$ cm s^{-1} we obtain $\varepsilon \cong 10^{-6} n_H$ from equation (12) so that equation (11) gives

$$I \cong 10^{-6} n_H \frac{12Q_J}{5-26Q_J} \text{ erg cm}^{-2}\text{ s}^{-1} \cong 7{\cdot}5\times10^3\, n_H \frac{Q_J}{5-26Q_J} \text{ keV cm}^{-2}\text{ s}^{-1} \qquad (13)$$

The excess flux of X-rays in the galactic plane is thus related to the extent of alignment defined by Q_J and to the gas density n_H. The required value of Q_J depends on the optical asymmetry of the grains which is at present somewhat uncertain. Adopting $Q_J \cong 0{\cdot}1$ as a plausible estimate we obtain from equation (13)

$$I \sim 300\, n_H \text{ keV cm}^{-2}\text{ s}^{-1} \qquad (14)$$

With $n_H \sim 10$ cm^{-3}, in a typical interstellar cloud, the required galactic X-ray flux in the energy range 0·2–0·4 keV is thus $\sim 3\times10^3$ keV cm^{-2} s^{-1}. The galactic X-ray flux at low galactic latitudes must be in excess of the flux measured at high latitudes by this amount.

As we have already noted, Cooke *et al.*[8] have recently reported an excess X-ray flux in the energy range $E \sim 1{\cdot}4$–18 keV, of intensity comparable with that of the isotropic background, in directions close to the galactic plane. At lower energies there seems to be considerable uncertainty in the flux of diffuse X-rays. Several recent measurements of the diffuse flux at 0·25 keV differ by a factor of as much as five, with a mean value close to 450 cm^{-2} s^{-1} sr^{-1} keV^{-1} (refs. 13–17). There is evidence of an increase in flux with galactic latitude (for some galactic longitudes), suggestive of an extragalactic origin for this radiation. For our purposes we would thus require an excess flux $\sim 3{\cdot}10^3$ keV cm^{-2} s^{-1} in at least one direction close to the galactic plane so as to offset the effect of the reported extragalactic background which dominates at high galactic latitudes. Bunner *et al.*[17] have already found evidence to indicate a galactic flux at the Sun amounting to ~ 10 keV cm^{-2} s^{-1} at 0·25 keV from a region in the galactic plane close to $l^{II} \cong 155°$. The possibility cannot be excluded that a higher total flux amounting to $\gtrsim 3\times10^2$ keV cm^{-2} s^{-1} arises from other, yet unobserved directions in the galactic plane. This flux could occur either over a wide waveband or in the form of narrow emission lines.

In the absence of a total X-ray flux in the galactic plane exceeding ~ 300 keV cm^{-1} s^{-1} dust grains near the Sun would be aligned with their long axes preferentially parallel to the galactic plane. The required excess galactic flux would certainly exist in the vicinity of soft X-ray sources, however. The soft X-ray source Vela XR-2 (ref. 18) may be a prototype for such sources, and the excess galactic radiation observed by Bunner *et al.*[17] may also be attributed tentatively to unresolved sources of a similar kind. It would seem reasonable to suggest that the density of the appropriate type of X-ray sources may be sufficiently large to ensure that the required excess X-ray flux exists over a large part of the galactic disk. Such a situation would produce grain alignment in the sense required by the available polarization data while also explaining the observed heating and ionization of the interstellar gas[19,20].

The alignment mechanism discussed here differs from the usual magnetic theory in certain respects which may permit an observational distinction to be made. Magnetic alignment theories naturally predict a very close coincidence between the direction of symmetry of grain alignment (that is, the direction of maximum electric vector of starlight) and the direction of the local galactic magnetic field. In the present theory, on the other hand, a close coincidence of these directions is unlikely to be generally valid—although an approximate coincidence could arise indirectly due to a distribution of sources which is confined within the spiral arms. The relevant astronomical observations are yet too scanty to permit a conclusive distinction to be made. In a fairly localized region of the galaxy it appears that the two directions in question coincide only approximately to within $\sim 25°$ (ref. 21). A more detailed comparison between the directions of the maximum electric vector of starlight and that of the galactic magnetic field at various distances is clearly of crucial importance in deciding between the two alignment theories. It is also of interest to search for a possible relationship between the stellar polarization vectors and the distribution of X-ray sources in regions of the spiral arms which can be viewed from a transverse direction. Regions completely devoid of X-ray sources might be expected to show polarization vectors indicating the alignment of grain axes parallel, rather than perpendicular, to the direction of the local spiral arm. These effects may be distorted, however, if interstellar polarization in most cases arises from local dust clouds in the solar neighbourhood.

I thank Professor E. M. Purcell for pointing out a numerical error in an earlier version of this paper and Professor Purcell, Professor F. Hoyle, Mr P. G. Martin and Dr M. J. Rees for helpful comments and discussions.

Galactic Scattering and Discrete Sources as Possible Origins of the Diffuse Galactic X-ray Background

Cooke, Griffiths and Pounds[1] have recently reported an excess in the diffuse X-ray background intensity observed at low galactic latitudes, compatible with a line source of radiation in the galactic plane. Wickramasinghe[2] has put forward an explanation based on small angle scattering of the universal isotropic flux of X-rays by grains in the galaxy. The purpose of this article is seriously to question this hypothesis. Briefly, Wickramasinghe first argues that the albedo of the galaxy is near unity in the X-ray band, that is, the scattering cross-section of galactic material is quite high in certain directions, while the absorption cross-section is quite low. The second point in the argument is a derivation of a first order solution to the scattered component of the diffuse X-ray background. The answer obtained is

$$I_1(\theta) \simeq I, \ \theta \gtrsim 3^\circ \qquad (1)$$

where θ is the angle of the detector axis with the galactic plane, I_1 is the intensity of once-scattered X-rays observed in the direction θ, and I is the intensity of extra-galactic diffuse X-rays. Hence the observed intensity in a direction close to the plane would be about double that observed at large θ.

Although in the light of previous work by Bowyer, Mack and Lampton[3] it seems that the scattering cross-sections used by Wickramasinghe are overly optimistic, my argument is based on geometry only. The intention of this approach is to avoid the considerable uncertainties in the present state of knowledge about interstellar grains. I suggest that, if interstellar absorption of X-rays is neglected, the proper expression for the observed diffuse intensity in any direction is

$$I_{obs}(\theta) = I_1(\theta) + I_2(\theta) \qquad (2)$$

Here I_1 and θ are as in relation (1) and $I_2(\theta)$ is the intensity of unscattered X-rays arriving from the direction θ. Following Wickramasinghe, we write

$$I_1 \simeq \gamma(1 - e^{-\tau_1 \operatorname{cosec} \theta})\ I$$

where γ is the spherical albedo of a scattering particle, and $2\tau_1$ is the optical depth for scattering of the galaxy, considered as an infinite slab with the Sun on the central plane. Because $\gamma \simeq 1$, as mentioned already,

$$I_1 \simeq (1 - e^{-\tau_1 \operatorname{cosec} \theta})\ I$$

But

$$I_2 = I e^{-\tau_1 \operatorname{cosec} \theta}$$

Therefore $I_1 + I_2 \equiv I$.

In summary, this expression states that if photons are indeed deflected toward the Sun by interstellar grains, an equal number must be deflected away. Another explanation must be sought for the observed excess of diffuse X-rays near the galactic plane.

The discoverers of the galactic excess have argued against an origin in discrete sources, on the grounds that the excess is too smoothly distributed in space. One can calculate the flux due to unresolved sources in various models of the galaxy and compare the results with observation. One model, certainly wrong on the scale of one or two kpc, but possibly realistic on a galactic scale, is a uniform source distribution model. Let us consider the galaxy as a two dimensional disk of radius $R = 15$ kpc. The density of sources is $n = N/\pi R^2$, where $N \simeq 10^3$ (ref. 4) is the total number of sources in the galaxy. A typical source luminosity has been estimated as $L = 5 \times 10^{36}$ erg s^{-1} (ref. 4) in the X-ray band 1–10 Å, which corresponds to about 6×10^{44} photons s^{-1} at 5 keV, approximately the centre of the counter sensitivity,

The intensity to be expected from such a distribution of sources is

$$I = \frac{nL}{4\pi} \ln \frac{r_2}{r_1} = \frac{NL}{4\pi^2 R^2} \ln \frac{r_2}{r_1}$$

where r_2 is the distance to the edge of the galaxy along the line of sight, and r_1 is the distance of the nearest source. In order to estimate the intensity due to unresolved sources, I shall take r_1 as the distance beyond which no galactic sources have been unambiguously located, about 4 kpc.

In the direction $l^{II} = 300^\circ$, $r_2 = 1{\cdot}1\ R = 17$ kpc. Therefore, in the X-ray band

$$I \simeq 10 \text{ photons cm}^{-2}\text{ s}^{-1}\text{ rad}^{-1}$$

This number is almost embarrassingly large, twenty times the flux that has to be explained. The reason that such a large unresolved contribution is not observed might be a lower average source luminosity than previously estimated, or a lower number of sources in the galaxy, or a very strong concentration of sources toward the galactic centre, in contradiction to the uniform model of the galaxy considered here. The fact remains, however, that an estimate of the X-ray intensity due to far-away sources, based on presently accepted ideas about sources, is actually higher than the observed effect. Surely this simple calculation indicates that the discrete source hypothesis cannot be dismissed lightly in discussions of this effect.

Galactic Component of the Diffuse X-ray Background

WICKRAMASINGHE'S model for the galactic component of the diffuse X-ray background[1], which involves scattering of the isotropic component by dust grains, unfortunately contains a fundamental error which completely invalidates it. Particles along a line of sight may indeed scatter isotropic background radiation into the line of sight, but by the same process they will also scatter out of the line of sight the background radiation originally travelling in this direction (ref. 2, for example). If there is no absorption (that is, the albedo is unity) the two scattering effects are equal; this situation now satisfies the first and second laws of thermodynamics and ensures that the galactic disk is quite indistinguishable from the rest of the background. If the albedo is less than one, then the disk should show up in absorption, in contradiction with the observations. In no conditions can the model increase the flux from the disk relative to that of the isotropic background.

Reply to Mack and Webster

As pointed out in my article[1] dust grains distributed throughout the disk of the galaxy will scatter X-ray photons from the isotropic cosmic background as well as from discrete sources. While I agree with the comments of Mack and Webster concerning the scattering of the isotropic background by dust I would like to point out that a diffuse galactic X-ray component similar to that observed[2] could arise from the scattering of X-rays from discrete sources. In discussing the contribution from discrete sources Mack neglects scattering by dust. It is likely that this effect is important for distances exceeding a few kiloparsecs. The analysis presented earlier is evidently valid for this case with two provisos: (*a*) discrete X-ray sources are distributed more or less uniformly (with respect to mean volume emissivity) throughout the hydrogen–dust layer of the galaxy, and (*b*) the intensity I (equations (6) and (7) of ref. 1) is defined as the ratio of the mean X-ray emissivity (due to sources) per unit volume to the X-ray extinction per unit distance, and this quantity is assumed comparable with the intensity of the isotropic background.

The data at present available on X-ray sources do not conflict with these requirements. A scattering model of the type considered could produce a fairly smooth galactic X-ray background with the observed concentration towards the galactic plane without requiring an excessive concentration of weak unresolved sources very near the galactic plane.

Effect of Quantum Conditions in a Friedmann Cosmology

THE observed isotropy of the microwave background and its primordial interpretation has led many to investigate the nature of particle horizons in cosmological models near the initial singularity. The standard Friedmann radiation universe

$$ds^2 = dt^2 - \lambda t[dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2)],\ \lambda = \text{constant} \quad (1)$$

has a particle horizon at

$$r = 2\left(\frac{t}{\lambda}\right)^{1/2} \quad (2)$$

at epoch t. Thus near the singularity $t=0$, very limited causal communication is possible between different parts of the universe. The observed isotropy of the microwave background cannot be understood in such a model except as arising from artificially imposed initial conditions. Misner[1] has sought to remedy the situation by looking for solutions of the classical Einstein equations very different from the Robertson-Walker form (to which that given by equation 1 above belongs). These solutions permit unlimited communication near $t=0$.

The purpose of this note is to point out that near the singularity quantum effects are important and may permit unlimited communication near $t=0$, even in the Robertson-Walker form.

There have been many different approaches to a quantum theory of gravitation. Here we adopt Feynman's path integral approach[2], for it best illustrates the difference between the classical and quantum theories. The basic concepts in relation to gravitation have been discussed by Wheeler[3] and are briefly described below. Suppose the system is specified by an action S. Classically, the transition of the system from a state I to a state II is described by a unique path Γ_c given by the principle of stationary action:

$$\delta S = 0 \quad (3)$$

In quantum theory, there is no unique path Γ_c; all paths from I to II are possible. The probability amplitude for the system to adopt a given path Γ is proportional to

$$\exp\{iS/\hbar\} \quad (4)$$

where S is computed along Γ. The classical limit (3) follows when $\hbar \to 0$ or alternatively when $S \gg \hbar$. In this case only paths close to Γ_c contribute any significant amplitude.

In Einstein's theory of gravitation, the action is

$$S = \frac{1}{16\pi G}\int R\sqrt{-g}\, d^4x - \sum_a \int m_a\, da \quad (5)$$

where radiation is temporarily omitted. R is the scalar curvature, g the determinant of the metric tensor, m_a the mass of a typical particle a. The volume integral is over the entire space time and the line integral is over the world line of a. Einstein's equations follow in the classical limit (3); but in the quantum theory this is not the case. We wish to consider equation 5 in relation to a Friedmann cosmology satisfying Einstein's equations

$$R_{ik} - \tfrac{1}{2} g_{ik} R = -8\pi G\, T_{ik} \quad (6)$$

Using the Robertson-Walker form of the metric

$$ds^2 = dt^2 - Q^2(t)\left[\frac{dr^2}{1-kr^2} + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2)\right], k = 0, \pm 1 \quad (7)$$

and specifying the 4-dimensional volume by $0 \leq t \leq t_0$, $0 \leq r \leq r_0$, we get

$$S = -\tfrac{1}{2} t_0\, \rho Q^3 \int_0^{r_0} \frac{r^2\, dr}{\sqrt{1-kr^2}} \quad (8)$$

In arriving at equation 8 we have assumed ρ to be the mean density of matter so that ρQ^3 is constant, and used the fact that from 6

$$R = 8\pi G\rho \quad (9)$$

Evidently, for a specified r_0, we can choose t_0 smal enough to make $S \sim \hbar$. If, for example, we fix r_0 so as to include the part of the universe that we observe at the present day (and which is known to be isotropic from the microwave background observation), $t_0 \lesssim 10^{-102}$ s! At or before this epoch, classical conditions are no longer valid, and we are no longer limited to solutions of Einstein's equations. Any space time metric can be chosen provided the magnitude of S computed for it is comparable with $\hbar$. It is possible, for example, to take the metric

$$ds^2 = dt^2 - \alpha^2 t^2\left[\frac{dr^2}{1+r^2} + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2)\right] \quad (10)$$

$$\alpha = \text{constant},$$

for this gives $R = 0$. Such a universe with trace free T_{ik} would therefore have $S = 0$.

This metric has the desired property of unlimited communication near $t = 0$. A light signal emitted at $t = t_1$ from $r = 0$ reaches $r = r_0$ at time $t = t_2$, where

$$r_0 = \sinh\left\{\alpha^{-1} \ln \frac{t_2}{t_1}\right\} \quad (11)$$

Thus for any t_2, r_0 can be made arbitrarily large by taking t_1 near enough to $t = 0$. Because the restriction of Einstein's equations is removed, many more Robertson-Walker type models with unlimited communication and $S \sim \hbar$ are possible. The quantum universe could have taken any one of these possible paths.

The question now arises of whether the above argument would be seriously changed by an electromagnetic field, such as the microwave background, assumed primaeval. The action is changed by

$$\frac{1}{8\pi} \int (E^2 - H^2) d^4x \quad (12)$$

where (E, H) is the electromagnetic field. This is zero for a transverse field, so such a field has no action contribution that would affect the argument directly. Nor does the gravitational action change, for T_{ik} is traceless. It follows that a transverse field would have no effect on the argument if it were uncoupled from matter. Near $t = 0$, however, the background would have a very high temperature and a profusion of particle pairs would be created. But such particles would not be comoving with respect to the coordinate system. For pairs produced by very high energy quanta $da \sim 0$ instead of $da = dt$ assumed in arriving at equation 8. In so far as particles move at speeds close to that of light they behave essentially as quanta, in which case the situation is not changed. There would seem therefore to be a strong *prima facie* case that quantum effects are important in establishing communication near the singularity of a Friedmann cosmology.

Is Ball Lightning a Nuclear Phenomenon?

BALL lightning is characterized by the presence of a luminous mobile globe of high energy density produced in regions of considerable electrical activity. The properties of ball lightning have been outlined in recent surveys[1-4]. We are interested here in the few but significant cases of high energy ball lightning.

In one incident a lightning ball fell into a rain barrel and boiled 18 l. of water for a few minutes[5]. The energy of the ball was estimated as 8×10^6 J with an energy density between 2×10^9 and 5×10^9 J m^{-3} (refs. 4, 6, 7).

Another report[8], brought to our attention by C. M. Botley, describes a red lightning ball about 60 cm in diameter which dug a trench 100 m long and 1·2 m deep in soft soil near a stream, and then tore away another 25 m of stream bank. If the trench was about 1 m wide, the energy expended by the ball must have been at least 3×10^6 J and very likely more than 10^7 J, with an energy density in the ball exceeding 10^8 J m^{-3}. On the other hand, if this ball had an energy density of 4×10^9 J m^{-3}, as in the rain barrel case, the total energy would have been 4×10^8 J.

There are reports of ball lightning exploding or shattering wooden logs[9], cutting metal cables and wires[10], or doing damage requiring surprisingly large amounts of power.

In both of the cases cited, and in several other cases also indicative of high energy ball lightning, an energy density significantly higher than 10^8 J m^{-3} is indicated. This means that if the energy were stored by chemical means, the ball would have to consist of air or gas which is at least singly ionized. Experimental results, however, indicate that an ionized ball of air, ozone or any of the nitrogen oxides could not remain ionized in the atmosphere for longer than a few tenths of a second without an external supply of power[11]. The decay of an ionized ball of air would most likely be explosive. According to the rain barrel report, however, the water boiled for a few minutes, and remained hot even after 20 min. We conclude that the ball lightning supplied at least 5×10^4 W of power to the water in the rain barrel for a few minutes at a relatively steady rate (in other words, not explosively). The case of the trench-digging ball also indicated a large but continuous power release.

Another difficulty with the idea that all the energy of ball lightning is stored in the form of ionized air is the absence of any indications of intense heat. Ball lightning does not rise like hot air nor is it disrupted by convection into a thermal plume as are hot fireballs. Magnetic containment of a hot plasma under normal atmospheric conditions is not possible at the required energy density[12] and in any case would be subject to convective disruption as well. A cold degenerate plasma ball[13] held together by exchange forces or collective plasma modes would not emit enough light to make the ball visible.

If the energy of ball lightning were maintained by the focusing of microwaves[14] or electric currents[11] into a small volume perhaps through standing waves[14] or converging electric fields[11], then ball lightning could not enter metallic enclosures. Nevertheless, we have several reports of ball lightning floating for several seconds down the aisles of metallic passenger aircraft[15,16], as well as into homes[10]. No luminous trails leading to the ball from the outside environment have been reported, as far as we know. Such trails should be visible or noisy if they transmit 10^4 to 10^6 W of power and should affect the geometry and luminosity of ball lightning as it moves around inside the enclosure. This is not the case[15].

An adequate theory of high energy ball lightning must explain (1) the large energy density, (2) the large but non-explosive power release, (3) the absence of convective effects, (4) the small amount of acoustic, visible, infrared, and ultraviolet radiation, (5) the reported electrical effects, and (6) the stability of ball lightning. In our opinion, none of the theories so far proposed[3,17] regarding the nature of high energy ball lightning is satisfactory if we assume the veracity of the reports.

We consider the possibility that ball lightning is a nuclear phenomenon. The most abundant isotopes in a thundercloud are ^{14}N and ^{16}O from the air, and ^{1}H (protons) from water vapour and droplets. If nuclear reactions do occur in a lightning discharge, those reactions induced by electron–nucleon collisions would not be important because of the large mass difference and small energy transfer per collision. A set of nuclear reactions for consideration in lightning is

$$^{14}N + p \rightarrow {}^{15}O + \gamma$$
$$^{16}O + p \rightarrow {}^{17}F + \gamma$$

The protons are supplied by dissociated water molecules in the lightning discharge. If a sufficient quantity of ^{15}O and ^{17}F nuclei could be produced within a relatively small volume (less than a metre in diameter) by a lightning stroke, the beta decay of these nuclei might produce an effect such as ball lightning. The beta decay reactions are

$$^{15}O \rightarrow {}^{15}N + \beta^+ + \nu$$
$$^{17}F \rightarrow {}^{17}O + \beta^+ + \nu$$

The half-lives of the ^{15}O and ^{17}F nuclei are 123 s and 66 s respectively. Electron-capture competes with positron-emission but accounts for only about 0·1 per cent of the beta-decay events[18].

By this hypothesis, to produce high energy ball lightning of 10^7 J would require a blob of air containing roughly 10^{20} nuclei of ^{15}O or ^{17}F. If such a ball had a diameter of 20 cm, one out of every 2,000 nuclei would be either ^{15}O or ^{17}F. The beta decay process produces positrons, most with energies around 0·5 MeV, which dissociate the surrounding air molecules. The visible effects are similar to those of a glow discharge. Of the roughly 10^5 W emitted by the ball, about 100 W might appear as visible radiation. When the positrons annihilate with electrons after traversing less than 2 m in air, the energy is converted into 0·5 MeV gamma rays which dissipate the energy over a radius of several hundred metres. In contact with water, the entire energy dissipates in about 40 cm, causing boiling or explosions from sudden vaporization of water.

The cohesion of the ball would result from a radial electrostatic field in a partially ionized plasma. As positrons leave the centre of the ball, a negative charge remains behind; where the positrons annihilate electrons in the air surrounding the ball, a positive charge is generated. The positron current from the centre to the periphery of the ball is about 0·1 A. (From the rain barrel report, 10^7 J was dissipated in about 100 s, which means about 10^{20} positrons in 10^2 s, or 0·1 A.) It is likely that the radial electric field will increase to a large value in the lightning ball, because free electrons readily attach to oxygen and to halogen contaminants, so that the neutralizing current is a relatively slow ion drift. If the electric field can be limited by ionic drift, the ball will die silently. If the electric field cannot be limited by ionic drift but continues to increase, an avalanche will eventually occur and create a radial arc discharge. The ball will then assume a dazzling brightness, the cohesive electric field will be shorted out and the ball will disappear with an implosive noise.

The primary theoretical difficulty with the nuclear hypothesis is the production of 10^{20} nuclei of either ^{15}O or ^{17}F in a small volume in a time scale of 10^{-3} s. When dissociated, water vapour in a thick cumulus cloud (10^{-5} g cm^{-3}) could supply protons at 7×10^{17} cm^{-3} and ^{16}O nuclei at $3{\cdot}5 \times 10^{17}$ cm^{-3}. In heavy rain the water (10^{-3} g cm^{-3}) could supply 100 times as many protons as water vapour.

A detailed calculation shows it would be possible to create sufficient numbers of ^{15}O and ^{17}F nuclei with lightning parameters, if thermal equilibrium conditions could prevail for 10^{-3} s in a sphere less than 20 cm in diameter at a mean proton energy between 0·1 and 1·0 MeV. Thermal equilibrium conditions, however, seem extremely unlikely.

Consider instead a beam of protons travelling down the lightning channel. The cross-section for the reaction of ^{14}N with a proton at 1 MeV is 2×10^{-28} cm^2. If we assume an ^{14}N background of 4×10^{19} cm^{-3}, the absorption coefficient is only 8×10^{-9} cm^{-1}. If all the available protons, between 7×10^{17} and 7×10^{19} cm^{-3}, were accelerated to 1 MeV (or $1{\cdot}4 \times 10^9$ cm s^{-1}), the reaction rate would be between 8×10^{18} and 8×10^{20} cm^{-3} s^{-1}. In 10^{-3} s there would be between 8×10^{15} and 8×10^{17} reactions cm^{-3}. A volume of between 10^4 and 10^2 cm^3 (that of a sphere between 20 and 5 cm in radius) would be required to create ball lightning. It is likely, however, that only a very small percentage of the protons is accelerated to 1 MeV because the mean free path of a proton in air is small (10^{-5} cm). In fact, even a 1 MeV proton can travel only about 1 cm through air before it becomes thermalized. Even if enough reactions can occur in a lightning flash, there is the problem of localizing and confining the radio-isotopes to a small volume during the creation process.

According to the nuclear hypothesis, an observer standing within 2 m of high energy ball lightning (10^7 J) for a few seconds might receive a radiation dosage of a few hundred rad, enough to cause radiation sickness or death. Most ball lightning, however, is probably 10 to 100 times less energetic, so that the radiation dosage would not cause biological effects.

Although the theoretical objections against a nuclear energy source for ball lightning are numerous and difficult, the nuclear hypothesis can at least be tested experimentally. The isotope abundances of air and water can be measured just after tornadoes, intense thunderstorms and (if possible) ball lightning decay. If the relative abundances of ^{15}N and ^{17}O in the sample are found to be a few tenths of a per cent higher than normal, the result would support the idea of a nuclear origin for ball lightning.

We thank C. M. Botley for many reports of ball lightning, and J. D. Sartor and A. Skumanich for useful comments.

Plate Tectonics of the Red Sea and East Africa

McKenzie *et al.*[1] have produced a strong case for considering the East African rifts and the Afar triple junction in terms of oceanic plate tectonics. I should like to present some arguments suggesting that modification to plate analysis of continental regions is required, for tensional as well as for compressional zones[2].

The Afar triple junction is unique in being a land area so that its stratigraphical, volcanological and structural evolution is exposed. McKenzie *et al.* seem to pass over what is known about this evolution[3,4], with the result, for example, that they have recourse to a "jumping" of the Red Sea spreading axis across the Danakil horst. The evidence for Quaternary crustal spreading in northern Afar, associated with rotation of the Danakil horst[3-6], indicates that two parallel lines of spreading are pushing apart at the southern end of the Red Sea. This requires uncoupling of the sialic Danakil block from the underlying spreading movements, as does the non-parallelism of the spreading axes with the opposing margins of the Red Sea basin. Furthermore, McKenzie *et al.* ignore the existence of the Aisha horst, another sialic block in Afar, against which the Gulf of Aden abruptly impinges. Both the Danakil and Aisha horsts show evidence of considerable compressional deformation.

A coast-to-coast fit across the Red Sea[1] is unrealistic when the geology of Afar is considered. The visible outcrop of sialic rocks in the vicinity of latitude 14° N limits the width of neo-oceanic crust between the Ethiopian and Yemeni plateaux to 250 km along the postulated spreading direction here, or to only 200 km according to Tazieff and Varet[7]. Although the sialic crust exposed in Afar and the bordering horsts is undoubtedly thinned by normal faulting, calculation shows that continental crust must extend for some tens of kilometres offshore under the Red Sea. In western Afar sialic rocks extend for as much as 60 km eastwards of the Ethiopian plateau escarpment in the downwarped and antithetically faulted margin zone between plateau and rift[8].

The extension of continental crust under the margins of the Red Sea requires a reappraisal of McKenzie *et al.*'s rotational pole for the Nubian and Arabian plates. Phillips *et al.*[8] have shown that in the central Red Sea (vicinity of latitude 20° N) the axial trough and associated magnetic anomalies have a zigzag pattern, which seems to fit best with a Quaternary spreading vector between N and NNE. This vector simplifies the analysis of the Sinai triple junction given by McKenzie *et al.*, the Dead Sea representing a transform fault, and the opening of the Gulf of Suez is reduced to a magnitude more consistent with the geology. The NNE spreading vector, and a 20 km extension of continental crust under the Red Sea margins, are mutually consistent if the Nubia–Arabia pole of McKenzie *et al.* is placed farther south near Benghazi, Libya.

If the validity of the Gulf of Aden (Arabia–Somalia) pole is accepted, adjustment of the Red Sea pole requires a corresponding adjustment of the East African rift pole. Also the geology of the African rift system shows that this latter pole is not placed correctly. The model of McKenzie *et al.* shows a total separation of 60 km between Nubia and Somalia at the north end of the principal Ethiopian rift. This is almost the whole width of the rift at this latitude. Although the basement rocks of the rift are obscured by thick silicic volcanics here, structural evidence suggests that at least the greater part of the rift is underlain by sialic rocks[9]. Further south, in the Lake Margherita basin, the principal Ethiopian rift is visibly floored with Pre-Cambrian gneisses[10]. The model of McKenzie *et al.* requires about 50 km of total spreading here, which is irreconcilable with the known amounts of normal faulting, even including the imposing Amaro horst.

A rotation pole for the East African rifts at 8·5 S, 31·0 E, is incongruous with the apparent unity of the African rift system as a whole, which continues well to the south of the proposed pole. If a single pole could be applied to the African rift system, then structural evidence suggests it would lie south of Beira. This is in keeping with the adjustment of the Red Sea pole discussed earlier.

But McKenzie *et al.* acknowledge, from the evidence of seismicity, that the applicability of a single pole to the rift system is doubtful. This is confirmed by the occurrence of structural triple junctions within the system (for example, in southern Tanzania and central Kenya), of rift bifurcations (for example, at Lake Rudolf), and rift and fracture zones within supposedly rigid plates (for example, at Lake Tana and at Jebel Dumbeir in the Nubian plate[11]). In terms of plate tectonics, at least four small plates must be considered in eastern Africa, all moving apart or transforming with respect to one another. This reduces the value of seismic slip vectors from eastern Africa in analysing the Afar triple junction.

The evaluation of plate boundaries in the African rift system is complicated by the lack of a ridge-transform fracture pattern, from Afar southwards, and the curvilinear plan of the Western Rift, like that of the Baikal rift, seems inexplicable in terms of oceanic tectonics. Gilluly notes[12] precisely the same difficulties in reconciling the Basin and Range tectonics of the western United States with a presumed sub-crustal extension of the East Pacific Rise. As Gilluly remarks, if this presumption is true, then uncoupling must occur, a mechanism also proposed for the Rhine graben[13] in relation to sub-crustal processes.

Does plate theory tend to break down at very small rates of relative motion? Unfortunately, the African rift system is ill suited to answering this question, because the complicating effect of the presence of continental crust over a spreading zone is not yet evaluated. It is striking that very similar rift valleys occur in other continents (for example, the Baikal and Rhine rifts), which are apparently unconnected with sea floor spreading processes. The manner in which some continental rifts peter out laterally (for example, the Kavirondo and Tana rifts) suggests that an analysis of the mechanical properties of continental crust above a spreading layer is required. It is clear that the total vertical and horizontal displacements in continental rift valleys are of a comparable order[14].

Finally, if McKenzie *et al.*'s analysis of the Afar triple junction is correct, the Arabian, Nubian and Somalian plates should fit back against the spreading axes. A triple junction of three spreading axes is theoretically stable[15], but the gross asymmetry of, for example, the spreading axis in the western Gulf of Aden indicates (i) an asymmetric axial spreading[16], which raises problems of the manner of dyke injection, or (ii) lithospheric uncoupling such that the spreading axis has a component of motion independent of the continental margins. Whichever suggestion might be correct, oceanic-type plate tectonics is evidently subject to modification in the Afar region.

The importance of realizing this is underlined where McKenzie *et al.* consider the 1969 Sardo seismicity, and its sinistral shear along NW fracture lines[17], as being related to movement along a major plate boundary. Not only

is this difficult to reconcile with the regional structure of Afar[3], but sinistral shear has affected much of eastern Afar during the Quaternary, across a zone more than 100 km wide. Furthermore, in spite of the evidence of ground deformation and focal-mechanism analysis for a NW–SE fault plane[1,17], the Sardo aftershocks are distributed along an east–west line[18], a structural direction which is not expressed by surface faulting in Afar[7].

Elsewhere[19] I reconcile the bifurcation of spreading axes at the south end of the Red Sea with the tectonics of Afar, in particular with NW–SE sinistral shear in eastern Afar. It turns out that the Danakil and Aisha horsts have played a determining part in the evolution of Afar, and are far from being passive sialic fragments of accidental import. If my model is correct, the regional tectonism of Afar underwent a drastic change in the late Pliocene–early Pleistocene such as would not be inferred from previous studies[1,15].

I thank Mr B. H. Baker for suggestions towards clarifying the arguments set out here, and Dr D. Davies for helpful discussions.

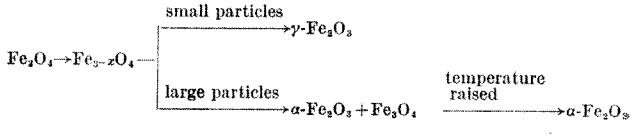
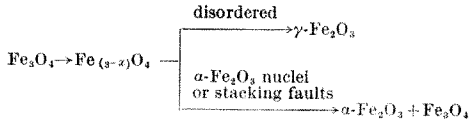
Mechanisms for the Oxidation of Fe_3O_4



We have published results[1] of a study of the kinetics of the oxidation of a sample of Fe_3O_4 consisting of submicron crystals almost perfectly cubic and almost uniform in size[2]. In agreement with Egger and W. F.[3] and W. F.[4,5], it was found that the reaction was single phase topotactic ($Fe_3O_4 \rightarrow Fe_{3-x}O_4 \rightarrow \gamma\text{-}Fe_2O_3$). The mechanism proposed was based on the diffusion of iron cations, the coefficient of which was found to depend on the Fe^{2+}/total iron ratio. When a model of this mechanism was simulated on a computer, an accurate prediction was obtained of the kinetic behaviour over all composition ranges.

The model also predicted that during oxidation a high concentration gradient of cation holes would develop in the monocrystalline particles, leading to a gradient in the lattice constant. Thus lattice strain would develop, and we found that the broadening of the reflexions in quenched samples increased to a maximum at about 16 per cent Fe^{2+} and then diminished and returned to the original value when the reaction was complete. The effect on large particles must be greater than on small particles. Lattice strain was assumed in earlier work to be the cause of nucleation of $\alpha\text{-}Fe_2O_3$ in large particles to explain the role of particle size in controlling the path taken by the oxidation; in other words, why the end product is $\gamma\text{-}Fe_2O_3$ for small particles, $\alpha\text{-}Fe_2O_3$ for large particles[3–5].

Colombo *et al.*[6] have criticized these views and suggested that $\alpha\text{-}Fe_2O_3$ forms only when nuclei of $\alpha\text{-}Fe_2O_3$ or stacking faults are present in the Fe_3O_4. They maintained that their results indicate clearly the incorrectness of the interpretation of the part played by grain size in the mechanism proposed by K. J. G. *et al.* We wish to point out that this claim is based on a misunderstanding; grain size as such played no part at all in our mechanism for cation transport in the reaction $Fe_3O_4 \rightarrow \gamma\text{-}Fe_2O_3$, and thus Colombo's results are irrelevant to any discussion of the validity of this mechanism.



On the question of oxidation to $\alpha\text{-}Fe_2O_3$ their results disagree with evidence previously presented[3–5], which established that particle size was chiefly responsible for determining whether $\alpha\text{-}Fe_2O_3$ would appear in the end product. Our view may be summarized as follows. In all preparations of Fe_3O_4 the first step of the oxidation of Fe_3O_4 is a single phase topotactic reaction leading to the intermediate solid solution phase, $Fe_{3-x}O_4$, which is a solid solution phase. If the particles are small (less than about 3000 Å), the reaction rate is great even at low temperatures and the oxidation comes to an end in a reasonable time. With increasing size, the temperature has to be raised to complete the reaction. As $\gamma\text{-}Fe_2O_3$ undergoes a phase transition to $\alpha\text{-}Fe_2O_3$ at higher temperatures[8] a point is reached when nuclei of $\alpha\text{-}Fe_2O_3$ appear spontaneously in the surface layer of $\gamma\text{-}Fe_2O_3$. The underlying intermediate solid solution phase then disproportionates to $\alpha\text{-}Fe_2O_3$ and Fe_3O_4, the former building up a layer at the surface, hindering further oxidation.

We formulate the reaction path

The first step in the reaction path of Colombo *et al.* is the same as ours. But they maintain that during the second stage only disordered samples oxidize readily to $\gamma\text{-}Fe_2O_3$ and that $\alpha\text{-}Fe_2O_3$ is formed only when $\alpha\text{-}Fe_2O_3$ nuclei or stacking faults are present.

Their reaction path can be formulated

We would like to make the following comments on their arguments. The sensitivity of X-ray diffraction for the detection of traces of $\alpha\text{-}Fe_2O_3$ is given by Colombo *et al.* as "$\pm$0·05 per cent" (they refer to accuracy; we assume they mean sensitivity which is more relevant to the detection of one phase in the presence of another); this is much lower than anything we and other authors have found, using the same technique and time of exposure. The sensitivity with which traces of a second phase in another can be detected depends much on the crystal size of the former. To be detected the trace component would have to be considerably larger than 300 Å. For a sample of Fe_3O_4 with a size of 3000 Åa content of 0·05 per cent $\alpha\text{-}Fe_2O_3$ would mean that on the average there would be just one $\alpha\text{-}Fe_2O_3$ particle in one Fe_3O_4 crystal. We do not therefore understand how the autocatalytic growth of $\alpha\text{-}Fe_2O_3$ nuclei could lead to a continuous layer of $\alpha\text{-}Fe_2O_3$

on the surface and prevent further oxidation inside the particle.

Contrary to Colombo *et al.*[6], samples of Fe_3O_4 prepared by the wet oxidation method never showed traces of α-Fe_2O_3 in X-ray diagrams. To test whether samples prepared by this method[7], but in conditions which produce large particles ($\sim 0{\cdot}5$ μm) and thus oxidize to α-Fe_2O_3, might contain initial traces of α-Fe_2O_3 which had escaped detection, we have carried out a few simple experiments (after the appearance of the report by Colombo *et al.*). We did this by heating a sample for 60 h in a CO/CO_2 (1 : 9) mixture at 550° C. The oxidation behaviour was similar to that of the untreated sample, that is, disproportionation of the intermediate phase at 320° C and the formation of α-Fe_2O_3 without any appearance of γ-Fe_2O_3.

Furthermore, the isothermal oxidation of two samples of Fe_3O_4 prepared by reduction of α-Fe_2O_3 in an H_2/H_2O mixture[3] (particle size $\sim 0{\cdot}6$ μm), one with traces of α-Fe_2O_3 and one without, yields in both cases, after oxidation at 220° C for 4 h, about the same small amount of α-Fe_2O_3 in addition to $Fe_{3-x}O_4$. When these two samples were then treated in the same CO/CO_2 mixture at 550° C for 60 h they also produced small amounts of α-Fe_2O_3 and $Fe_{3-x}O_4$ after oxidation, also at 220° C for 4 h.

These new results confirm that spontaneous nucleation of α-Fe_2O_3 occurs and that it is not necessary for nuclei to be present in the original sample for the formation of α-Fe_2O_3. During isothermal oxidation, nucleation of α-Fe_2O_3 can occur at a much lower temperature in large particles. For example, nucleation was observed in a particle size of $\sim 0{\cdot}5$ μm at 180° C after about 96 h. We are convinced that, if Colombo *et al.*[9] had oxidized their sample described as "stoichiometric Fe_3O_4 particle size 0·4" of their Fig. 2, somewhat more than 4 h at 220° C, nucleation of α-Fe_2O_3 would have taken place.

Colombo *et al.* mention that stacking faults in the Fe_3O_4 preparations produced chiefly by ball milling yield nuclei of α-Fe_2O_3. We do not find in any of the articles of Colombo *et al.* mentioned in the letter to *Nature*[6], nor in an earlier communication[9], a clear proof by, for example, electron diffraction, that any of their preparations of Fe_3O_4 contained stacking faults.

Colombo *et al.*[6] conclude from their Fig. 1 "that oxidation of magnetite to yield solid solution does not lead to any lattice strain". We have observed, however, that during the oxidation leading to the solid solution phase the shift of the Fe_3O_4 lines is accompanied by a small broadening in quenched samples. For samples with small particles which yield γ-Fe_2O_3 as the end-product the width of the reflexion reaches its maximum at about half-way through the oxidation, then diminishes, and in the γ-Fe_2O_3 the lines become as sharp as those of the initial Fe_3O_4, again in quenched samples. As pointed out in the previous article[1], the line broadening disappears when samples are annealed in the absence of oxygen. Colombo *et al.*[6] do not state whether their samples were quenched during the reaction. Quenching is essential for preserving the concentration profile for cation vacancies which develops during the reaction. As the crystal size does not change, line broadening in samples quenched after oxidation can be caused only by the lattice parameter varying with the concentration gradient; this means that strain must be present. It is irrelevant which method is used to calculate the degree of strain from the shape and width of the reflexions. The method we used was due to Kochendörfer, which Colombo *et al.* allege to be inaccurate.

We agree with Colombo *et al.* that considerable strain develops when α-Fe_2O_3 forms during isothermal oxidation. This is to be expected in any situation where a new phase the lattice of which is different from the host lattice nucleates *in situ*. This strain, however, does not require quenching to be observed.

Colombo *et al.* write that disordered samples oxidize readily to γ-Fe_2O_3. No details are given[6,10] what kind of disorder is meant; in other words, whether it is irregular lattice disorder[11], faulting on certain *hkl* planes, dislocations or clusters of dislocations[12]. No direct evidence is given for such disorder.

BIOLOGICAL SCIENCES

Thermodynamics of the Reversible Oxygenation of *Bis*(Acetylacetone)-Ethylenediiminecobalt (II) in Pyridine

The reversible reaction of certain cobalt chelates with molecular oxygen can be considered as a simple model of the reversible oxygen binding by haemoglobin and myoglobin[1,2]. It was recently pointed out[3–6] that in

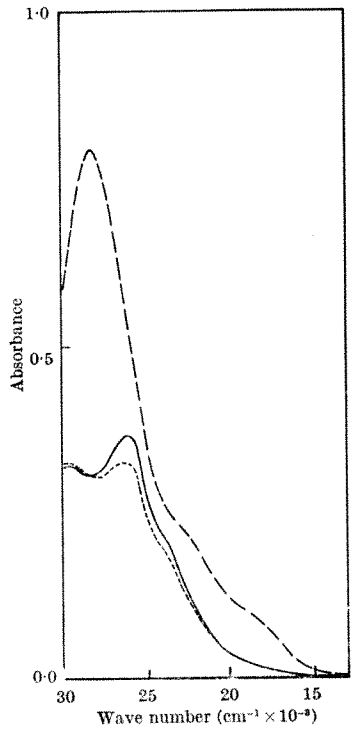

Fig. 1. Visible spectra of: Co^{II}BAE in $6{\cdot}7 \times 10^{-4}$ M pyridine (———); the same solution saturated with oxygen (– – –); after 20 min bubbling nitrogen (- - -).

suitable experimental conditions synthetic oxygen carriers show a reaction stoichiometry corresponding to one oxygen molecule per metal atom. In both cases the six-coordinated complex with oxygen can be formed by an equatorial tetradentate chelating agent and a donor ligand in the axial position *trans* to oxygen[4]. The reversibility of oxygenation seems to depend on a non-polar environment of the metal provided by the aprotic solvents in the simple complexes and by the hydrophobic pocket accommodating the haem in haemoglobin[7].

In spite of numerous descriptions of cobalt complexes in recent years[1], there has been no detailed analysis of the equilibrium and kinetic aspects of the reaction with oxygen. A preliminary survey of several oxygen binding cobalt(II) complexes indicated that *bis*(acetylacetone)-ethylenediiminecobalt(II) (Co^{II}BAE) was the most suitable for a study of the thermodynamics of oxygen binding, the results of which we report here.

The solid complex was prepared according to Morgan and Smith[8] and stored under nitrogen. The oxygen equilibrium curves were determined in pure pyridine by a spectrophotometric method[9], and in all the experimental conditions we tested the complex was stable as judged by the constancy of spectra after equilibrium was reached (Fig. 1). In all the intermediate saturation states, the spectral properties of the solution could be accounted for in terms of two absorption species, one corresponding to the fully deoxygenated, the other to the fully oxygenated, compound.

Fig. 2*A* shows the oxygen equilibrium curves of Co^{II}BAE at different temperatures. In all cases the shape of the curve corresponds to a rectangular hyperbola, as expected for a reversible equilibrium of the simple form

$$Co^{II} + O_2 \rightleftarrows Co^{II}O_2$$

This is brought out more clearly in the double logarithmic plot (Fig. 2*B*). The data correspond to a value of $n = 1$ in the Hill equation, commonly used in work with haem proteins:

$$\frac{Y}{1-Y} = \frac{[Co^{II}O_2]}{[Co^{II}]} = K\ pO_2^n$$

Thus the reversible reaction of Co^{II}BAE with oxygen differs from that reported for other Co^{II} complexes, where several distinct equilibria had to be formulated to account for the shape of the equilibrium curves and stoichiometry[10,11]. At 20° C the value of $p_{1/2}$ (the oxygen pressure for half saturation) is 2·75 mm Hg, corresponding to $K = 6{\cdot}6 \times 10^4\ M^{-1}$ (taking the solubility of oxygen in pyridine as $8{\cdot}6 \times 10^{-4}$ M at 20° C and 156 mm Hg).

The dependence of the oxygen affinity on temperature (see Fig. 3) corresponds—in the temperature range investigated—to the Van 't Hoff relationship with $\Delta H = -15{\cdot}03 \pm 1{\cdot}35$ kcalories/mole of oxygen (gas) at 20° C. From these values the thermodynamic data at 20° C for the reaction of Co^{II}BAE with oxygen are as follows:

$\Delta G = -6{\cdot}45$ kcalories/mole; $\Delta H = -15{\cdot}03$ kcalories/mole; $\Delta S = -29$ e.u.

The oxygen affinity of Co^{II}BAE in pyridine is much greater than that reported in the presence of N,N-dimethylformamide, confirming the suggestion that the tendency to form the oxygen adduct increases with increase in base strength[1]. Our preliminary data indicate that complexes like *bis*(salicylaldehyde)ethylenediimine-cobalt(II) and *bis*(salicylaldehyde)phenylenediiminecobalt (II) have an oxygen affinity in pyridine lower by about two orders of magnitude than Co^{II}BAE.

As far as the comparison can be made, it is interesting to note a parallel between the data for the reaction of Co^{II}BAE with oxygen and those for the same reactino of whale myoglobin. For the latter, in dilute buffer solutions, at *p*H 7 and 20° C, the values of ΔG, ΔH and ΔS are $-8{\cdot}08$ kcalories/mole, $-14{\cdot}8$ kcalories/mole and -23 e.u., respectively (unpublished results of G. A., E. A., M. B. and E. Magnusson).

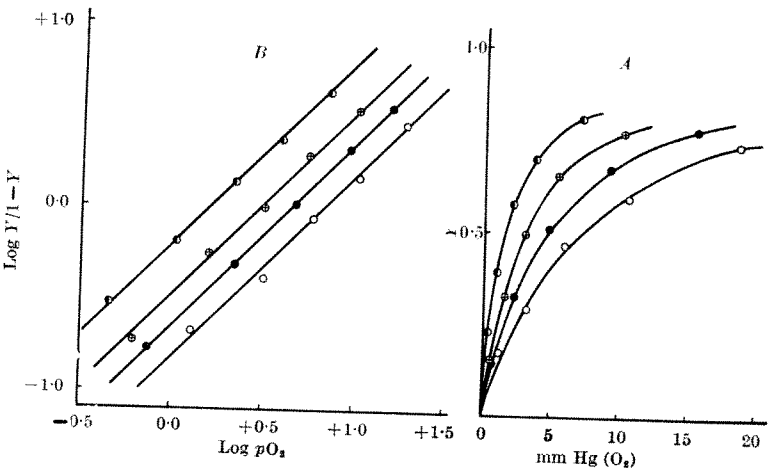

Fig. 2. Oxygen dissociation curves of 2×10^{-3} M Co^{II}BAE in pyridine at different temperatures. *Y* is the fractional saturation with oxygen. ◐, 15° C; ⊗, 20·7° C; ●, 26° C; ○, 31·5° C.

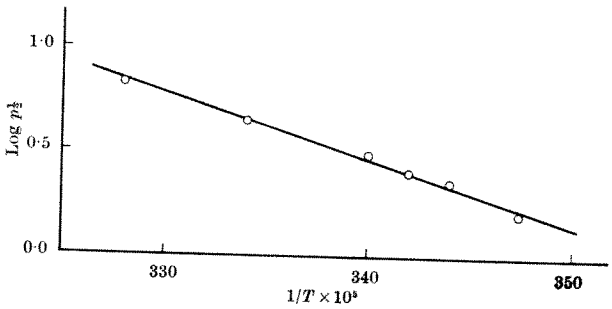

Fig. 3. Influence of temperature on the oxygen affinity (as log $p_{1/2}$) of 2×10^{-3} M Co^{II}BAE in pyridine.

Thus the known similarities between respiratory proteins and cobalt(II) complexes can be extended to the thermodynamic parameters of the oxygen reaction. A systematic study of the effect of the chelating agent, the *trans* axial ligand and the solvent on the reaction of Co^{II} complexes with oxygen might offer insight into the mechanisms by which the polypeptide chains of haem proteins control the reactivity of the haem iron.

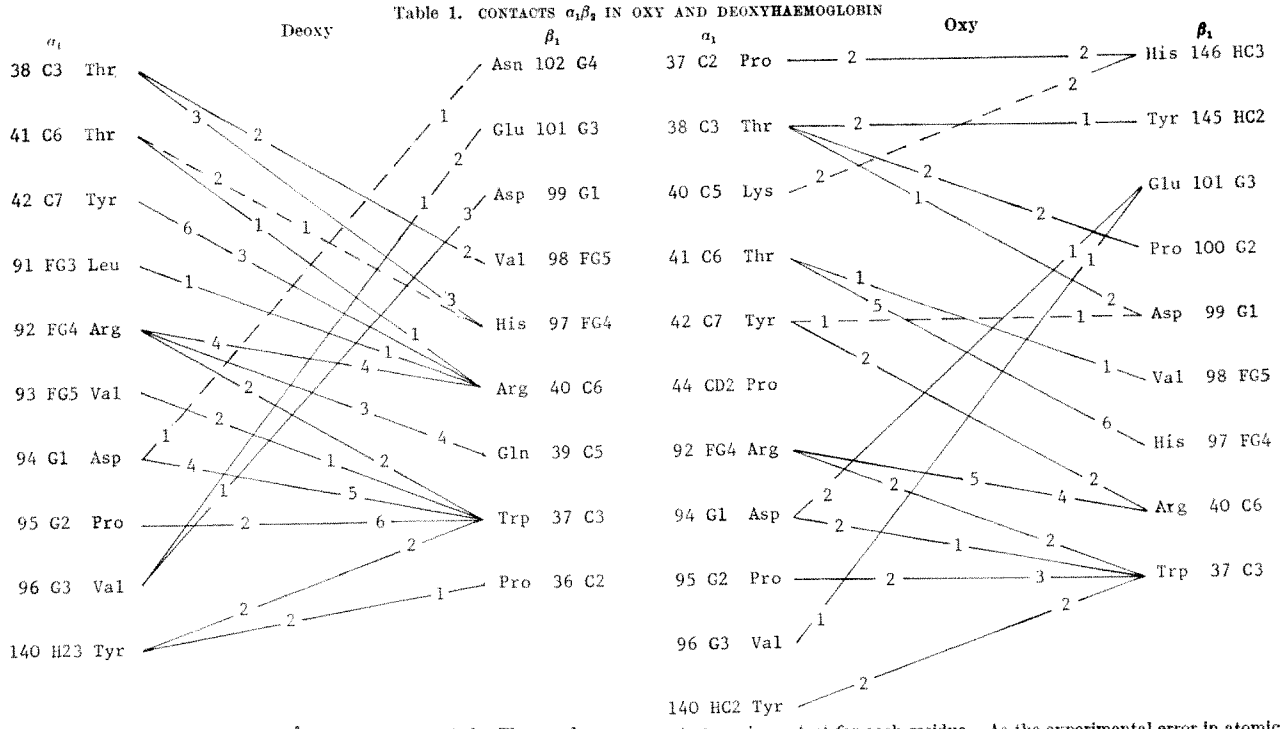
Three Dimensional Fourier Synthesis of Horse Deoxyhaemoglobin at 2·8 Å Resolution

THE deoxyhaemoglobin of horse forms orthorhombic crystals with the space group $C222_1$ and four molecules in the unit cell, which lie on two-fold symmetry axes. A Fourier synthesis at 5·5 Å resolution showed the tertiary structures of the individual subunits to be closely similar to that of oxyhaemoglobin, but the quaternary structure of the tetramer to be markedly different[1,2].



X-ray reflexions were recorded on precession photographs and measured on a flying spot integrating microdensitometer[3] for the native protein and four heavy atom derivatives. Heavy atom positions were first determined from centrosymmetric projections and refined in three dimensions after phase angles had been determined separately for each plane of data as described by Matthews *et al.*[4]. The mean figure of merit was 0·63. An electron density distribution was calculated using "best" angles and plotted on the scale of 1 Å = 2 cm. An atomic model of the molecule was constructed on the same scale using Richards's reflecting box[5]. Detailed comparisons of the atomic models of horse oxy- and deoxyhaemoglobin will take some time to complete. Here we wish to describe some significant differences between the two structures.

In methaemoglobin the iron atoms are displaced by 0·3 Å from the mean plane of the porphyrin ring on the side of the proximal histidine (F8). In both the α and β chains of deoxyhaemoglobin this displacement is increased to 0·75 Å. The porphyrin ring probably deviates from planarity, as it does in other iron porphyrin derivatives, but the extent of such deviation is hard to judge at 2·8 Å resolution. In the α and β subunits of methaemoglobin the cavity between the haem group and helix E is sufficiently wide to accommodate oxygen, while in the deoxy form this is true only of the α chain. In the β chain one of the γ-methyl groups of valine E11 blocks the ligand site. There are many small differences between the tertiary structures of the two subunits in the oxy and deoxy forms which will be described elsewhere.

We now come to the contacts between neighbouring subunits. The β chains are not in contact with each other in either the oxy or deoxy forms, but the gap between them is much wider in the deoxy form (see Fig. 11 of ref. 6). There is no contact between the α chains in the oxy form, but in the deoxy form they are linked by salt bridges. The α carboxyl group of arginine HC3(141) of one α chain is in contact with the α amino group of valine 1 and the ε amino group of Lys H10(127) of its partner chain. The C-terminal guanidinium group of one α chain forms a salt bridge with Asp H9(126) of its partner chain.

The contact $\alpha_1\beta_1$ undergoes slight changes which seem to involve a loosening, rather than sliding, at certain areas of contact. A table of the residues in contact looks very similar to that given for methaemoglobin (Table 2 of ref. 7) except for the omission of twelve lines and the addition of two new ones. There seem to be 32 residues or 98 atoms in contact in deoxy, as compared with 34 and 110 in the oxy form. The number of hydrogen bonds has remained constant at four or five. The contact $\alpha_1\beta_2$ undergoes drastic changes as the two subunits turn relative to each other by 13° (Table 1). Note that the hydrogen bond linking Asp G1(94)α_1 to Asn G4(102)β_2 in oxy is replaced in deoxy by another linking Tyr C7(42)α_1 to Asp G1(99)β_2. There are 20 residues or 69

Table 1. CONTACTS $\alpha_1\beta_1$ IN OXY AND DEOXYHAEMOGLOBIN

All contacts at distances of 4 Å or less were counted. The numbers represent atoms in contact for each residue. As the experimental error in atomic positions is at least 0·5 Å, these figures are only approximate.

atoms in contact in deoxy, as compared with 19 and 80 in oxy. If we omit residues involved in salt bridges, the number of interatomic contacts between α and β subunits seems to be less in deoxy than in oxyhaemoglobin. This point will have to be checked by further refinement of the two structures.

Human and horse haemoglobin differ chemically by 43 out of 287 residues in the half-molecule. Many of these differences show up clearly in comparisons of the electron density maps of human[8] and horse haemoglobin, but they are without influence on the tertiary or quaternary structure, which seem to be identical within the limits of our resolution. The two proteins crystallize in two completely different lattices dictated probably by the different patterns of side chains on the surface of the two species. The identity of the internal structures shows that these are not affected by the nature of the crystal lattice.

We thank Mrs A. Parkinson, Mr A. G. Tagg and Mrs S. Porter for technical assistance.

Higher Plant Cytochrome *c*

Zuckerkandl and Pauling[1] have pointed out the potential value of proteins as documents of evolutionary history for the species from which they have been extracted, and various aspects of the structure of proteins have been used for this purpose. These include serological cross-reactivity, amino-acid composition, peptide maps, electrophoretic mobility, catalytic activity and chromatographic characteristics[2]. It is generally agreed, however, that the greatest insights in this area are liable to come from comparisons of the primary structure of proteins, that is by partial or complete amino-acid sequence determination, for only these comparisons are likely to indicate accurately enough the mutation distance between the homologous genes involved.

There are two principal methods for the mathematical treatment of sequence data from a large number of species[3,4]. The matrix method (for example ref. 5) is used to construct a tree so that the reconstructed matrix derived from it is the closest approximation to the original matrix obtained from the observed sequences. Alternatively, it is possible to construct trees using inferred ancestral sequences[1,4], and because the structures of all sequences are used in the derivation of the nodes, this method is preferable; in the common ancestor method the derived tree should involve the smallest possible total number of amino-acid replacements.

In the animal kingdom classical comparative methods and a reasonable fossil record allow considerable confidence in the suggested relationships of many groups; for example, a generally acceptable phylogenetic tree for the vertebrates has been established from the fossil record[6]. Plants, however, do not have an adequate fossil record from which a tree could be constructed. By the Upper Cretaceous, when flowering plant fossils became abundant, many of the major present-day orders were already represented. In the absence of a fossil record indirect methods have been used to construct phylogenies, and as a consequence there are several conflicting schemes[7]. The use of more objective data from plants could therefore be extremely important in this connexion, and we hope to establish a phylogenetic tree based on amino-acid sequence data.

For the initial study we chose cytochrome *c* from the many proteins which are widespread in plants for several reasons. (1) It is ubiquitous in aerobic organisms; (2) its relatively small molecular weight makes it very suitable for amino-acid sequence determination, for although present techniques can be applied to proteins of molecular weight up to 40,000 other things being equal, progress is more rapid the smaller the molecule; (3) the sequence of cytochrome *c* has already been established from various animals, bacteria, fungi and for wheat germ[8]; (4) although the synthesis of cytochrome *c* is directed by only a small part of the genome, the fact that the phylogenetic tree constructed from animal cytochrome *c* sequence data is essentially similar to that constructed from the fossil record[5] means that the cytochrome *c* information is representative of the whole genome. It is likely, however, that before a complete phylogenetic tree can be constructed, proteins other than cytochrome *c* will have to be used, particularly in determining the final delimitations of the branches, because compared with other proteins cytochrome *c* appears to be relatively conservative; at present it is not clear what will be the most suitable choice of more rapidly evolving proteins in plants.

We wish to present here the sequences of cytochrome *c* from mung bean (*Phaseolus aureus* L.), sunflower (*Helianthus annuus* L.), sesame (*Sesamum indicum* L.) and castor (*Ricinus communis* L.), and to make a preliminary comparison of these four dicotyledonous plant sequences with that of the monocotyledon wheat (*Triticum aestivum*)[9], the only higher plant sequence determined at the start of this investigation.

The methods used to purify and sequence the cytochromes *c* have been described before[10–12]. Paper electrophoresis combined with the Dansyl/Edman sequence

technique[13] makes it possible to obtain a complete sequence on 2 μmoles of pure cytochrome *c* and, because cytochrome *c* occurs in only small amounts in plants, the use of these methods has considerably extended the range of possible plant sources.

The amino-acid sequences of cytochrome *c* from the five higher plants are given in Table 1, and Table 2 gives the number of differences in amino-acid residues, from which the matrix of minimum mutation distance differences, as defined by Fitch and Margoliash[5], is derived; these data have been used to construct a topology based on the minimal mutation distance method (Fig. 1). This topology places castor (family Euphorbiaceae) closest to sesame (Pedaliaceae), then mung bean (Leguminosae), then sunflower (Compositae) and then wheat (Gramineae).

Table 3 gives the minimal mutational distances interrelating pairs of cytochrome *c* sequences as calculated from the leg lengths of the data of Fig. 1, together with the input data from the sequences themselves. These are in good agreement as shown by the percentage standard deviation of the calculated to input data[5] of 8.

Alternatively the data can be processed using the common ancestor method of Dayhoff and Eck[4]. In this case, where five species are being considered there are five possible ways of constructing a topology in which the nodes have three branches. Four topologies (Fig. 2*a*) are chosen from these fifteen because they involve the smallest total number of mutations, that is thirty-three.

Table 2. TABLE OF DIFFERENCES

	W	Su	M	Se	Ca
W	×	15	16	15	14
Su	15	×	11	11	11

Ca	14	11	9	7	×

Amino-acid residues.
W, Wheat; M, mung bean; Su, sunflower; Se, sesame; Ca, castor.

Table 3. MINIMUM MUTATIONAL DIFFERENCES TO INTERRELATE PAIRS OF CYTOCHROME *c*

	W	Su	M	Se	Ca
W		18	18	18	19
Su	18		14	13	14
M	19	13		10	10
Se	19	13	9		8
Ca	17	15	11	8	

Figures at the top are calculated from leg lengths (values rounded off). Figures at the bottom are input data.

After the best closed topologies have been established with the data from the five flowering plants, the next question is what is the relationship of these sequences to those of the fungi and animals already established? The flowering plant cytochromes *c*, like those of the fungi and animals, are basic and of the eukaryotic, mitochondrial type. They have an N-acetylated tail of 8 residues, giving a total length of 111–112 residues, which is not found in any other group. They also have Σ-N-trimethyllysine residues in positions 80 and 94; this unusual amino-acid does not occur in animal cytochromes, but does occur in position 80 in the cytochrome *c* of the fungus, *Neurospora crassa*[14]. It has been found in only two other proteins[15]. There are ninety-one residues common to all the five flowering plant sequences, of which eighteen are unique in their positions compared with all other cytochromes *c*; they can therefore be accepted as a closely knit group.

In considering all the known eukaryotic cytochrome *c* sequences, there are thirty-five residues which are un-

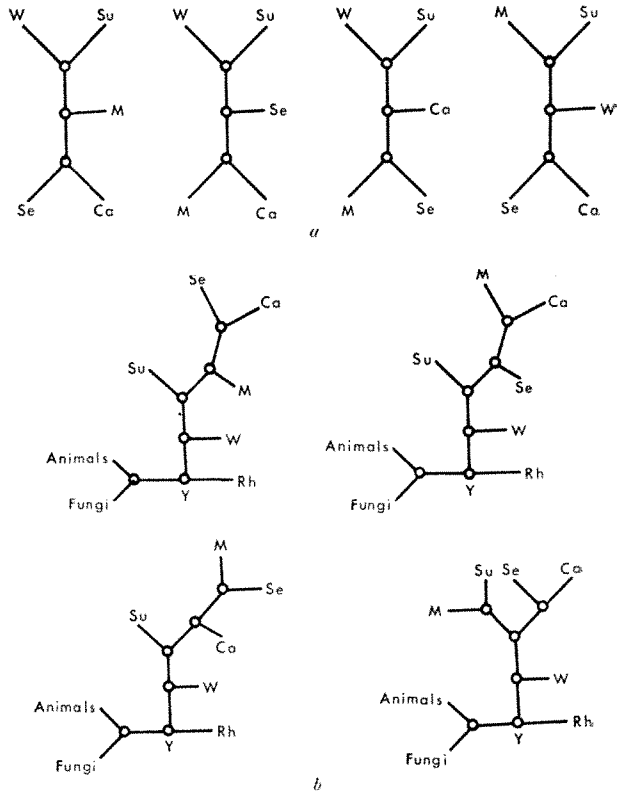

Fig. 2. Various possible topoolgies obtained using the common ancestor method of Dayhoff and Eck[4]. See text. Rh, Rhodospirillum.

varied, and the new flowering plant data do not reduce this number. It is quite clear therefore that at an early stage in evolution there was an ancestor common to plants, fungi and animals. With regard to the point at which the plants diverged as a distinct group, this could have taken place between *Rhodospirillum* and the point of divergence of the fungi, or between the latter and the point of divergence of the animals[8]. Analysis of the data in relationship to the ancestral nodes of the fungi and insects shows that the flowering plants diverged before the fungi.

In joining the flowering plant sequences onto the main phylogenetic tree between *Rhodospirillum* and the point of divergence of the fungi, the calculation of a common ancestral sequence is subject to error because of the considerable divergence between the adjoining groups and their corresponding cytochrome *c* sequences. A sequence of this node (node Y), however, has been determined (Fig. 3), which suggests the four different ways involving the minimum of mutations in which the five flowering plant sequences could be attached to the main branch of a phylogenetic tree (Fig. 2*b*), taking into account the established closed topologies of Fig. 2*a* and based strictly on amino-acid sequence data. From the position of wheat and from biological considerations, it seems possible that the first flowering plants were primitive dicotyledons from which the monocotyledons diverged before the four dicotyledons which we have examined. All statements based on this preliminary tree are of course liable to amendment as the number of species from which data are obtained and from which trees are constructed increases. For this reason it is not justifiable to discuss differences between the data in Fig. 2 and those of published phylogenetic schemes for flowering plants, for these differences might represent sampling error due to the small number of differences in amino-acids compared.

DNA Synthesis and Hormone-induced Elongation in the Cucumber Hypocotyl

It has been reported[1] that inhibition of DNA synthesis also inhibited shoot elongation induced by the hormone gibberellin (GA). GA treatment, which induced elongation, was shown to enhance DNA synthesis without any apparent increase in number of cells[2]. On the other hand, elongation induced by indolеacetic acid (IAA) did not seem to depend on DNA synthesis[3]. Katsumi *et al.*[4] have shown that both gibberellin and auxin induce elongation in the cucumber hypocotyl. We therefore chose this system to compare the effects of the two hormones on DNA synthesis as associated with hypocotyl elongation.

Cucumber seedlings (*Cucumis sativus* L., cr. Beit Alpha) were first germinated for 24 h on facial tissues, then grown uniformly in soil-filled flats in a growth chamber which was run at 29°, 16 h light ('Grolux' plus incandescent, about 700 foot candles at plant level) and 8 h dark. This lighting cycle was necessary for an optimal auxin response. 96 h later seedlings had reached the "initial state" very uniformly: the hypocotyls were about 35 mm long and the cotyledons spread out. The hypocotyl section—a 5 mm section starting 5 mm below the cotyledonary node—was marked with ink and measured at various times after hormone treatment. One of the important criteria for choosing the specified developmental stage and hypocotyl section was the absolute lack of mitotic figures at the time of hormone application. Mitotic activity in the elongating organ would complicate any conclusions to be drawn from measurements of DNA synthesis.

Gibberellin (supplied by ICI as a mixture of A_4 and A_7—about 1 : 1—10 mg/l.), IAA (100 mg/l., Calbiochem) and 5-fluorodeoxyuridine (FdUrd 10^{-5} M, a gift from Hoffmann-La Roche) were applied to seedling apices in 10 μl. droplets of solutions containing 0·05 per cent 'Tween 20'. A 1 h pulse of ^{3}H-thymidine (17·5 Ci/mmole, 10 μCi/ml.; Radiochemical Centre, Amersham) was given to freshly harvested hypocotyl sections by shaking them continuously in the labelling solution. The ^{3}H-thymidine pulses were always given at the same time of day, 12 h after the beginning of the light period. This was done to avoid complications caused by diurnal fluctuations (as found before) in rate of DNA synthesis. The sections were then rinsed thoroughly, fixed, dried, extracted, homogenized, washed on membrane filters and counted as described by Jakob and Bovey[5]. Tests have shown that 80 per cent of the radioactivity thus measured is removed by treatment with deoxyribonuclease. Radioactivity in DNA formed in all treatments approximately 10 per cent of

total radioactivity taken up by the tissue. When rate of transport of hormones and FdUrd in the intact seedling was checked, by using labelled compounds (2-^{14}C-IAA and 6-^{3}H-FdUrd, Radiochemical Centre; 3,4-^{3}H-GA, Dr H. Kende, Michigan State University) which were applied in 10 μl. droplets to the apex, all three compounds reached the hypocotyl section in appreciable amounts within 4 h after application. Although GA_1 is less effective than A_{4+7} in this system, there is no indication for difference between the two kinds of gibberellin in rate of transport.

Total DNA was determined by the diphenylamine reaction[6] on material which was homogenized and extracted according to Smillie and Krotkov[7].

Fig. 1 shows the differences in the effects of the two hormones on the rate of hypocotyl elongation: (*a*) the peak of auxin effect occurs earlier and is lower than that of the GA effect; (*b*) the effect of auxin is shorter than that of GA; whereas rate of elongation of auxin treatment falls back to control level by 48 h after treatment, GA effect at that time is significantly higher.

Fig. 2 shows that the effects of the two hormones on rate of incorporation of ^{3}H-thymidine into DNA parallel very closely the growth curves shown in Fig. 1. All differences between treatments (both in elongation and in ^{3}H-thymidine incorporation) were significant at the 5 per cent level.

The relatively early fall in auxin effect could be explained either by rapid inactivation of the hormone in the plant or by a drop in the sensitivity of the tissue to the hormone.

An experiment with repeated hormone treatment showed that whereas a second GA treatment was relatively ineffective, a second auxin treatment, 36 h after the first, significantly raised the rates of elongation and incorporation of ^{3}H-thymidine as measured 48 h after the first treatment. Absolute amounts of DNA in the hypocotyl section increased significantly from initial state to 72 h after hormonal treatment. The largest increase was in the GA-treated material (Table 1).

Table 1. EFFECTS OF HORMONAL TREATMENTS ON DNA/HYPOCOTYL SECTION

	Initial state	After 72 h		
		Control	GA	IAA
μg DNA/hypocotyl section	0·75	1·080	1·845	1·425
Increase in μg DNA/hypocotyl section	—	0·330	1·095	0·675
Percentage increase	—	44·0	140·6	90·0

100 hypocotyl sections were used for each determination.

In view of all these findings it was of interest to check the effect of FdUrd—an inhibitor of DNA synthesis—on the hormone-induced elongation in this system. FdUrd is known to act through inhibition of thymidylate

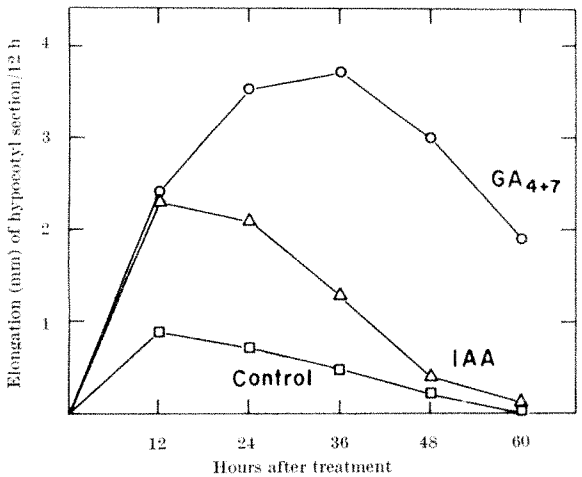

Fig. 1. Auxin (IAA) and gibberellin (GA_{4+7}) induced elongation in the cucumber hypocotyl. Hormonal treatments were given at time 0 (the "initial state"): the hypocotyl section was 5 mm long; length increments were recorded at 12 h intervals. Results represent average of nine seedlings per treatment.

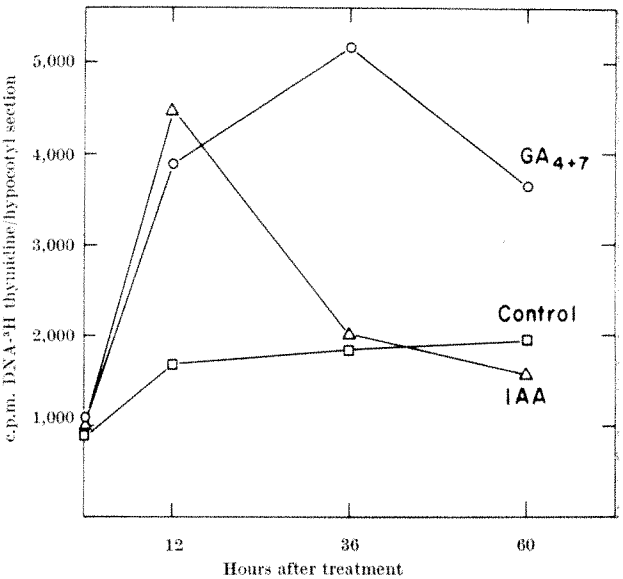

Fig. 2. Effects of auxin and gibberellin on the rate of ^{3}H-thymidine incorporation in the cucumber hypocotyl. 1 h pulses of ^{3}H-thymidine were given 12, 36 and 60 h after the hormone treatments. Results represent average of nine seedlings per treatment.

synthetase[8], causing thymidylic acid starvation, so we applied the FdUrd 12 h before hormone treatment. It was found that FdUrd inhibited very effectively both auxin and GA-induced elongation. This inhibition was largely reversed by thymidine, but not by uridine (both were used at 5×10^{-3} M concentration): it therefore seems likely that it was caused by the inhibition of DNA synthesis. Additional tests showed that ^{3}H-thymidine incorporation was enhanced by the FdUrd treatment, providing evidence that FdUrd acts by depleting the tissue of thymidylic acid. It has been found before[9–11] that the mitotic poison, colchicine, is a very effective inhibitor of AG-induced elongation. There are therefore at least two possible explanations for the inhibiting effect of FdUrd: (*a*) a certain fraction of the DNA synthesis is a prerequisite for hormone-induced elongation; or (*b*) FdUrd, by inhibiting DNA synthesis, acts as a mitotic poison (like colchicine), thus interfering with hormone-induced elongation. Another, parallel, possibility is that most of the hormone-induced DNA synthesis is another manifestation of the enhanced growth, rather than a prerequisite for it. The present data do not allow us to distinguish between all these possibilities. Other observations[11] indicate that most of this enhanced DNA synthesis takes place outside the cell nucleus, in chloroplasts and possibly also in mitochondria.

Fall in Liver DNA Polymerase Activity in Cortisone-treated Rats

THE physiological properties of glucocorticoid hormones include inhibitory effects on growth and cell division both in intact animals and in tissue culture: administration of these compounds stops net DNA synthesis in the livers of growing rats[1], inhibits mitosis in various cells in tissue culture[2–4], and reduces the burst of DNA synthesis which ordinarily follows partial hepatectomy[5,6]. Administration of glucocorticoid hormones is well known to inhibit DNA synthesis in a number of systems, but the mechanisms by which this might occur remain obscure. While Guzek has shown that the administration of cortisone or ACTH to partially hepatectomized rats quickly inhibits incorporation of radioactive thymidine into liver DNA *in vivo*[7], attempts to demonstrate a direct effect of glucocorticoid hormones on DNA polymerase activity *in vitro* have been unsuccessful[8]. The possibility exists, however, that the administration of these hormones *in vivo* may result in significant changes in enzyme activity, and because of the good correlation between mitotic activity and DNA polymerase activity of liver in a number of different conditions[9–13], we thought it of interest to examine the effects of glucocorticoid administration on the DNA polymerase activity of rat liver. We shall show that the administration of cortisone to young rats rapidly decreases liver DNA polymerase activity. This decline can be demonstrated within a day of the onset of treatment and can be observed at considerably lower doses of hormone than have generally been used in other studies on rat liver.

Enzyme extracts were prepared thus: rats were stunned and exsanguinated. The livers were removed immediately, chilled and homogenized with ten strokes of a hand-driven Dounce homogenizer equipped with a loosely fitting pestle in five volumes of 0·1 M Tris-HCl buffer at *p*H 7·4 containing 1 mM EDTA and 6 mM 2-mercaptoethanol. Homogenization and all subsequent operations were carried out at 0°–4° C unless otherwise noted. The homogenates were centrifuged at 8,500*g* for 10 min and the resulting supernatants subjected to a further centrifugation at 105,000g_{av} for 1 h. The supernatant material from this second centrifugation was used for the subsequent enzyme assays. Protein determinations were performed by a modification of the Folin–Ciocalteu method[14], and enzyme assays were carried out as described by Bollum[15]. Incubation conditions are described in the legend to Fig. 1. When required, native DNA was denatured by heating a solution in a boiling water bath for 15 min followed by immediate chilling in an ice–water mixture.

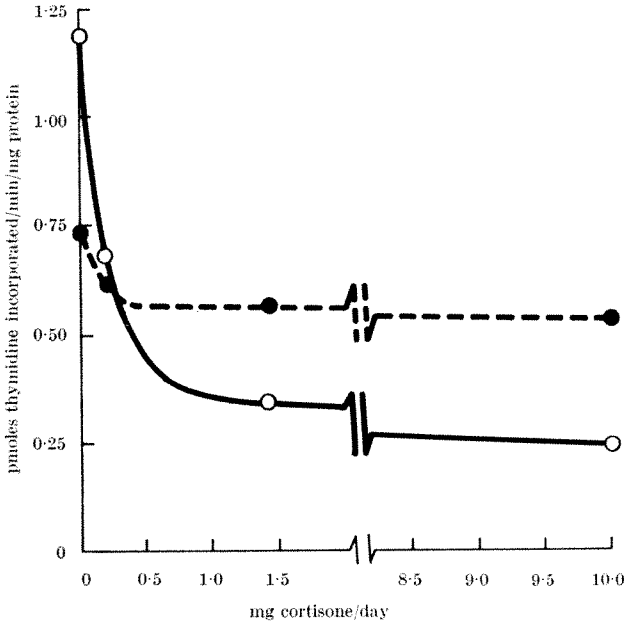

Fig. 1. Decline in DNA polymerase activity as a function of cortisone dose. Rats were treated with cortisone acetate as described in the text and were killed 72 h after the onset of treatment. The enzyme activity of each liver supernatant was tested with both native and denatured DNA as templates. Calf thymus DNA and the four deoxyribonucleoside triphosphates were purchased from the Sigma Chemical Corp. and were of the highest grades; [*methyl*-^{3}H]-thymidine triphosphate (13·3 Ci/mmole) was purchased from the New England Nuclear Corp. Assays were performed with the following components present in a final volume of 0·2 ml.: 50 mM KCl; 3·3 mM $MgCl_2$; 37 mM Tris-HCl at *p*H 7·3; 0·5 mM EDTA; 6 mM 2-mercaptoethanol; dATP, dGTP and dCTP at 150 μM each; 75 μM TTP (7·5 μCi/ml.); 1·6 per cent ethanol (contributed by ethanol present as a preservative in the stock solution of ^{3}H-TTP); DNA, 0·18 mg/ml.; and 0·5–0·6 mg liver protein (added in a volume of 50 μl. of 105,000*g* liver supernatant). Incubations were carried out at 37° C, and at zero-time and after 1 h of incubation 25 μl. samples were withdrawn in duplicate and applied to filter paper disks. Samples were prepared for radioactivity determinations, and enzyme activities (●- - -●, native DNA template; ○—○, denatured DNA template) were calculated as described by Bollum[15]. Incorporation was found to be absolutely dependent upon the addition of both DNA and enzyme extract, and in the conditions used thymidine incorporation was linearly related to the quantity of crude enzyme added.

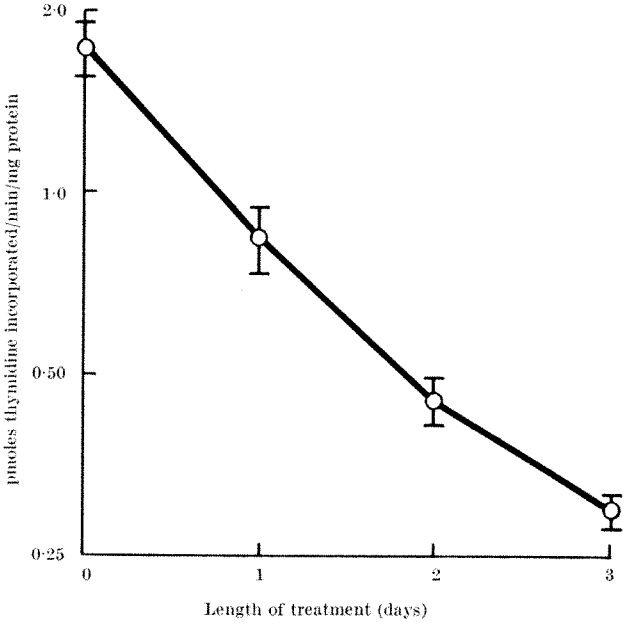

Fig. 2. Decline in DNA polymerase activity as a function of length of cortisone treatment. Rats were injected with 5 mg cortisone acetate twice daily for the number of days shown on the abscissa and were killed 14 h after the last dose. Each point shown above gives the mean ±1 standard error for groups of four to six animals (denatured DNA template). Note that the scale of the ordinate is logarithmic.

In the first experiment twenty male Sherman (Columbia strain) rats weighing 45 to 55 g were subcutaneously injected twice daily, in groups of five, with 0, 0·1, 0·7 or 5 mg cortisone acetate (Merck, Sharp and Dohme) in 0·2 ml. 0·15 M NaCl. Seventy-two hours after the first injection all animals were killed and liver supernatant fractions prepared as described. Fig. 1 shows the DNA polymerase activity of the extracts when tested with both native and denatured calf thymus DNA as templates. While cortisone treatment results in a decline in thymidine incorporation when either native or denatured DNA is used, the decrease in enzyme activity is far more striking when denatured DNA is used as a template and can be observed in rats receiving as little as 0·2 mg of hormone per day. The normal secretory rate of corticosterone, the principal glucocorticoid hormone of the rat with about half the potency of cortisone[16], is estimated at between 0·25 and 1·5 mg per 100 g of body weight per 24 h (refs. 17 and 18).

In the second experiment DNA polymerase activity was studied as a function of the length of cortisone treatment.

Fig. 2 indicates that administration of the hormone results in a decline in enzyme activity within 24 h, and continued administration of the hormone for an additional 2 days results in a further fall in activity to less than 20 per cent of control levels.

Earlier observers have noted that the administration of cortisone not only arrests somatic growth[19,20] and stops the normal increase in DNA content of the livers of growing animals, but also markedly decreases the incorporation of radioactive thymidine in regenerating liver. Our results are consistent with these earlier observations and are, we believe, the first demonstration of an effect of the hormone on an enzyme directly involved in DNA synthesis. Although the relationship between DNA polymerase activity as measured *in vitro* and DNA synthesis *in vivo* has still not been clearly established[21–24], the good correlation between enzyme activity and mitotic activity of liver tissue in a number of different conditions suggests that the enzyme activity measured *in vitro* may be of physiological significance. For example, DNA polymerase activity has been observed by others to be significantly increased in extracts of regenerating liver[9,10], in liver tissue from foetal and weanling animals[11,12] and in liver tissue which has undergone malignant transformation[12,13]. It is not known whether the decrease in polymerase activity described here reflects changes in the rates of synthesis or degradation of the enzyme, or instead a modification of the activity of pre-existing enzyme. Although the effect of hormone treatment was more striking when denatured rather than native DNA was used as a template, the respective roles of the polymerases which respond to native and to denatured DNA as templates remain the subject of much debate[21–24]. Whatever the mechanisms by which the administration of cortisone results in diminished polymerase activity, it is of interest that these effects can be observed with doses of hormone which are close to the "physiological" range.

Effect of Rate of Cell Division on RNA Synthesis in Developing Frog Embryos

Endoderm cells of developing *Xenopus laevis*[1] and *Rana pipiens* embryos[2,3] synthesize more RNA per cell, including DNA-like RNA, than do the more rapidly dividing ectoderm–mesoderm cells. Slowing the rate of cell division by culturing frog embryo explants in LiCl increases the amount of RNA synthesized per cell, including DNA-like RNA[2], while increasing the rate of cell division by exposure to $NaHCO_3$ has the opposite effect[3]. These data suggest that a reduction in the rate of cell division allows higher levels of RNA (including DNA-like RNA) to be synthesized per cell.

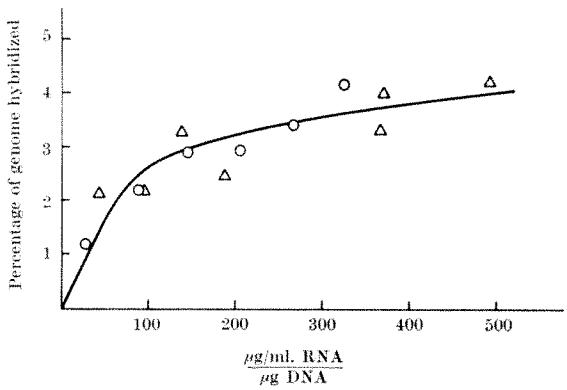

Fig. 1. Increasing amounts of RNA isolated from tailbud (stage 19) embryos raised at 10°–11° C (△) and 20° C (○) were incubated for 48 h in 2 × SSC, 50 per cent formamide at 37° C with 2·8 μg of denatured frog red blood cell DNA immobilized on nitrocellulose filters.

We examined changes in amounts and kinds of RNA synthesized resulting from alteration of the rate of cell division without chemical treatment. Frog embryos were raised at lower and higher temperatures than the normal culture temperature of 20° C. Groups of 200 dejellied blastulae, stage 9 of Shumway[4], were cultured at 10°–11° C and 23°–24° C until they were stage 19 tailbuds that had hatched from their membranes. It took 2–3 days for development to stage 19 at 23°–24° C and 8–9 days at 10°–11° C. Both of these groups of embryos were perfectly normal in appearance. At this time determinations of DNA and RNA were made[5]. The stage 19 tailbuds raised at the two temperatures had similar amounts of DNA (414 ± 8 μg at 10°–11° C and 419 ± 9 μg at 23°–24° C), indicating that they underwent a similar number of cell divisions. But the embryos raised at the colder temperature had more RNA ($1{,}278 \pm 12$ μg) than those raised at the higher temperature ($1{,}040 \pm 10$ μg). This gave a higher RNA/DNA ratio for the embryos raised in the cold (3·09), compared with those raised at the higher temperature (2·48); this is a 25 per cent difference. The results of five similar experiments showed that embryos raised at 10°–11° C had 27 per cent ± 8 per cent more RNA than those raised at 23°–24° C, even though there was a similar amount of DNA per embryo in the tailbuds raised at the two temperatures. This agrees with the work of Krugelis *et al.*[6] who found higher RNA/DNA ratios in salamander embryos raised at 10° C than in embryos developing to a similar larval stage at 20° C.

It has been shown that there is a gradual increase in the kinds of DNA-like RNA which can be detected as development proceeds in whole embryos[7]. In order to determine if the greater amounts of RNA present in embryos raised at the lower temperature are because of synthesis of new kinds of RNA, saturation hybridization experiments were performed. RNA from tailbud embryos raised at 10°–11° C and 20° C was prepared[8], polysaccharide was removed[9], and the RNA was labelled *in vitro* with

^{3}H-dimethyl sulphate[10]. Increasing concentrations of this RNA were incubated with nitrocellulose filters containing 2·8 μg of denatured frog red blood cell DNA, in 0·15 ml. of 2 × SSC (1 × SSC is 0·15 M NaCl, 0·015 M sodium citrate) and 50 per cent formamide at 37° C. It has been shown that in these conditions there is no degradation of RNA[11] and the specificity of annealing is equivalent to incubating at a temperature of 72° C in 2 × SSC (ref. 12). After 48 h the filters were removed, washed with 3 × SSC, treated with ribonuclease (20 μg/ml.) in 2 × SSC, washed again with 3 × SSC and air dried. The nucleic acids were hydrolysed with ribonuclease–deoxyribonuclease (500 μg/ml. each in 0·01 Tris, *p*H 7·5, 2 mmoles $MgCl_2$) for 20 h at 37° C. The hydrolysates were dissolved in scintillation fluid containing Beckman 'Bio-Solv' solubilizer and counted in a scintillation counter. It can be seen that the saturation curve obtained for the stage 19 tailbud embryos raised at 10°–11° is the same as for embryos raised at 20° (Fig. 1), indicating that the same number of kinds of DNA-like RNA are present in both populations in spite of the fact that the embryos raised at the lower temperature have more total RNA per cell.

In order to compare the percentage of DNA-like RNA present in the RNA obtained from tailbud embryos raised at 10°–11° and 23°–24° C, an annealing procedure was used which allowed progressive depletion of the DNA-like RNA. Samples of RNA (100 μg/ml.) prepared from stage 19 tailbuds raised at the two temperatures were incubated with nitrocellulose filters, each having 15 μg of denatured frog red blood cell DNA, in 0·2 ml. of 2 × SSC, 50 per cent formamide at 37° C for 48 h. New filters were added to the same RNA samples and incubated as before. This procedure was repeated six times and the percentage of DNA-like RNA binding to each filter was calculated. This type of depletion experiment, because it is well below the saturation level, does not allow the detection of qualitative differences in the two RNA preparations. It does, however, compare the number of copies of DNA-like RNA present in the two RNA samples. This technique does not permit the detection of RNA from the unique sequences[13].

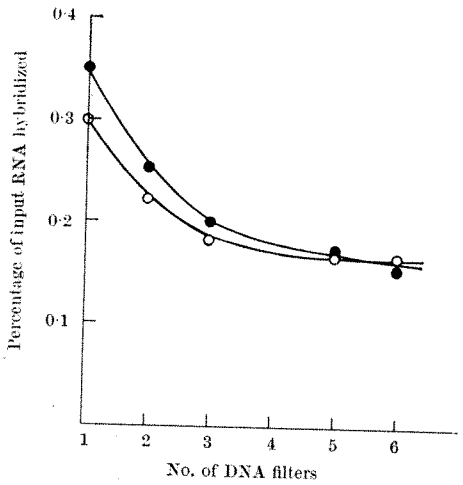

Fig. 2. The depletion of hybridizable RNA from 20 μg RNA samples by the addition of successive nitrocellulose filters containing 15 μg denatured frog red blood cell DNA is shown for RNA isolated from embryos raised at 10°–11° C (●) and 23°–24° C (○).

The percentage of input RNA hybridized plotted against the number of DNA filters added is shown in Fig. 2. It can be seen that the RNA from the embryos raised at 10°–11° C initially has a greater level of hybridization than the RNA from the embryos raised at 23°–24° C. As progressively more of the hybridizable RNA is depleted, however, the levels of hybridization of the two RNA samples approach the same values. This means that the amount of DNA-like RNA hybridized, per equal amounts of RNA added in the two incubations, was greater for the RNA isolated from embryos raised at 10°–11° C (Fig. 2). The simplest explanation for these results is that the percentage of DNA-like RNA is greater in the RNA extracted from the embryos raised at the lower temperature. The apparent plateau is probably caused by ribosomal RNA, transfer RNA and those DNA-like RNAs which are present in excess by comparison with their complementary DNA sequences.

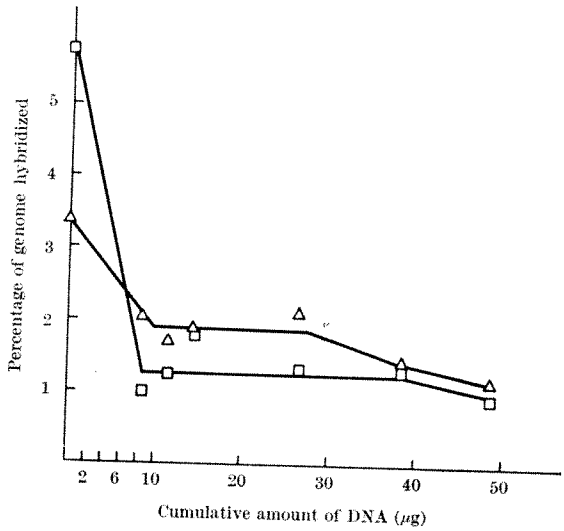

Fig. 3. The depletion of labelled RNA of stage 19 tailbuds raised at 10°–11° C (△) and stage 19$^+$ tailbuds raised at 23°–24° C (□) was measured by successive incubations with filters containing denatured DNA.

In order to compare the number of copies of DNA-like RNA of older embryos raised at a higher temperature with DNA-like RNA of younger embryos raised at a lower temperature, exhaustion experiments were performed using equal amounts of RNA extracted from stage 19$^+$ embryos raised at 23°–24° C and state 19 embryos raised at 10°–11° C. Saturation experiments showed 7 per cent of the DNA had been transcribed in the older embryos, compared with 4 per cent for the younger embryos. In these experiments near saturating amounts of RNA (1,100 μg/ml.) were exposed to consecutive DNA filters for 24 h in 2 × SSC, 50 per cent formamide at 37° C. It can be seen (Fig. 3) that although the initial hybridization level is greater for the RNA extracted from the embryos raised at 23°–24° C, the rate of exhaustion is also much faster. This indicates that although the younger embryos raised at 10°–11° C had fewer kinds of DNA-like RNA than the older embryos raised at 23°–24° C, the younger embryos raised at 10°–11° C had more copies of DNA-like RNA.

These experiments demonstrate that although the amount of RNA synthesized per cell is increased in embryos in which the rate of cell division has been retarded, the number of kinds of DNA-like RNA present are not changed. Culture at lower temperature does change the relative amount of DNA-like RNA as compared with total RNA. This means that although the absolute amount of ribosomal RNA per cell is greater in embryos raised at lower temperatures, the amount of DNA-like RNA is increased even more. Earlier determination of lens[14] and ciliary polarity[15] occurs in amphibian embryos raised at temperatures that are lower than normal. It is possible that the relative increase in DNA-like RNA in these embryos may result in earlier attainment of necessary threshold levels of DNA-like RNA, leading to earlier determination.

This research was sponsored by grants from the National Science Foundation and National Institutes of Health. We thank Mr Frank Roche for technical assistance.

Influence of Mouse Neural Retina on Regeneration of Chick Neural Retina from Chick Embryonic Pigmented Epithelium

In vertebrates such as bony fishes, amphibians, birds and mammals, neural retina can regenerate from the pigmented epithelium early in embryonic life[1]. This capacity persists thoughout life in some salamanders, and is maintained until metamorphosis in some tailless amphibians.

In the early chick embryo Orts-Llorca and Génis-Galvèz[2] showed that neural retina regenerated from the pigmented epithelium when a strand of thread was introduced into the cavity of the optic vesicle. On invagination of the optic vesicle to form the optic cup, the thread locally separated the presumptive neural retina from the presumptive pigmented epithelium. Neural retina regenerated from the pigmented epithelium in such areas of separation.

Until at least as late as 4 days of incubation, pigmented epithelium of the chick embryo can give rise to neural retina. At this age, in a previous study[3], we completely removed the neural retina from embryonic eyes; in some cases we re-implanted a small piece of neural retina. Neural retina did not regenerate when we completely removed the neural retina, but proceeded rapidly if we re-implanted a small piece of neural retina. The new chick neural retina regenerated from the cut edge of the pigmented epithelium at the margin of the eye cup and also in isolated patches in the pigmented epithelium away from the edge of the eye cup. Otocysts from 4-day old embryos also elicited neural retinal regeneration, but pieces of optic tectum from donors of the same age were not effective. So this phenomenon is at least partially tissue specific.

Sologub, using the frog tadpole, also demonstrated that the presence of neural retina was necessary for regeneration of neural retina from pigmented epithelium[4].

Fig. 1. Portion of the eye wall of a fourteen day old chick embryo. The neural retina had been removed at 4 days of incubation and replaced by a piece of mouse embryonic neural retina. The mouse neural retina lies to the right. To the left chick neural retina has regenerated from the pigmented epithelium with which it is still continuous.

To determine whether or not the retinal influence is species specific we replaced the neural retinas of the right eyes of twelve 4-day-old chick embryos with pieces of undifferentiated neural retina taken from mouse embryos with crown-rump lengths of thirteen to seventeen millimetres. At all stages of development the neural retina of the mouse is easy to distinguish from that of the domestic fowl after fixation in Carnoy's fluid and staining by the Masson procedure. Mouse cells have more densely stained nuclei than those of the domestic fowl; also the nuclear and fibre layers of the mouse retina are distinctively different in structure from those of the domestic fowl.

The host animals were killed and their right eyes were examined histologically at 13 or 14 days of incubation. In each of the twelve specimens the implanted mouse neural retina was still present in the vitreous cavity of the host eye. The implants were usually normal histologically. While mitotic figures were still present, the mouse retinas had differentiated a ganglion cell layer and rod and cone precursors in some places.

Neural retina regenerated in all twelve cases in the same way that it had when chick retina had been introduced into the retina-less eye (Fig. 1). In each case a new retinal sheet arose from the cut margin of the pigmented epithelium at the edge of the eye cup. Neural retina originating here grew back into the cup and differentiated so that its rods and cones faced the pigmented epithelium in the normal orientation. In addition to this type of regeneration, in ten of the twelve cases chick neural retina regenerated as isolated patches from pigmented epithelium some distance from the edge of the eye cup. Each patch was surrounded on all edges by, and was continuous with, the adjoining pigmented epithelium. In these cases the neural retina differentiated so that its rods and cones faced the vitreous cavity.

This 180 degree difference in polarity between the neural retina that regenerated as a sheet from the edge of the eye cup and that which regenerated as patches in the pigmented epithelium may be explained by the fact that rod and cone outer segments are in part derivatives of cilia. Early in development the ciliary surface of the presumptive retina is the inner surface of the optic vesicle (Fig. 2). This surface is continuous through the optic stalks with the ciliary surface of the brain wall facing the ventricle. When the optic vesicle invaginates to form the optic cup its ciliary surface becomes the inner wall of the pigmented epithelium of the retina and the

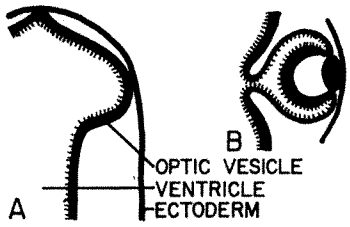

Fig. 2. The ciliary surface of the optic vesicle is continuous with the inner surface of the primitive brain wall (A). After invagination of the vesicle to form the optic cup (B) the ciliary surfaces of the pigmented epithelium and the neural retina face one another.

outer wall of the neural portion of the retina. So the apparent difference in polarity between neural retina which regenerates from the edge of the optic cup and that which regenerates in patches within the pigmented epithelium disappears when ciliary polarity is taken into consideration.

The neural retinae that regenerated in the presence of mouse retinal implants were composed of chick-type cells. They had the histological structure typical of the chick retina and not that of the mouse. The results demonstrate two points. The influence of the neuroepithelium is not highly species specific. The regenerated neural retina arises by metaplasia of the pigmented epithelial cells and not from cells that have migrated from the implant to the pigmented epithelium.

Separating the Sheep from the Goats on the Basis of their Chromosomes

THE karyotypes of fifty species of ruminants in the family Bovidae have been examined and the fundamental number of sixty chromosome arms has been established for thirty-two of them. Reporting this, Taylor, Hungerford and Snyder[1] pointed out that the distribution of the numbers of metacentric chromosomes among forty-nine species of Bovidae supports the view that Robertsonian[2] translocation has been a common feature of the evolution of the bovid karyotype. There are more Bovidae with few or no metacentrics than there are with many, or a complete complement of them.

The form of the ruminant karyotypes, a series of many acrocentrics which often differ only in size, makes identification difficult. It seems likely, however, that work can be done which exploits the knowledge that these species are the product of evolution from a common ancestor. A meticulous comparative examination of karyotypes, which may indicate translocations and the possibility of different linkages, could be combined with a knowledge of phenotypes to provide a basis for chromosome mapping. In karyotypes with more prominent features, such as that of man, work with one species can be productive. In the case of the Bovidae a comparative study seems likely to be most helpful. With this in mind a comparative study was undertaken of ten goats ($2n = 60$[3]) and ten sheep ($2n = 54$, six metacentrics[4]).

All the sheep in this survey were normal Clun Forest lambs, aged between 2 days and 2·5 months. The goats were British Alpines, Saanens and Welsh × Saanen cross-bred animals, aged between 6 months and 4 years. Five sheep and five goats of each sex were used and all the males were castrated.

Chromosome spreads were prepared from blood lymphocytes by a modification of the method of Basrur and Gilman[5]. The chromosome spreads were photographed with a flat-field × 100 oil immersion objective and a × 15 or × 10 ocular in the photographic tube. Kodak 'Photomechanical' cut film was used for the negatives, which were then mounted between glass sheets for projection onto paper taped to a wall. The size of the projected image was large enough for the observers to measure a difference of at least 0·02 per cent and one particular spread was measured and computed five times to demonstrate that karyotype construction by this method is repeatable. A pencil was used to mark the centromere in each chromosome and to trace its length along the core of each duplicating chromatid. A map-measurer of the "drawing" type was used to measure the length of the pencil lines and the arms arranged in a list of sixty, by length. Adjacent chromosomes were then paired, from the longest to the shortest into thirty homologous pairs and each recorded as a percentage of the total length of chromatin in that spread. Adjustments were made in the male series to bring it into line with the female, by subtracting the length of the Y chromosome and making a "synthetic" X pair by adding the length of the single X chromosome after it had been multiplied by an appropriate factor. The factor was derived from the ratio of the length of the two female X chromosomes and from a preliminary observation that the single male X is a little longer than the longest female X. The longest acrocentric pair in the sheep and the third longest in the goat was assumed to be the X pair as a result of the findings of J. J. Evans[6] in the goat, and in the sheep, because one of these chromosomes is the largest unpaired acrocentric in the male. Measurements of length were used because of their obvious simplicity and the choice of this method is supported by Neurath and Enslein[7] who showed that it provides a quantitative and objective method of assigning chromosomes to groups in the human karyotype. It must be pointed out that the homologous pairs are identified by length only, which is a reasonable but not a fundamental criterion, so that any pair might be displaced in a neighbouring group.

I have assumed that the sheep and goat nuclei contain equal quantities of material[8,9], so that it is satisfactory to

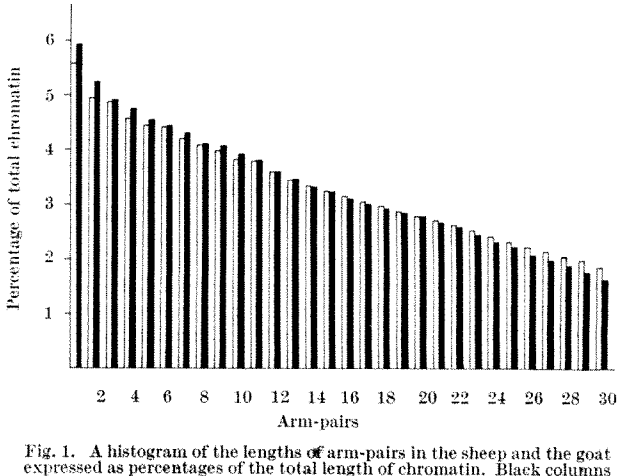

Fig. 1. A histogram of the lengths of arm-pairs in the sheep and the goat expressed as percentages of the total length of chromatin. Black columns represent goat and open columns represent sheep.

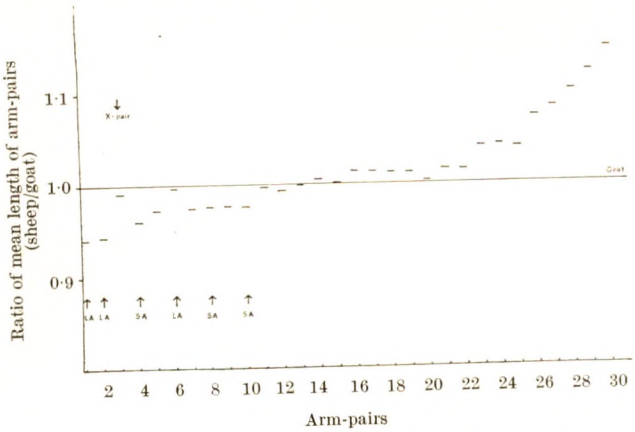

Fig. 2. A graph of the ratio of the mean length of arm-pairs in the sheep to the mean length of corresponding pairs in the goat. The metacentric pairs in the sheep are indicated by arrows with subscripts. SA, Short arms of metacentric; LA, long arms of metacentric.

use percentages in the comparison. A comparison of size is then valid, but real pairing by identity is not yet possible. In view of the close phenotypic and karyotypic resemblance of sheep and goats, there is a fair chance that pairing by size does not give a wild distortion of the true situation. The series of arm-pairs in the sheep was compared with that in the goat (Figs. 1 and 2). The longest arm-pairs of the goat are longer than the longest arm-pairs of the sheep and the shortest arm-pairs of the goat are shorter than the shortest arm-pairs of the sheep.

Robertsonian translocation has been suggested as one of the mechanisms of evolution in the bovid karyotype. Of the two species in question, it is the sheep which shows the form associated with Robertsonian change. The differences in length between the chromosomes, of the sheep and the goat could represent a translocation of chromatin from the large chromosomes, which took part in Robertsonian translocation, to the smallest chromosomes in the complement. Such fusion would have involved the junction of two acrocentrics, each of which had a pair of short arms and a centromere in addition to the long arms. It is likely that the material associated with one pair of short arms and one centromere would be displaced. The differences between the two species at both ends of the series support the theory of a translocation of material from the large chromosomes to the small ones when fusion occurred. If it could be shown, however, that the sheep nucleus contains less DNA than the goat nucleus, a loss of this material could be inferred. Two large acrocentric pairs in the sheep, the sixth and the ninth, also contribute to the differences in length between the species and this suggests that other translocations beside those caused by Robertsonian fusion may have contributed to the evolution of the karyotypes of these two species from a common ancestor. The study is to be extended to the karyotype of the Barbary sheep, *Ammotragus lervia* ($2n = 58$, one pair of metacentrics).

Immunofluorescent Localization of Chorionic Gonadotrophin in Monolayer Cultures of Human Trophoblast Cells

ALTHOUGH the ability to synthesize chorionic gonadotrophin by human trophoblast cells grown *in vitro* has been reported[1,2], there is still considerable doubt as to which of the cell types is responsible for production of the hormone.

We have attempted to localize this hormone by the "indirect" immunofluorescent method using a commercial preparation of rabbit anti-human chorionic gonadotrophin (Hyland, USA) and a goat anti-rabbit globulin labelled with fluorescein isothiocyanate, kindly provided by Dr Lachmann of the Immunology Division.

Fig. 1. Early trophoblast culture showing large, flattened cells with abundant granular cytoplasm and smaller polygonal cells with one nucleus. ×128.

Villi were dissected off 12–13 week old placentae obtained by hysterotomy from therapeutic abortions. These were minced with a scalpel into 1–2 mm pieces, rinsed three times with Eagle's basal medium at room temperature and then trypsinized for 10 min at room temperature in a 0·05 per cent solution of trypsin (Difco Bacto) in calcium and magnesium free phosphate buffered saline (PBS) using a magnetic stirrer. The tissue was allowed to settle and the supernatant discarded, fresh trypsin being added. This process was repeated three or four times but subsequent supernates were retained, placed in conical centrifuge tubes containing 1 ml. growth medium, and centrifuged at 500*g* for 5 min. The resulting cell pellets were gently resuspended in 2 ml. growth medium (199 containing 20 per cent foetal calf serum) and a cell count made.

The volume was adjusted to give concentrations of 1×10^6 cells/ml. and 4 ml. aliquots of cell suspension placed in flat 30 ml. plastic, screw-capped culture flasks (Falcon plastics), gassed with a 5 per cent CO_2 with air mixture and incubated at 37° C. The cells were examined daily and the medium changed every third day.

After 10 days of growth, the cultures were washed gently with three changes of PBS. After fixation in methanol, the base of the flask with the monolayer was cut away and left to dry at room temperature. This was then incubated for 30 min at room temperature with rabbit anti-HCG diluted 1 : 5 with PBS. The antiserum was washed off and fluorescein isothiocyanate-labelled goat anti-rabbit globulin applied, and left for 30 min at room temperature. The preparation was washed in six changes of PBS and mounted in buffered glycerol. The cultures were examined by a Zeiss Ultraphot fluorescence microscope.

Controls were set up by staining some monolayers with fluorescein-labelled anti-rabbit globulin alone and also by repeating the whole staining procedure on human foetal skin cells.

Fig. 2. Small polygonal cell showing specific fluorescence. ×128.

Initial examination of the cultures revealed three cell types, the most conspicuous being a very large, frequently multi-nucleated cell with abundant granular cytoplasm. Its shape was irregular and the cell appeared firmly flattened against the culture flask. The second type was a much smaller polygonal cell with one nucleus and surrounded by a relatively thin zone of cytoplasm (Fig. 1). The third type was a thin spindle-shaped cell with an elongated nucleus, the appearance of which was not unlike that of a fibroblast. After staining, only the small polygonal cell showed specific fluorescence. This appeared as a bright area within the cell localized around the nucleus (Fig. 2). The other cell types and the controls showed no fluorescence.

The question of the relative importance of cytotrophoblast and syncytiotrophoblast in the production of human chorionic gonadotrophin has still not been settled. In an immunohistochemical study[3] on formalin-fixed placental tissue, it was concluded that the syncytiotrophoblast was the cell of origin of human chorionic gonadotrophin. In a tissue culture study[1], however, it was found that the amount of gonadotrophin present in the culture medium was directly related to the growth of what appeared to be cytotrophoblasts in the culture.

The three types of cells obtained in our culture of human chorionic villi were very similar to those previously described[4,5]. Our results point to the small polygonal cell as the producer of human chorionic gonadotrophin, and their appearance suggests that they may be cytotrophoblasts.

Unexpected Features of the Action of Dinitrophenol on Cortical Neurones

2,4-Dinitrophenol (DNP) uncouples oxidative phosphorylation by interfering with mitochondrial activity[1,2]. It has been widely used to inhibit the metabolism of central or peripheral neural tissue[3–5]. The reduction in supply of ATP slows ion pumping and so leads to the accumulation of Na^+ inside cells and a corresponding loss of K^+. Blockage by DNP is therefore a criterion for identifying energy-driven processes.

Nishi, Soeda and Koketsu[6], and Kawamura and K. K.[7] recently showed that in sympathetic ganglia and the cerebral cortex, DNP readily blocks the slow excitatory muscarinic action of acetylcholine (ACh). This observation seemed to confirm the hypothesis that in this muscarinic role, ACh has a primary influence on cellular metabolism, associated with only secondary changes in excitability[8]. Such a mechanism would be in sharp contrast to the better-known, quick-acting nicotinic excitation, accompanied by a large increase in membrane permeability. A metabolic involvement was suggested by the long time course of excitation by ACh, and the absence of a clear increase in membrane conductance[8,9].

To understand better how DNP acts, we examined its effects with microelectrodes inserted into cortical neurones. The experiments were performed on cats anaesthetized with a mixture of nitrous oxide and methoxyflurane ('Penthrane', Abbott). To reduce pulsation of the brain, the chest was opened and succinylcholine ('Anectine', Burroughs Wellcome) was infused intravenously. The technique of recording the membrane potential and resistance (tested with 20 ms pulses), combined witd extracellular microiontophoresis, has been describeh before[10,11]. DNP was released from a 0·1 M solution of the sodium salt, at *p*H 9, by an inward current (microelectrode relatively negative). In some experiments a Linc 8 computer was used on-line to apply pulses, sample membrane potentials and derive voltage-current lines[12]. The computer rapidly made available estimates of the membrane resistance and the reversal levels of inhibitory synaptic potentials (IPSPs).

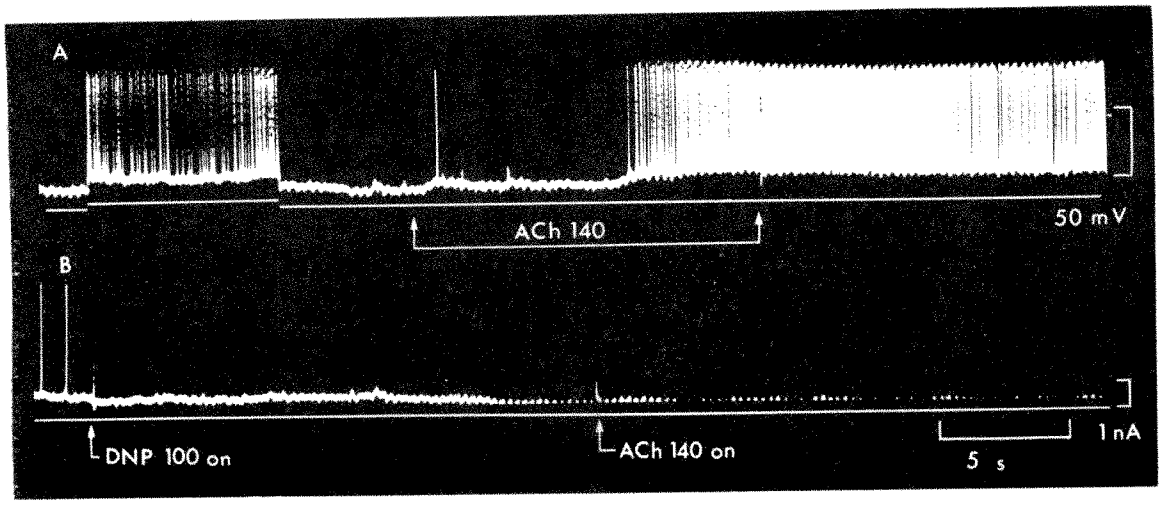

Fig. 1. Intracellular recording from pre-cruciate neurone. *A*, Excitation, first by depolarizing current, monitored on second trace, and then by extracellular application of ACh (iontophoretic current of 140 nA). *B*, Effect of DNP: release by inward current of 100 nA began at arrow and continued to end of trace; at second arrow, start of another application of ACh.

The results of these experiments revealed several unexpected features. The application of DNP leads to a pronounced decrease in electrical excitability, associated with a tendency to hyperpolarization and a lower resistance of the membrane. These effects are illustrated by traces obtained from a pre-cruciate neurone. In Fig. 1*A*, there is strong firing, initiated either by a depolarizing current (at left) or by an application of ACh. The action of the latter has the characteristic slow onset and long duration[13]. The lower trace (*B*) shows the effect of DNP, its release beginning at the first arrow: spontaneous spikes disappear, and the potential trace gradually shifts down (in the negative direction) towards the limit of visibility on the oscilloscope screen. Starting at the second arrow ACh was also applied, as in *A*, but for a longer period. This failed to evoke firing, or even subthreshold depolarization. All the effects of DNP were fully reversible, clear recovery beginning within 1–2 min of ending the application.

Further tests, on the same cell, showed other changes in membrane properties. The oscilloscope traces in Fig. 2 illustrate IPSPs evoked by surface shocks (at arrows in *A*). The IPSP is initially partly reversed, because acetate ions have diffused into the cell from the recording micropipette[14]. In the left-hand row, each trace consists of only a single sweep, with two 20 ms negative pulses of current applied respectively just before and about 30 ms after the surface shock (the current pulses are monitored on another trace). The corresponding voltage pulses clearly demonstrate the following: a lower resistance during the IPSP, a sharp fall in both resting and IPSP resistance during the application of DNP (*B*), and at least partial recovery after the end of the release (*C*). In the right-hand row, several traces were superimposed photographically, and the testing current was systematically reversed to include both positive and negative pulses in each record. The repetitive firing evoked by positive pulses was prevented by DNP (*B*).

Comparable observations have been made on more than twenty neurones, particularly clear effects being recorded from cells having relatively high and stable resting potentials. The hyperpolarizing tendency was seen more often than the resistance changes, possibly because of the technical difficulties involved in measurements of membrane resistance[10,11]. Unlike neurones, cortical neuroglia[15] showed no definite effects of DNP.

This rapid hyperpolarization of cortical neurones differs greatly from the slow depolarizing action of DNP on peripheral nerves[16]. The associated conductance increase points to a rise in membrane permeability as the underlying mechanism. The direction of potential change is consistent with an increase in permeability to K^+ or Cl^-; but the fact that DNP causes a hyperpolarization even when IPSPs are reversed (Fig. 2) makes an increase in anion permeability very unlikely. It is therefore likely that DNP acts by raising the permeability (P_K) of the membrane to K^+. The mechanism of this phenomenon may be comparable with the large increase in proton conductance induced by DNP in artificial phospholipid membranes[17,18]. In view of the high probable cytoplasmic *p*H (ref. 19), the observed negative shift

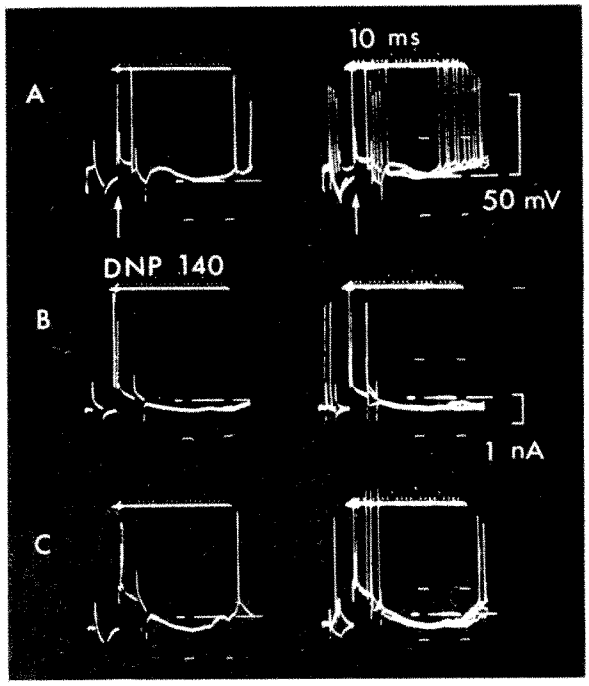

Fig. 2. IPSPs evoked in same neurone by surface shocks (0·1 ms, 12 V, at 3 Hz). In each record, top trace gives time calibration and d.c. reference level; main trace shows, from left to right, pulse monitoring electrode resistance (not visible in *B* and *C*), pulse indicating membrane resistance, stimulus artefact (at arrows in *A*), and IPSP, with second pulse indicating resistance near peak of IPSP; testing current pulses are monitored on third trace. Note single traces at left, with negative pulses only, and several superimposed traces at right, including both positive and negative pulses. *A*, Controls; *B*, during release of DNP; *C*, 1 min after end of release. Recording electrodes contained 1 M potassium acetate.

is probably not generated by a flow of protons; but DNP may act in the membrane of cortical neurones as a carrier of K^+.

Another possible explanation is that the increase in P_K is secondary to metabolic inhibition by DNP. There is some evidence that in red blood cells, metabolic activity is required to maintain a very low internal concentration of free Ca^{2+}, and that a rise in free Ca^{2+} is soon followed by an increase in membrane P_K[20,21]. DNP could augment the internal free Ca^{2+} in two ways: by reducing the Ca^{2+} binding resulting from mitochondrial accumulation[22] or chelation to cytoplasmic ATP[23]. Whatever its mechanism, the enhancement of P_K by DNP is not evident in all tissues (for example, cortical neuroglia or peripheral nerves[16]), but it may occur in cardiac muscle[24].

In conclusion, the depressant action of DNP can be fully explained by the observed changes in membrane properties, which probably result from an enhancement of membrane P_K. The blocking effect of DNP therefore gives no support for the hypothesis of a primarily metabolic action of ACh.

The explanation for the particularly effective antagonism of ACh excitation by DNP seems to be that as a muscarinic excitant, ACh may act in a precisely opposite fashion, that is by reducing P_K. We have some evidence that ACh tends to raise the membrane resistance of cortical cells; a similar muscarinic effect has been observed by Kobayashi and Libet[9] in sympathetic ganglia. In several respects, the action of ACh is analogous to that of Ba^{2+} (ref. 25). It is therefore of interest that Ba^{2+} has a muscarinic excitatory action on a variety of tissues[26–28], including the cerebral cortex (our unpublished observations).

Mode of Action of 5-Hydroxytryptamine on Isolated Rat Vas Deferens

It has been suggested that 5-hydroxytryptamine (serotonin) might cause the rat vas deferens to contract by interacting directly with the α-adrenergic receptors in the organ[1]. We found that vas deferens isolated from reserpinized rats could not respond to serotonin, so we have investigated the mode of action of serotonin on this preparation, and compared it with the action of tyramine.

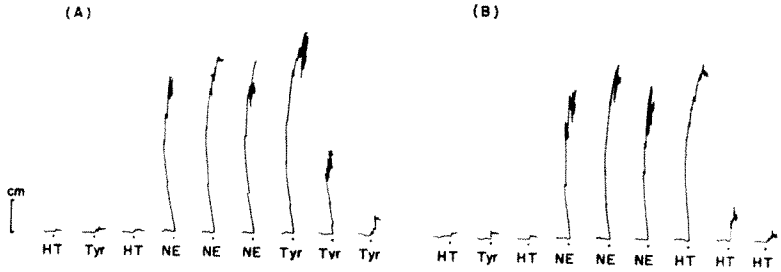

Fig. 1. Responses of vas deferens isolated from reserpinized rat to tyramine (*A*) and 5-hydroxytryptamine (*B*). NE, Norepinephrine 10^{-5} g/ml.; HT, 5-hydroxytryptamine 3×10^{-5} g/ml.; Tyr, tyramine 3×10^{-6} g/ml.

Vas deferens obtained from rats weighing about 200 g was suspended in a 10 ml. organ bath filled with Tyrode solution at 32° C and gassed with a mixture of 95 per cent O_2 and 5 per cent CO_2. The responses of the vas deferens to test drugs were recorded on a smoked paper. In most experiments, cumulative dose–response curves were obtained. The concentrations (g/ml.) of agonists refer to base, and those of antagonists to salt. All values are means of at least ten experiments.

The vas deferens isolated from reserpinized rat (2·5 mg/kg, intraperitoneal, 24 h before death) showed little response to serotonin or tyramine (Fig. 1). But after three successive 2 min exposures of the tissue to norepinephrine 10^{-5} g/ml., the responses of the organ to serotonin (3×10^{-5} g/ml.) or tyramine (3×10^{-6} g/ml.) recovered and equalled the maximum response to norepinephrine. Tachyphylaxis rapidly developed to further doses of serotonin or tyramine.

Contractions of vas deferens from normal rats by norepinephrine, serotonin and tyramine were blocked by a 20 min pretreatment with dibenamine (3×10^{-6} g/ml.). Tolazoline (10^{-6}–3×10^{-6} g/ml.), also an α-adrenergic blocking agent, had a similar effect, the block being competitive in nature. pA_2 values for tolazoline were calculated from parallel shifts in the dose-response curves for norepinephrine, serotonin and tyramine[2] and equalled $6{\cdot}29\pm0{\cdot}13$, $6{\cdot}40\pm0{\cdot}06$ and $6{\cdot}22\pm0{\cdot}14$, respectively.

The response of the vas deferens to serotonin was not affected, but the responses to norepinephrine and tyramine were slightly potentiated by 3-2-benzylaminoethyl-5-methoxyindole hydrochloride (10^{-6} g/ml.) which was reported to be a competitive inhibitor of serotonin. Incubation of the tissue with guanethidine (3×10^{-7}–10^{-6} g/ml.) or imipramine (10^{-7} g/ml.) until the response to norepinephrine was maximally potentiated resulted in an inhibition of the responses to serotonin and tyramine.

The responses to serotonin were more easily inhibited by guanethidine and imipramine than those to tyramine. Contractions produced by serotonin, tyramine and norepinephrine were equally potentiated by 45 min incubation of the vas deferens with procaine hydrochloride (3×10^{-5} g/ml.). Morphine (3×10^{-6} g/ml.) and tetrodotoxin (10^{-6} g/ml.) did not affect the contractions produced by these amines.

We conclude that serotonin causes the rat isolated vas deferens to contract through being taken up into sym-

pathetic nerve terminals[4] and causing the release of norepinephrine from storage.

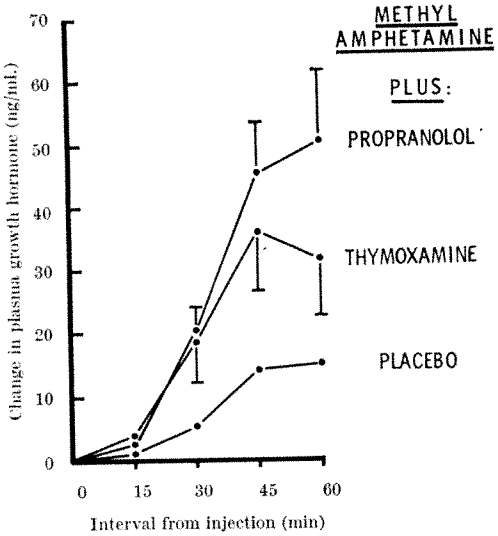

Fig. 2. Changes in mean plasma growth hormone levels after intravenous propranolol (0·15 mg/kg) or thymoxamine (0·10 mg/kg) or a placebo, each given 5 min before 15 mg intravenous methylamphetamine at 1800 h. Vertical bars represent 1 standard error of the differences between active and placebo effects.

Adrenergic Blockade and the Corticosteroid and Growth Hormone Responses to Methylamphetamine

THE observation that the hypothalamus has a high concentration of adrenergic neurones[1] and the highest catecholamine content of any central nervous system structure[2] has focused attention on the possible role of central catecholamines in neuroendocrine regulation. In a previous study[3] we have shown that the sympathomimetic and central stimulant drugs dextro- and methylamphetamine cause significant elevation of plasma corticotrophin, corticosteroids and growth hormone levels in human subjects. The rise in corticosteroids is most pronounced in the evening. It seems likely that the amphetamines act either directly on the hypothalamic neurones responsible for secretion of pituitary hormone releasing factors, or that they result in the local accumulation of catecholamines which then cause these neurones to secrete.

We now report the effects of α and β adrenergic blocking drugs on the corticosteroid and growth hormone responses to methylamphetamine. Thymoxamine, which has relatively specific α blocking activity[4], and propranolol, a β blocking drug[5], were used. Six healthy male volunteers aged 19–34 years were studied on three occasions at 1800 h after a fast of 5 h. A forearm venous cannula was inserted under local anaesthesia. Thirty minutes later either thymoxamine, 0·10 mg/kg body weight, or propranolol, 0·15 mg/kg, or a saline placebo was given, followed in 5 min by 15 mg methylamphetamine. Blood samples were taken before and 15, 30, 45 and 60 min after the methylamphetamine for plasma growth hormone and corticosteroid determinations.

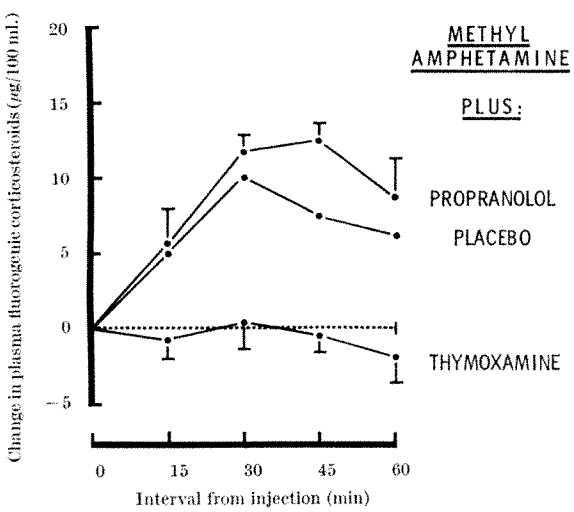

Fig. 1. Changes in mean plasma fluorogenic corticosteroids after intravenous propranolol (0·15 mg/kg) or thymoxamine (0·10 mg/kg) or a placebo, each given 5 min before 15 mg intravenous methylamphetamine at 1800 h. Vertical bars represent 1 standard error of the differences between active and placebo effects.

Treatments were allocated using a double-blind, cross-over method and a "Latin square" design, with 7 day intervals between tests in each subject. The differences were calculated between the control values and those recorded at each time interval after the blocking drugs or placebo. These differences were compared using Student's *t* test (two tailed). Plasma fluorogenic corticosteroids were measured by the method of Mattingly[6] and growth hormone by radioimmunoassay[7].

The administration of the placebo and methylamphetamine combination produced a mean maximum plasma corticosteroid rise of 10·8 μg/100 ml. (s.e. ± 1·43 μg/100 ml.). When the thymoxamine–methylamphetamine combination was given, however, there was no rise in mean plasma corticosteroid concentration (Fig. 1). The differences between the mean rises in plasma corticosteroids produced by thymoxamine – methylamphetamine and placebo–methylamphetamine were statistically significant at each time interval (P values between $< 0{\cdot}01$ and $< 0{\cdot}001$). Methylamphetamine given after propranolol caused a rise in mean plasma corticosteroids which was greater at each time than that produced by the placebo–methylamphetamine combination (Fig. 1), but this reached statistical significance only at 45 min ($P < 0{\cdot}05$).

There was a rise in mean plasma growth hormone with each treatment combination (Fig. 2). Propranolol–methylamphetamine caused a greater rise than that produced by placebo–methylamphetamine ($P < 0{\cdot}05$ at 30, 45 and 60 min). The mean growth hormone rise produced by thymoxamine–methylamphetamine was also consistently greater than that after placebo–methylamphetamine although the differences did not reach the 5 per cent level of significance at any individual time interval. The mean maximum plasma growth hormone increments were 17 (s.e. ± 6·4) ng/ml. after placebo–methylamphetamine and

52 (s.e. ± 11·7) ng/ml. after propranolol–methylamphetamine.

The adrenergic blocking drugs did not significantly change the mean blood pressure responses to methylamphetamine.

This study has shown that the corticosteroid rise produced by the sympathomimetic drug methylamphetamine could be prevented by prior administration of the α blocking drug thymoxamine and increased by the β blocking drug propranolol. By contrast, the effect of both of these adrenergic blocking drugs on the growth hormone increment was to cause an augmentation of the response to methylamphetamine.

The midbrain reticular formation is closely concerned with the control of hypothalamic corticotrophin releasing factor and consequent hypophyseal corticotrophin secretion[8]. Amphetamines act on the reticular formation[9,10], so it is possible that their effect on plasma corticosteroids is a result of an action at this site.

The amphetamine-induced rise in corticosteroids can be prevented by previous administration of thymoxamine, which suggests that this rise results from an α effect of amphetamine. This α effect is enhanced by the β adrenergic blocking drug propranolol. These actions of adrenergic blocking drugs are similar to the changes which they produce in the amphetamine-induced alterations of the electroencephalogram[11].

Because both α and β adrenergic blockade enhance the growth hormone response to amphetamine, it seems that amphetamine-sensitive control mechanisms for growth hormone secretion differ from those involved in corticotrophin release.

Relation of Occipital Spikes evoked by Intermittent Photic Stimulation to Visual Evoked Responses in Photosensitive Epilepsy

Patients suffering from photosensitive epilepsy show generalized discharges in their electroencephalogram (EEG) during intermittent photic stimulation. In some patients, these discharges are preceded by occipital spikes, suggesting a focal onset. Hishikawa *et al.*[1] have reported that the occipital spikes obtained in photosensitive epileptics have the same latency as some components of the visual evoked responses (VER), and suggested that this might explain the origin of the occipital spikes in photosensitive epilepsy. The spikes were, however, obtained at flash rates of 10–16 s^{-1} (that is, the interval between the flashes was limited to a range of 63–100 ms) and the comparison of the occipital spikes was made not with the VER of the individual patient, but with VERs of a normal population. Further, the latencies for positive and negative components of the VER, as given by the authors, show a very wide range and in fact overlap. The relatively small interval between the flashes and the wide range of the VER components could result in a fortuitous relationship between occipital spikes and VER components. It has also been reported by Rodin *et al.*[2] that spikes preceding generalized seizures, induced by 'Megimide' during intermittent photic stimulation, were related to normal VERs and consisted of a marked exaggeration of the secondary VER components. Their report, however, is concerned with normal animals (cats); and no details of the photic stimuli and the spikes are given. For these reasons we felt that we should re-examine the problem. The existence of a relationship between abnormal and "normal" responses would be critical to any theory attempting to explain the genesis of the occipital "epileptogenic" spikes.

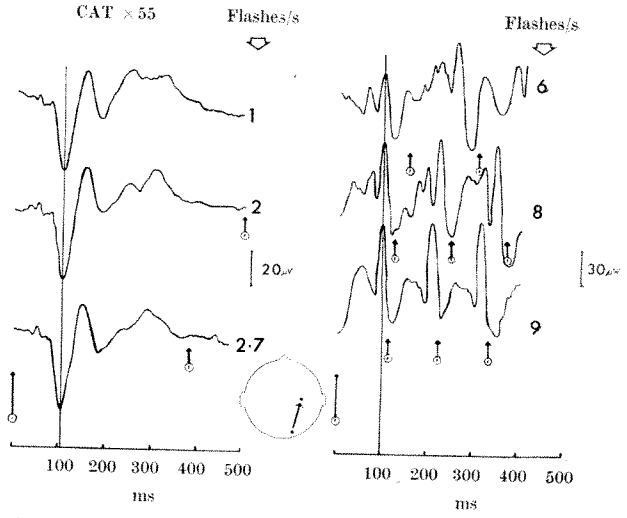

Fig. 1. Responses to photic stimulation in a female patient (R. O'B., code 34/60, aged 18) with photosensitive epilepsy. On the right are the responses to 6, 8, and 9 flashes/s. The negative spike at 100 ms is shown on the right by a vertical line. The only component of the average VER evoked by 1, 2 and 2·7 flashes/s which is of a similar latency is a positive one, indicated on the left of the figure by a vertical line. The horizontal line indicates time in ms. Flash stimuli are indicated by arrows. The CAT write-out is the average at 55 sweeps.

We have examined 23 patients with photosensitive epilepsy. The intermittent photic stimulation was delivered by a Kaiser stroboscope at 0·2 J. This stroboscope contains a metallic grid between a diffuse glass and the light source. The response to intermittent photic stimulation was recorded using a 'Mingograf' EEG machine at increased paper speed (15 and 30 cm/s) and increased gain (25 and 50 μV/cm). A frequency modulated tape recording was made at the same time, and was subsequently played back through an oscilloscope or Technical Measurement Corporation Computer of Average Transients (CAT). A special VER montage[3] was used.

All patients showed high amplitude generalized discharges during intermittent photic stimulation. In 21 of the patients (91·3 per cent) occipital spikes preceded the generalized discharges. This high incidence of occipital origin of the generalized discharges is much greater than has previously been reported[1] and is probably the result of the particular photic stimulus we used.

The responses to flash rates of 1–10 s^{-1} were examined in more detail in ten of these patients. We studied the VER produced by flash rates from 1–4 s^{-1} and occipital spikes occurring in response to 5–9 flashes/s. The occipital spikes[4] were triphasic (Fig. 1). The initial occipital positive component followed the preceding flash with a latency of 85·5 ± 9·5 ms. The most obvious part of the spike was a negative occipital component occurring at a latency of 102 ± 6 ms and followed by a variable positive component. The negative spike exhibited the following characteristics: (*a*) the spike appeared at 0·2–3·0 s after the onset of a train of stimuli and was never seen following the first flash; (*b*) the latency of the spike was constant for the same patient irrespective of the flash frequency over a range of 5–9 s^{-1}; (*c*) in all patients the frequency of the spike was fundamentally related to the flash rate. Some patients showed a gradual increase in the amplitude of the occipital spikes preceding a generalized discharge.

In nine of the ten patients no simple relationship could be found between the latency of the occipital spike and the VER of the individual patient, obtained at the same time and using the same technique. In four of these nine patients the latency of the negative occipital spike was similar to a positive VER component occurring with a latency of 100–112 ms. In only one patient was the occipital spike related in latency to the triphasic VER component V (Fig. 2) described by Gastaut and Regis[5]. No component of the generalized discharges following the occipital spikes showed any consistent or repeatable latency relationship to the flash stimuli.

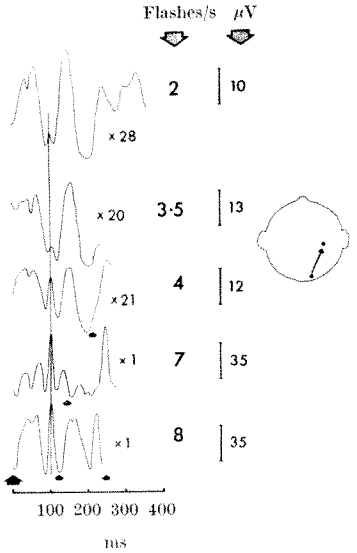

Fig. 2. Responses to photic stimulation in a female patient (M. F., code 33735, aged 24) with photosensitive epilepsy. The three upper traces show the average VER responses to 2, 3·5 and 4 flashes/s. The occipital spike evoked by 7 and 8 flashes/s is shown in the two lower traces and coincides with VER component V. The vertical line crosses the negative component of the occipital spike and the V *b* component of the VER. The horizontal line indicates time in ms. The flash stimulus is shown by a thick arrow.

The comparison of responses obtained at higher frequency intermittent photic stimulation (5–9 flashes/s) with those obtained at lower frequency intermittent photic stimulation (1–4 flashes/s) seems arbitrary. We have therefore compared the responses of ten normal subjects obtained at higher flash rates (5–9 s^{-1}) with those obtained at lower flash rates (1–4 s^{-1}). We found that the components of the VER whose latencies might have been related to those of the negative occipital spike remained unchanged over the range of 1–9 flashes/s. Further, no negative component appeared at latencies related to that of the negative occipital spike of photosensitive patients at 5–9 flashes/s intermittent photic stimulation.

Our observations show that (with the exception of one patient) no simple relationship exists between VER components and occipital spikes. The finding (*a*) that in one patient the occipital spike coincided with the VER triphasic component V, and (*b*) that there was a latency relationship between the positive VER component (equivalent to VER component V) and the negative occipital spike in four other patients, may be significant in that wave V has been related[5] to the scotopic and photopic system of the retina.

Inhibition of Norepinephrine Stimulated Adenyl Cyclase by Theophylline

Theophylline, at a concentration of 10^{-2} M, has been extensively used as an inhibitor of the enzyme phosphodiesterase, which decomposes adenosine 3′,5′-phosphate (cyclic AMP) to adenosine 5-phosphate[1]. It has therefore found widespread use in the determination of the activity of adenyl cyclase which catalyses the formation of this cyclic nucleotide. A recent assay developed by Weiss and Costa[2] eliminates the need for theophylline by using a pool of unlabelled cyclic AMP to trap that generated from labelled ATP and to protect it from destruction by phosphodiesterase. While using this procedure to study the adenyl cyclase of rat erythrocyte ghosts, it was observed that the addition of theophylline inhibited the enzyme.

Adenyl cyclase activity of rat erythrocyte ghosts was determined by a modification of the method of Weiss and Costa[2] as described previously[3]. The results of three experiments reported in Table 1 demonstrate that 2×10^{-2}–4×10^{-2} M theophylline inhibits both the basal and norepinephrine stimulated adenyl cyclase but has no effect on fluoride stimulation. The decrease in norepinephrine stimulation appears to be greater than can be accounted

Table 1. Inhibition of adenyl cyclase activity

Experiment	Addition	Basal	10^{-4} M norepinephrine	10^{-2} M fluoride
1	None	0·117 ± 0·011	0·373 ± 0·017	0·537 ± 0·082
	2×10^{-2} M Tris	0·103 ± 0·004	0·328 ± 0·015	0·643 ± 0·068
	2×10^{-2} M theophylline	0·069 ± 0·004*	0·176 ± 0·012‡	0·754 ± 0·107
2	None	0·092 ± 0·023	0·148 ± 0·006	0·442 ± 0·015
	2×10^{-2} M theophylline	0·059 ± 0·003	0·105 ± 0·003†	0·440 ± 0·014
3	None	0·063 ± 0·007	0·154 ± 0·009	
	4×10^{-3} M theophylline	0·039 ± 0·004	0·140 ± 0·015	
	2×10^{-2} M theophylline	0·048 ± 0·008	0·078 ± 0·004†	
	4×10^{-2} M theophylline	0·024 ± 0·002*	0·069 ± 0·01†	

The data represent the means of three determinations along with their standard errors and are expressed in nmoles cyclic AMP/0·2 ml. ghosts/30 min.

* $P < 0.05$; † $P < 0.01$; ‡ $P < 0.001$.

for by a decrease in the basal level. Thus norepinephrine stimulated production of 0·256, 0·056 and 0·091 nmoles of cyclic AMP in experiments 1, 2 or 3, respectively, was reduced to 0·107, 0·047 and 0·03 nmoles by theophylline.

The addition of 2×10^{-2} M theophylline would increase the tonicity of the medium, so it was conceivable that the decrease in production of cyclic AMP resulted from a decreased permeability of the ghosts to ATP. In experiment 1, a comparable increase in tonicity was achieved by the addition of 2×10^{-2} M Tris buffer. As can be seen, no change in norepinephrine or fluoride stimulation of adenyl cyclase was obtained.

When the theophylline concentration was increased to 4×10^{-2} M, the inhibition of basal and norepinephrine stimulated adenyl cyclase was greater. The inhibition disappeared when the concentration of theophylline was reduced to 4×10^{-3} M.

This effect of theophylline becomes apparent only in those conditions where phosphodiesterase activity is not a factor. Such a situation exists by virtue of the fact that the cyclic AMP pool is so large that no significant decomposition of cyclic AMP occurs during the incubation period.

If the pool of unlabelled cyclic AMP is not used, the typical response to theophylline is noted, that is, it enhances the production of cyclic AMP by both norepinephrine and fluoride.

The implications of these observations are at the moment unclear because most, though not all, of the data obtained with theophylline (10^{-2} M) conform to its role as an inhibitor of phosphodiesterase. The recent finding that theophylline inhibited the increase in cyclic AMP produced by electrical stimulation of guinea-pig cortex slices[4] might be explained by an action at the level of the cyclase enzyme. Further work is obviously required to determine the nature of the inhibition of adenyl cyclase, its tissue specificity, and its significance in biological systems.

The results do serve once again to separate fluoride from hormone stimulation of adenyl cyclase as emphasized by Weiss[5] with the pineal gland. One might suggest that theophylline is acting at the level of the norepinephrine receptor or at the coupling between receptor and enzyme. Alternatively, it could act at the level of the cyclase such that the weak activation by norepinephrine, but not the strong activation by fluoride, is inhibited. We are not able to choose from among these suggestions.

Enhancement of the Pre-irradiation Action of TAB

GRAM negative endotoxin is able either to reduce radiation mortality or at least to enhance the recovery of the haemopoietic system following total-body radiation (TBR)[1-4]. These beneficial effects have been observed in several species, for example mice, dogs, rhesus monkeys. The mechanism whereby endotoxin reduces mortality is obscure. The earlier recovery of haemopoietic cells observed after endotoxin treatment may be secondary to endotoxin-induced changes that may allow these tissues better to tolerate the diverse pathophysiological effects of the acute radiation syndrome.

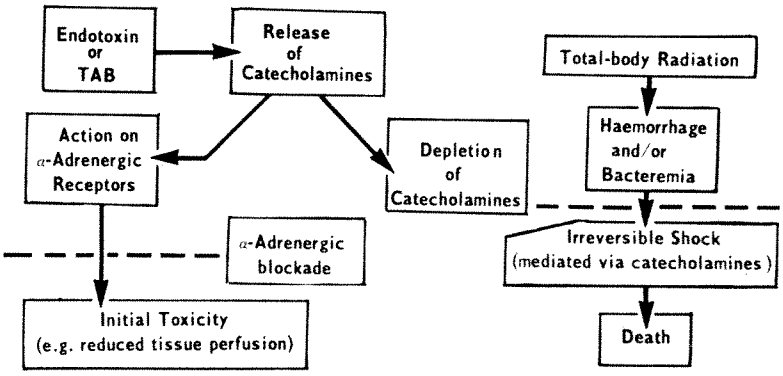

Fig. 1. Hypothesis for the post irradiation effect of TAB and endotoxins.

A recent study[2] suggests that some of the side effects seen shortly after the administration of endotoxin, given as typhoid paratyphoid A and B vaccine (TAB), may result from catecholamine release. Accordingly, the usefulness of TAB vaccine given after TBR could be increased by combining TAB with an α-adrenergic receptor blocking (α-ARB) agent. By contrast, the beneficial effects of endotoxin were lost (Table 1) if acetylation of the endotoxin molecule[5] was used to modify side effects. Substitution of β-adrenergic receptor blockage (β-ARB) for α-ARB also resulted in a loss of the benefits of post-irradiation treatment with TAB[6]. When the dose of TAB is lowered so as to minimize side effects, the mortality-reducing action of TAB is also lowered[3]; some of the beneficial effects of TAB, for example earlier platelet recovery, may be retained[4].

Table 1. ACETYLATED ENDOTOXIN ON RADIATION MORTALITY OF $C_3H \times AKR$ MICE

Treatment	Mortality (per cent)
700 rad only	62/64 (97)
700 rad + endotoxin*	35/63 (55)
700 rad + acetylated endotoxin	36/44 (82)

* *S. typhosa* endotoxin (Difco) 1 mg/kg 1 h after TBR.

The studies dealing with the side effects of TAB vaccine suggest that catecholamine release may, in the long term, play a part in the beneficial actions of TAB. Accordingly, a hypothesis was formulated for the post-irradiation action of TAB; this was based on the possibility that catecholamine depletion from tissues (especially from the adrenals) might allow better tolerance towards bacteraemic and/or haemorrhagic shock during the acute radiation syndrome[2]. The hypothesis is outlined in Fig. 1.

When given before irradiation, gram negative endotoxin more effectively reduces radiation mortality. Catecholamine release (leading to reduced tissue perfusion and hypoxia) might explain, in part, the pre-irradiation action of TAB. On this assumption, the pre-irradiation action of TAB should be enhanced by pre-irradiation treatment with a β-ARB agent and post-irradiation treatment with an α-ARB agent. This study was designed to test this hypothesis.

$C_3H \times AKR$ female mice (*Pseudomonas* free) were given various doses of TBR using 300 kVp X-rays as previously reported[2]. The irradiated animals were divided into four groups. Group I served as a control. One hour before irradiation, group II received 0·1 ml. of

TAB vaccine (Parke Davis) intraperitoneally. Groups III and IV received TAB as described; in addition group III was treated 0·5 h and 0·25 h before irradiation with the β-ARB agent propranolol hydrochloride ('Inderal', ICI). Each dose was 10 mg/kg intraperitoneally. (Given alone, propranolol does not reduce mortality.) In addition to TAB vaccine and β-adrenergic blockade, group IV was treated after irradiation with the α-ARB agent, phentolamine ('Rogitine', Ciba). The dosage schedule for phentolamine was as previously reported[2]. In all groups, animals started to die at about the middle of the second week following TBR. After a 30 day observation period, LD_{50} values and dose modifying factors (DMF) were calculated from the dose-mortality data[7]. Table 2 gives LD_{50} and DMF values for the four groups. β-ARB treatment alone enhanced the mortality-reducing action of TAB vaccine. Further enhancement was obtained when post-irradiation treatment with α-ARB was combined with pre-irradiation β-ARB.

Table 2. ADRENERGIC BLOCKING AGENTS ON PRE-IRRADIATION TAB

Group	Treatment		LD_{50}* (rad)	DMF
	Before TBR	After TBR		
I (Control)	—	—	620	—
II TAB	—	—	750	1·21
III TAB +	β-ARB	—	820	1·33
IV TAB +	β-ARB	α-ARB	860	1·39

* Similar slopes.

Assuming hypoxia (caused by reduced tissue perfusion) is partly responsible for the radioprotective action of TAB, then the enhancing action of the β-ARB agent, propranolol, could be due to further decreases in blood flow. Evidence for such an effect of propranolol was recently reported[8]. In these experiments, propranolol potentiated the ability of adrenaline to reduce blood flow through the superior mesenteric artery of the dog.

An effect of propranolol at the cellular level (for example, a cysteamine like action) is tentatively ruled out because this β-ARB compound does not modify the *in vitro* X-ray survival cure of a mammalian cell line[9]. Furthermore, no such effect would be expected for the known metabolites of propranolol.

TAB vaccine was administered shortly before TBR, so the long-term values of catecholamine depletion (Fig. 1) should add to the hypoxic action of TAB. This may explain why gram-negative endotoxin given before TBR is more effective in reducing radiation mortality than is post-irradiation treatment. For both the pre and post-irradiation actions of TAB, catecholamine release appears as a common factor. The earlier recovery of the haemopoietic system observed after endotoxin is explicable within the hypotheses proposed in this study. Hypoxia would reduce the effective radiation dose to the haemopoietic system, and catecholamine depletion might allow irradiated animals better to tolerate the bacteraemic and/or haemorrhagic shock associated with the acute radiation syndrome. Although additional studies will be required to substantiate the "catecholamine hypothesis", this study indicates that appropriate adrenergic receptor blocking agents may increase the capacity of gram-negative endotoxins to reduce radiation mortality.

Production of Pyrroles from Pyrrolizidine Alkaloids by Human Embryo Tissue

PYRROLIZIDINE alkaloids are produced by a number of common plants including *Senecio* and *Heliotropium* species. They have been implicated in cases of bread poisoning in man in South Africa[1], and the infusion of certain of these plants to make bush teas is believed to cause veno-occlusive disease in children in the West Indies[2]. Grazing animals are frequently affected by these hepatotoxins, and the disease has therefore been closely studied during experiments on domestic and laboratory animals, especially rats; but relatively little is known of the effects on man. The toxic effects of heliotrine and the resulting depression of RNA, DNA and protein synthesis in human liver cells in culture have been studied recently[3].

The production of pyrroles from pyrrolizidine alkaloids, by rat livers, *in vivo* and *in vitro*, has been reported[4]. A modified Ehrlich's reagent gives a magenta colour with pyrroles, but does not react with the parent alkaloids. The pyrroles are highly reactive alkylating agents and are probably far more toxic than the alkaloids themselves.

Fulvine causes both lung and liver damage in rats[5], and West Indian children given bush tea containing fulvine have been admitted to hospital with veno-occlusive disease and pleural effusions[6]. The tests for the ability to metabolize three alkaloids, lasiocarpine, retrorsine and fulvine, were therefore carried out on both lung and liver tissues from human embryos.

Slices of tissue about 5 mm across and 2 mm thick were added to tubes containing the alkaloids dissolved in 1 ml. Eagle's medium, and rotated at 37° C. The pieces of tissue were heated for 3 min with 1 ml. of the modified Ehrlich's reagent at 85°–90° C. The pieces were then washed in alcohol and examined.

The liver slices all gave positive reactions with all three alkaloids, but the lungs gave negative results, even when 200 μg of alkaloid was used. Liver pieces were incubated with 100 μg of alkaloid for 24 h. Lasiocarpine consistently gave stronger colours than retrorsine; fulvine produced an intermediate intensity. This is interesting because it is the reverse of the order of toxicity in rats, and tissue culture work indicates that retrorsine is more toxic to human embryo liver cells than lasiocarpine (unpublished work). Liver slices incubated with 100 μg lasiocarpine showed a steady increase in the production of pyrroles from 1 h, to at least 48 h. Pieces of liver treated with 100 or 200 μg lasiocarpine for 24 h gave strong reactions of similar colour intensity; a slight colour was obtained with 50 μg, and no colour was detectable with 10 μg. The indicator system is not very sensitive so it was not possible to detect pyrroles in the incubation fluid or in monolayers of hepatocytes.

The results indicate that human embryo liver tissue is able to metabolize pyrrolizidine alkaloids, producing pyrroles. Either lung tissue cannot perform this reaction, or the amounts of pyrroles produced are too small to be detected.

Preliminary results using tissue culture seem to confirm that the alkaloids themselves have little or no effect on lung cells. Trypsinized lung or liver cells were implanted in mouse plasma on polythene disks, forming monolayers[7]. The cultures were incubated with an alkaloid, and then examined with acridine orange, or used for autoradiography[8]. After 3 days' incubation with 100 μg lasiocarpine, 83 per cent inhibition of DNA synthesis was found with hepatocytes. Identical experiments with lung cells showed that neither 100 μg lasiocarpine nor retrorsine had any effect on DNA synthesis. Similarly, it was found that monolayers of lung cells incubated for 7 days with 25 μg lasiocarpine or retrorsine appeared histologically normal, whereas hepatocytes treated in the same way were obviously abnormal.

Chemically produced pyrroles, when administered to rats, cause lung damage similar to fulvine intoxication[4]. The lung oedema in children with veno-occlusive disease could therefore be due to pyrroles produced in the liver and carried to the lungs via the blood stream.

The production of pyrroles *in vitro* does not seem to correlate with the toxicity of the alkaloids. This could be a consequence of the presence of varying proportions of the more hydrolysed pyrrole derivatives, which are non-toxic but which react to give a positive colour.

We thank Dr H. E. M. Kay and members of the Tissue Bank of the Royal Marsden Hospital; also Dr A. R. Mattocks for his advice, and for the gift of fulvine and retrorsine, which he and Dr Barnes, both of the Medical Research Council Toxicology Research Unit at Carshalton, provided. Lasiocarpine was supplied by Dr C. C. J. Culvenor of the CSIRO Chemical Research Laboratories, Melbourne, Australia. This work was supported by a grant from the MRC.

Detection of H-2 Antigens on Mouse Spermatozoa by the Cytotoxicity Test

HISTOCOMPATIBILITY antigens of the type H-2 are found on most cells of the mouse, but there are conflicting reports concerning their expression on spermatozoa. Using the indirect immunofluorescence technique, Barth and Russell[1] found no H-2 antigen on spermatozoa. Using the techniques of immunogenicity, antibody absorption, and indirect immunofluorescence, Vojtiskova *et al.*[2] concluded that H-2 antigens were probably detectable on spermatozoa by all three procedures. As these authors point out, however, it is difficult to exclude entirely the possibility that contaminating cells were responsible for the positive findings with the first two techniques.

Fellous and Dausset[3] reported the presence of HL-A antigen on human sperm, and on the basis of the proposed homology between the *HL-A* and *H-2* loci it seems probable also that H-2 antigen is present on spermatozoa. In this investigation we used the cytotoxicity test[4,5] to obtain further evidence on whether or not H-2 antigens are in fact expressed on spermatozoa. The advantages of this test for the presence of cell surface antigens are (1) that individual cells carrying the antigen are seen to be lysed, so that minor contamination with cells of another type is immaterial, and (2) that control of serological specificity is easier than in the case of the indirect immunofluorescence method. It is therefore perhaps the most effective serological test available at the present time for demonstrating the presence of antigen on viable cells. Its application to spermatozoa, however, presented unforeseen technical difficulties. When these were overcome we were able to demonstrate without doubt that H-2 antigen is present on mouse spermatozoa.

The chief difficulty in applying the cytotoxicity test to spermatozoa is the toxicity of the sera used to provide complement. This is because of naturally occurring hetero-antibody. Rabbit serum is superior to guinea-pig serum in most immune cytolytic systems involving nucleate cells (reviewed by Haughton and McGehee[6]), but both are toxic for mouse cells. Thymocytes were already known to be more sensitive than other cells to hetero-antibody, and we soon found that spermatozoa are still more sensitive, making it essential to remove the hetero-antibody by pre-absorption with mouse cells. In our experience, this can only be done effectively (that is, without prohibitive loss of complement) by absorbing the rabbit serum with mouse cells in the absence of free calcium. Removal of calcium prevents the binding of complement and so permits the absorption of the hetero-antibody without concomitant loss of complement[7].

The mice used were from the inbred strains C57Bl/6 ($H\text{-}2^b$); A ($H\text{-}2^a$); C57Bl/H-2^k congenic with C57Bl/6; A.BY ($H\text{-}2^b$) congenic with A; AKR.K ($H\text{-}2^a$) congenic with AKR ($H\text{-}2^k$); the hybrid $(C57Bl/6 \times A)F_1$ ($H\text{-}2^{b/a}$); and the backcrosses $(BALB/c \times C57Bl/6)F_1 \times C57$ ($H\text{-}2^{d/b} \times H\text{-}2^b$) and $(C57 \times AKR)F_1 \times C57$ ($H\text{-}2^{b/k} \times H\text{-}2^b$); all were from the colonies maintained by E. A. B. (C57Bl/6 abbreviated to C57).

Sperm were obtained from different regions of the male reproductive tract. The vas deferens was removed and its contents extruded into a drop of phosphate-buffered saline (*p*H 7·0) containing 0·5 per cent fructose and 5 per cent foetal calf serum previously heated to 56° C for 30 min. The fructose and foetal calf serum were found to improve sperm viability. Epididymal spermatozoa were obtained by cutting the entire epididymis into sections in a few drops of medium; after 5 min the medium containing free spermatozoa was pipetted off. There was less than 5 per cent contamination with cells other than spermatozoa as determined in a haemacytometer by phase contrast microscopy.

Table 1. REMOVAL OF HETERO-ANTIBODY FROM SELECTED RABBIT SERUM BY ABSORPTION WITH MOUSE CELLS IN THE ABSENCE OF FREE CALCIUM

Number of absorptions of rabbit serum	Lowest dilution at which rabbit serum shows no toxicity*	
	For thymocytes	For epididymal sperm
0	1/16†	1/45
1	1/4	1/4
2	1/2	1/2

* Background < 15 per cent spermatozoa dead.
† Dilution before use in the test. Test constituents are equal parts of (*a*) serum dilution; (*b*) spermatozoa or thymocyte suspension (5×10^6/ml.); (*c*) medium 199 (for thymocytes) or phosphate buffered saline with 0·5 per cent fructose and 5 per cent foetal calf serum (for spermatozoa).

The four H-2 antisera used were prepared as described in ref. 8. They are as follows: C57/H-2^k (congenic with C57) anti C57 leukaemia EL4 designated H-2^k vs H-2^b; A anti-C57 leukaemia EL4 designated H-2^a vs H-2^b; C57 anti-A strain leukaemia ASL1 designated H-2^b vs H-2^a; and $(BALB \times C57)F_1$ anti-C3H sarcoma BP8 designated H-$2^{d/b}$ vs H-2^k. These had haemagglutination[9] titres of 1/1,000 to 1/8,000 and cytotoxic titres of 1/640 to 1/1,000 against lymphocytes of the relevant H-2 type.

Rabbit serum was used as the source of complement (C′) in the cytoxicity test. Twenty to thirty rabbits were bled from the ear and their sera titrated individually for toxicity against mouse thymocytes. Sera which were non-toxic at a dilution of 1/16 were then titrated for C′ activity in a known allogeneic cytotoxic system such as H-2. (The dilutions given refer to dilutions made before use in the cytotoxic test.) The rabbit with the highest C′ titre was then bled by cardiac puncture. Even these selected sera were toxic for

* The dilution of antiserum at which the highest percentage of spermatozoa were killed was usually 1/2 (undiluted antiserum was not tested).

mouse sperm at a dilution of 1/32 or more, and it was therefore necessary to absorb the hetero-antibody. For this purpose EDTA was added to the rabbit serum to a concentration of 0·01 M and the serum was then absorbed with washed viable mouse cells (8 : 1 v/v) for 30 min in an ice bath. The cells used for absorption were prepared by washing in Earle's balanced salt solution lacking calcium and magnesium. Preliminary tests indicated that testicular cells, prepared by gentle homogenization of testis, were most efficient in absorbing hetero-antibody. Spleen cells, leukaemia cells and thymocytes, as available, were also added. After absorption, $CaCl_2$ was added to restore the level of free calcium. These absorbed sera were non-toxic to sperm at a dilution of 1/4. A second absorption decreased toxicity further, allowing the use of the absorbed serum at a dilution of 1/2 (Table 1).

Doubling dilutions of H-2 antisera were prepared. Equal volumes (0·05 ml.) of antiserum dilution, sperm suspension (4×10^6–5×10^6/ml.), and absorbed rabbit serum diluted 1/4 (or 1/2 of doubly absorbed rabbit serum) were incubated for 45 min at 37° C. Then 0·1 ml. of trypan blue solution was added. (1 per cent trypan blue was made up in distilled water, and diluted immediately before use with 42·5 g/l. NaCl, 1 part in 5, to render it isotonic.) The percentage of dead spermatozoa was determined in a haemacytometer. Live spermatozoa do not take up trypan blue whereas dead spermatozoa take up stain in the head region.

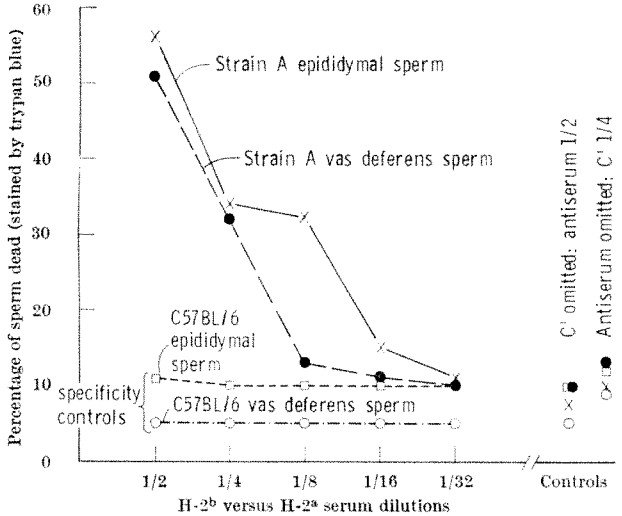

Fig. 1. Detection of H-2^a on epididymal and vas deferens sperm of A strain mice by the cytotoxicity test.

A representative test is illustrated in Fig. 1. Results summarized in Table 2 leave no doubt that spermatozoa are susceptible to H-2 antisera. Specificity of the reaction for H-2 is shown, for example, by the results with the H-2 antiserum H-2^k vs H-2^b prepared in congenic strains of mice (Table 2, experiment a). As a further test of specificity, spermatozoa from backcross mice already typed for H-2 by haemagglutination[9] were tested with H-2 antisera by the cytotoxicity test; these blind tests invariably showed a positive correlation (Table 3).

The proportion of spermatozoa lysed by H-2 antisera was greater when they were from the epididymis than when they were from the vas deferens, suggesting either that H-2 antigens are reduced in amount as the sperm matures, or that they are masked by secretions from the genital tract which are known to become adsorbed on spermatozoa[10]. Indeed, present evidence does not exclude the possibility that the H-2 antigen is actually carried by adsorbed secretions.

* Relevant H-2 specificities: 3, 4, 8, 10, 13.

The proportion of spermatozoa lysed by H-2 antisera was generally higher in H-2 homozygotes than in H-2 heterozygotes (Table 2, experiments e, f, g, m, n and o). This may indicate that only one H-2 haplotype is represented on epididymal spermatozoa. On the other hand, the cytotoxic reaction of H-2 antisera on spermatozoa obviously represents a weak detection system, and in such systems the reaction with heterozygotes is weaker than that with homozygotes because of the lesser amount of antigen on the former. The sensitivity of the H-2 cytotoxic reaction will have to be increased, or some other method found to distinguish between these two possibilities.

Sex Difference in Trophoblast Behaviour on Transplantation

STUDIES on conditions resulting in the premature termination of pregnancy indicate that the male conceptus may be less well adapted to survive in the maternal host than the female. Sex chromatin determinations[1] carried out on chorionic villi of spontaneously aborted foetuses have shown that the majority of foetuses lost are male[2,3]. Moreover, more male foetuses than female seem to be involved in premature termination as a result of antepartum haemorrhage[4]. Because the trophoblast is the foetal tissue most intimately associated with the maternal host during pregnancy, we decided to examine the influence of foetal sex on the ability of trophoblast cells to survive as allografts.

Foetuses with attached placentae were obtained by hysterotomy on 6–8 week pregnant guinea-pigs, under anaesthesia. Trophoblast tissue was separated from the placenta, and lung or skin removed from the foetus, and placed in dishes containing warm sterile Eagle's minimal essential medium (MEM). This tissue was washed in warm MEM, cut into 2 mm fragments and trypsinized (0·05 per cent trypsin in calcium and magnesium free PBS) at room temperature. After 5 min, the supernatant was discarded, fresh trypsin added, and the tissue agitated gently for a further 5 min using a magnetic stirrer. The supernatant was collected, 1 ml. growth medium (MEM + 20 per cent foetal calf serum) added and the procedure repeated four or five times. The resultant supernatants were combined and centrifuged at 500*g* for 10 min. The supernatant was discarded and the cell pellet resuspended in MEM to give a final cell concentration of 10^7 cells/ml.

Eight virgin female and twelve mid-term pregnant guinea-pigs (multiparous and primiparous) were used as recipients in this study. Each animal received six intradermal inoculations of 0·1 ml. of each of the following cell suspensions from one pregnant donor animal: (1) trophoblast cells from a male foetus; (2) lung or skin cells from the same male foetus; (3) trophoblast cells from a female foetus; (4) lung or skin cells from the same female foetus. Intradermal injections of cell suspensions were made into marked areas on the back of recipient guinea-pigs, and a sample of skin removed at various intervals for histological examination.

In the virgin female recipients, non-trophoblast foetal cells (skin or lung) were rapidly destroyed by the host, no donor cells being found later than six days post-inoculation. No obvious sex or tissue differences were found in the behaviour of the non-trophoblast foetal cells on transplantation. Trophoblast cells in the same recipients survived considerably longer than the other foetal tissues, the former being present in the recipient for up to 14 days post-inoculation for male trophoblast and 20 days for female trophoblast cells (Table 1).

With pregnant recipients, the non-trophoblast foetal cells were rejected less rapidly than they were by virgin females, healthy cells being present as late as 10 days post-inoculation. Trophoblast cells, however, were present at 35 days post-inoculation in the case of the female tissue, and at 20 days for the male (Table 1). Female trophoblast cells were also seen to be proliferating from 10 days onwards, large numbers of healthy cells, some showing mitotic activity, being present in the dermis of the recipient animals at the end of the experiments 35 days post-inoculation.

The results indicate that allografts of separated female trophoblast cells will survive considerably longer than the corresponding male cells, in both virgin and pregnant hosts, and that the female trophoblast cells are capable of proliferating in an ectopic environment, as late as 35 days after transplantation, in the pregnant host. No such obvious sex difference was found in the behaviour of the non-trophoblast foetal tissue. These results seem to confirm conclusions drawn from earlier studies on tumours of the trophoblast in which it was shown that most trophoblast tumours were chromatin positive[5,6], indicating that the foetuses concerned were genotypic females.

Table 1. SURVIVAL TIMES OF CELLS AFTER INTRADERMAL INOCULATION

Recipient	Allograft	Donor sex	Surviving cells. Days post-inoculation 3	6	10	14	20	35
Virgin	Foetal	Male	+++	+	0	0	0	0
		Female	+++	+	0	0	0	0
Female	Trophoblast	Male	+++	++	+	+	0	0
		Female	+++	+++	++	++	+	0
Pregnant	Foetal	Male	+++	++	+	0	0	0
		Female	+++	++	+	0	0	0
Female	Trophoblast	Male	+++	+++	++	++	+	0
		Female	+++	+++	++++	++++	++++	+++++

Surviving healthy guinea-pig trophoblast and foetal lung cells in serial sections of skin taken from recipient animals at various times after intradermal inoculation of 0·1 ml. of cell suspension (approximately 10^6 cells).

Thus, trophoblast cells arising from a female conceptu seem to be better able to survive as allografts in a maternal host than the corresponding male, and in certain circumstances the cells may even continue to proliferate in the absence of a viable foetus. We shall attempt to characterize the mechanisms underlying the observed sex-associated differences in the behaviour of the trophoblast and its tumours.

We thank Mrs J. Edmundson and Mr Alan King for technical assistance. The investigation was supported by a grant from the British Empire Cancer Campaign for Research.

Maturation of the Maternofoetal Transport System for Human γ-Globulin in the Mouse

THE plasma concentration of γ globulin (IgG) in the human conceptus after 22 weeks or less of gestation is a fifth to a twentieth of that in the mother[1,2], but from 26 weeks to the end of gestation the two concentrations are the same[1,2]. Because the foetus, even at term, can synthesize only small amounts of γG, this marked increase in the plasma IgG seems to be a consequence of an abrupt change in the permeability of the maternofoetal barrier to IgG. We have investigated the nature of this change in permeability in the pregnant mouse.

Swiss albino Webster mice were used. During 10 days, seven groups of females were placed with mature males for 1 or 2 days, each group being bred on a different day; two or three mice became pregnant in each group. On the eighteenth day after the first mating, all pregnant mice started to receive drinking water containing 0·25 g per cent of sodium iodide. On the next day, they were given a single intravenous injection containing 2 μCi of human IgG labelled[3] with iodine-131 and 2 μCi of human serum albumin labelled[3] with iodine-125; the amounts of IgG and albumin injected were less than 0·1 mg and 1 mg, respectively. Twenty-four hours after the injection, on the twentieth day after the first mating, mice were anaesthetized and bled. Aliquots of maternal serum were precipitated in 10 per cent trichloroacetic acid (TCA). The foetuses in a given litter were pooled, weighed and homogenized in 10–20 volumes of 10 per cent TCA. The maternal serum precipitates and the precipitates in aliquots of the foetal homogenates were washed twice in 10 per cent TCA, and assayed for radioactivity using a 400 channel spectrometer with a 3 inch sodium iodide crystal. The ratio of the amount of iodine-131 and iodine-125 per g of foetal tissue, F, to the amount of iodine-131 and iodine-125, respectively, per ml. of maternal serum, M, was taken as a measure[2,4] of the extent of maternofoetal transfer of human IgG and human albumin, respectively.

Fig. 1 shows that the F/M ratios for human albumin increased approximately four-fold from 11 days of gestation to term, and that most of this increase occurred after the sixteenth day. The F/M ratios for human IgG at 11 days of gestation were only slightly greater than for albumin, but by 12 days maternofoetal transfer of human IgG had increased dramatically. On the fifteenth day of gestation human IgG F/M ratios were 100 times those on the eleventh day, and remained so until term. Thus in the mouse maternofoetal barrier there is a rapid increase in permeability to human IgG between 11 and 15 days of gestation, much like the rapid increase in the permeability of the human placenta to IgG between 22 and 26 weeks of gestation.

In the pregnant mouse, human serum albumin is transferred from mother to foetus by a first order process[4], that is the amount of human albumin transferred to the foetus is proportional to the maternal serum concentration of human albumin, or F/M for albumin $= k$, where k is the proportionality constant. Human IgG in the pregnant mouse at term is transferred by two processes[4]: one is first order, like that for albumin, and the other is an enzyme or carrier-mediated process. The first order proportionality constant for human IgG transfer is similar in magnitude to that for human albumin[4], so that the ratio of the amount of human IgG transferred only by the first order mechanism, F_f, relative to the maternal human IgG concentration, M, or F_f/M, is closely approximated by the F/M ratio for human albumin[4]. The net amount of human γG transferred to the foetus solely by the enzyme or carrier-mediated process, F_c, relative to the maternal human IgG concentration, M, or F_c/M, is equal to F/M for human γG minus F_f/M; because F_f/M is approximately equal to the F/M ratio for human albumin F_c/M is approximated by F/M for human IgG minus F/M for human albumin. Applying this information to the data in Fig. 1, it is apparent that the sudden increase in the permeability of the maternofoetal barrier to human IgG after 11 days of gestation is attributable to a rapid increase in the activity of the enzyme or carrier-mediated transport system for human IgG.

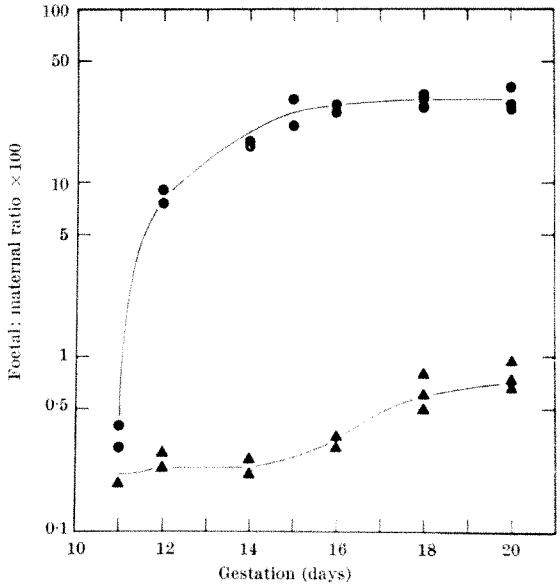

Fig. 1. Ratio of the foetal tissue concentration to maternal serum concentration of human IgG (●) and human albumin (▲) 24 h after intravenous injection into the mother. The period of gestation is that at the time of sampling.

Assessment of Marginal Malnutrition

MANY tests have been proposed for the early detection of protein–calorie malnutrition (PCM) of early childhood; the latest is based on morphological changes in the root of the hair from the head[1]. The tests may be classed as biochemical (for example, amino-acid ratio in plasma[2], serum transferrin[3], hydroxyproline excretion in urine[4], urinary creatinine/height ratio[5], urinary urea/creatinine ratio[6]); anthropometric (a single measurement like weight, mid-arm circumference, or a ratio—chest/head circumference, weight/height, weight/head circumference[7]); or miscellaneous (buccal mucosal changes[8], auricular cartilage elasticity[9] or hair root morphology[1]). Tests on young children, frequently of uncertain age, pose practical problems. Ideally, any biochemical test should require only a small (capillary) sample of blood or "spot" sample of urine and a minimum of equipment and skilled personnel. Other variables often influence the results of these tests; for example, infections and infestations, age, time and nature of meal before test[10–12] and for the blood tests the degree and type of PCM (refs. 3, 13). Anthropometry has the advantage of being easy to perform, rousing

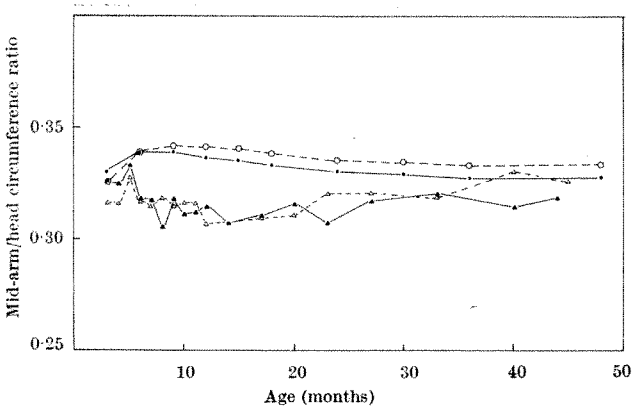

Fig. 1. Mid-arm circumference/head circumference ratio in relation to age and sex. The standard curves are from the data of Wolanski[15] and the Lebanese are mean values for 1,231 children in a field study. ●—●, Standard males; ○ - - - ○, standard females; ▲—▲, Lebanese males; △ - - - △, Lebanese females.

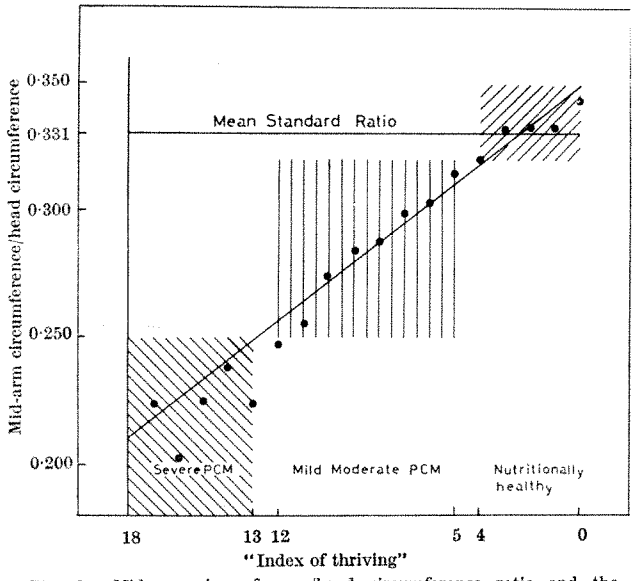

Fig. 2. Mid-arm circumference/head circumference ratio and the "index of thriving"[16] for 1,276 children (1,231 in a field study and 45 with acute marasmus on admission to the metabolic unit). The mathematical regression line for the highly significant correlation of these measurements is shown. The mean standard ratio is from the modified data of Wolanski[15]. ● = Group mean; $r_{1276} = 0{\cdot}75$ ($P < 0{\cdot}001$). $y = 0{\cdot}349080 - 0{\cdot}007688\,x$.

no antagonism and requiring only simple apparatus. But all of the measurements proposed hitherto are to some extent age-dependent. Mid-arm circumference is least affected, because it changes only slightly between 1 and 4 years[7]. Weighing requires a relatively expensive and delicate piece of apparatus that is often used incorrectly by junior personnel.

The hair root morphology test has several disadvantages. Epilation is traumatic to the subject and possibly to the hair. The procedure is tedious and time-consuming. Laboratory equipment and technicians are required. The authors criticize clinical signs for being "difficult to standardize and express quantitatively". The same may be said for their "subjective classification of the incidence of certain abnormalities" of the hair root, the method for which they do not make clear, "to assess the relative severity of protein–calorie malnutrition". They state that the differences in mean hair root diameter "were not highly significant ($P > 0{\cdot}05$)" for the intermediate weight/age groups, but this is the range where assessment is especially sought. Differences with $P > 0{\cdot}05$ are usually regarded as "not significant". It remains to be seen if comparable changes in hair morphology occur in other ethnic groups and where marasmus predominates.

When international standards[14,15] are used certain ratios of somatic measurements proposed by Jelliffe[7] vary considerably with age during the pre-school period and the chest/head ratio also differs for the two sexes. We propose a more satisfactory alternative in the mid-arm circumference/head circumference ratio. The measurements are easy to take and a stout tape measure cheap. As shown here, the ratio can be interpreted directly. This ratio shows virtually no sex difference and between 3 and 48 months is practically constant. The curve of the mean values for a group of 1,231 Lebanese children of low socio-economic status is slightly lower than that of the standard values and is also unaffected by age or sex (Fig. 1). We have developed an "index of thriving"[16], consisting of weight, height, head circumference, and mid-arm circumference measurements in relation to international standards. Fig. 2 shows the relationship between the mid-arm/head ratio and the "index of thriving" for 1,276 children (1,231 in the field study and 45 with acute marasmus on admission to our metabolic unit, each with an "index of thriving" of 13 or above). The following nutritional interpretation is recommended: ratio $> 0{\cdot}310$, nutritionally healthy; $0{\cdot}310$–$0{\cdot}280$, mild PCM; $0{\cdot}279$–$0{\cdot}250$, moderate PCM; $< 0{\cdot}250$, severe PCM.

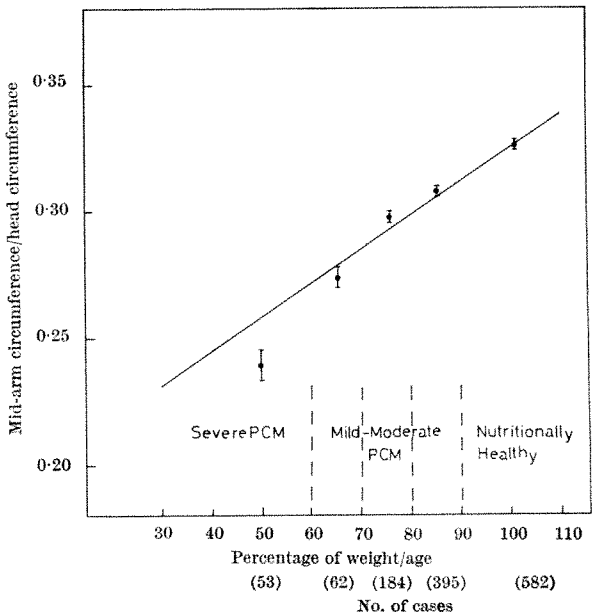

Fig. 3. Relationship between the mid-arm circumference/head circumference ratio and the percentage weight/age. Bars indicate group mean ± s.e.; $r_{1276} = 0{\cdot}68$ ($P < 0{\cdot}001$). $y = 0{\cdot}190905 + 0{\cdot}001341\,x$.

The mid-arm/head ratio data are compared with the weight for age in Fig. 3. Comparison should be made with Fig. 1 of Bradfield and Jelliffe[1]. Overall results are similar for the two tests, but for our data the differences between means of the ratios for all five of the weight/age groups were highly significant ($P < 0{\cdot}001$).

Enzymatic Destruction of Bone *in Vitro*

THE enzyme phosphoprotein phosphatase catalyses the rapid demineralization of tooth enamel[1,2]. It has no demonstrable proteolytic activity, does not seem to hydrolyse synthetic hydroxyapatite, and is thought to act by dephosphorylating the mineralized phosphoprotein matrix of the enamel.

Bone is destroyed *in vitro* by phosphoprotein phosphatase, and the enzyme could be involved in the resorption of bone in pathological and physiological conditions[3]. The bone specimens after treatment with the enzyme, however, demonstrated a protein-like coagulum. The major protein constituent of bone has been shown to be collagen, and so we have investigated the effect of collagenase plus phosphoprotein phosphatase on specimens of bone.

Fragments of bone were dissected from the mandibles of 21-day-old COBS albino rats and were defleshed and enclosed in dental wax so that an area of bone of approximately 3 × 3 mm was exposed to the test solutions. The specimens were incubated for 3 or 6 h at 37° C with constant shaking speed[4] in 2 ml. of the following solutions: Deionized water, 0·1 per cent trypsin, 0·1 M sodium acetate buffer at *p*H 6·0, 0·01 per cent phosphoprotein phosphatase, autoclaved, heat-inactivated, 0·01 per cent phosphoprotein phosphatase, 0·1 per cent collagenase or a combination of 0·1 per cent collagenase and 0·01 per cent phosphoprotein phosphatase. All enzymes were prepared in the acetate buffer.

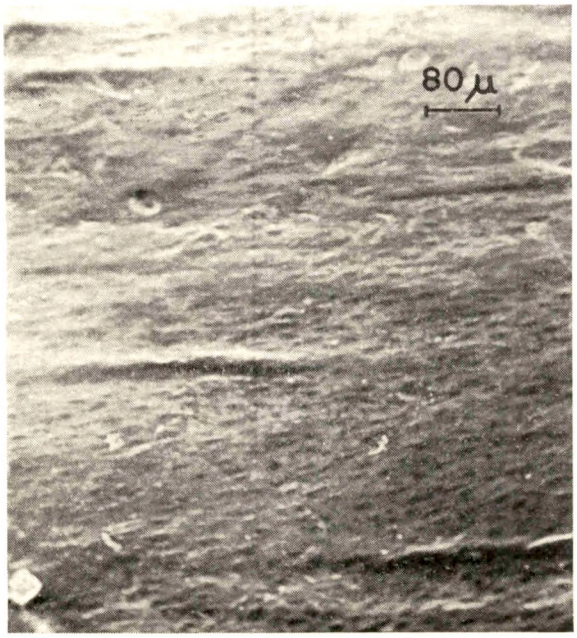

Fig. 1. Untreated surface of rat mandible.

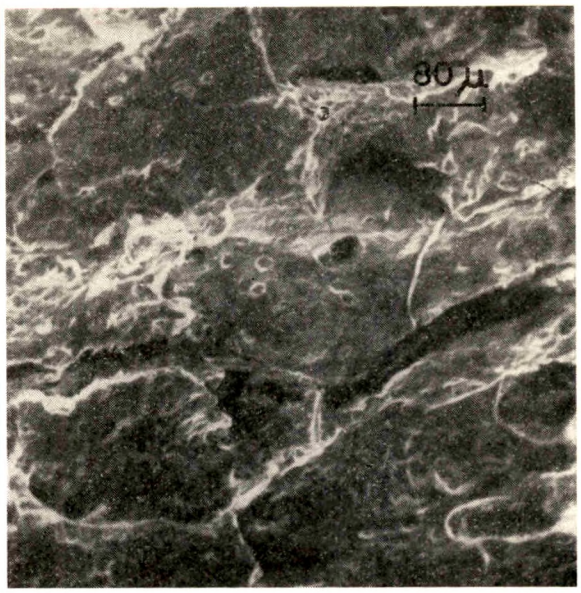

Fig. 2. Specimen of rat mandible incubated with 0·1 per cent collagenase for 6 h.

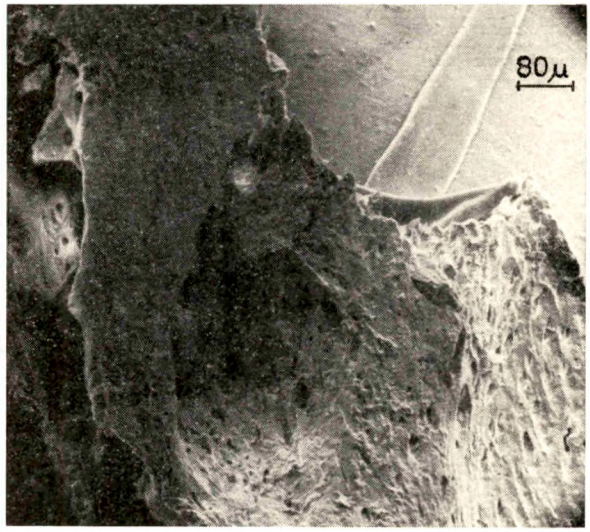

Fig. 3. Specimen of rat mandible incubated with 0·1 per cent collagenase and 0·01 per cent phosphoprotein phosphatase for 3 h.

After incubation all specimens were examined through a dissecting microscope and photographed. Selected specimens were then prepared for scanning electron microscopic study.

Fig. 1 shows an untreated control specimen of rat mandible as imaged by the scanning electron microscope. The surface is relatively smooth and intact, and there is no evidence of deformity. The surfaces of the mandibles exposed to buffer alone, water, trypsin or heat-inactivated phosphatase did not differ from those of untreated mandibles.

A typical specimen of bone exposed to collagenase for 6 h (Fig. 2) had a rough surface covered with numerous irregular holes, the length of which ranged from approximately 80 to 200 μm.

Fig. 3 is a representative scanning electron micrograph of a rat mandible exposed to a mixture of phosphatase

and collagenase for 3 h. There is extensive alteration of the mandibular surface topography with the formation of large craters, sometimes reaching several hundred microns across. Destruction was always more rapid when brought about with a mixture of phosphatase and collagenase than when either enzyme was used singly.

The scanning electron microscope has provided evidence that rapid destruction of bone can be accomplished *in vitro* by using enzymes. Similar enzymes are present in leucocytes and in the normal inflammatory process[5–7]. They can therefore be implicated in the mechanisms of bone destruction *in vivo*. Experiments are in progress to demonstrate enzymatic destruction of bone in the living animal in the hope of establishing a model for study of destructive bone diseases, such as periodontal disease.

We thank Mr James Webber for providing a scanning electron microscope. This work was supported in part by a grant from the National Institute of Dental Research and by Bowman's Children's Dentistry Research Fund.

Bimodal Cochlear Response Curves in Rodents

LITTLE work has been done on hearing in rodents at high frequencies (over 30 kHz). Ralls[1] has shown sensitivity at frequencies up to 80 kHz in wild mice (*Mus musculus* and *Peromyscus*) and Crowley *et al.*[2] showed marked sensitivity to 40 kHz in the laboratory rat. Ultrasound emission has been shown by Anderson[3], Zippelius and Schleidt[4] and later by Noirot[5] and Sewell[6–8] to be widespread among rodents. In the light of this work on ultrasound production and the paucity of work on such aspects of hearing, I undertook an investigation of the cochlear microphonic response to these high frequencies.

Three species were used in the study: wild-caught wood mice (*Apodemus sylvaticus* Linnaeus), voles (*Clethrionomys glareolus* Schreber) and laboratory bred gerbils (*Meriones shawi* Rozet). Cochlear responses (CMs) were recorded from the round window membrane. Two techniques were used to elicit this response. The first was that of "pure tone" pulses of 1 ms duration, including 0·25 ms rise and fall times, delivered by an ionophone loudspeaker from 2 kHz to 100 kHz at rates of 1–20/s. The sound intensity of the pulse "plateau" was maintained constant at 60 dB sound pressure (level with respect to 2×10^{-4} μbar root mean square) during experiments. The second technique involved a high voltage pulse generator producing a spark across an air gap. The broad-band sound so produced had a dependable spectrum ±5 dB between 5 kHz and 100 kHz and was less than 60 dB SPL. Spark pulses were delivered at 200/s. Radiation artefact in both techniques could be recognized and distinguished from the results.

The recording equipment consisted of a 63 μm diameter silver wire electrode with a small terminal sphere formed by melting the tip. The latter was placed on or near the round window membrane after a lateral approach through the bulla. A stainless steel earth electrode was placed in the neck. A head-stage amplifier with a gain of 1,000 was used with a variable band-pass filter. The filter was narrowly tuned to the frequency being investigated when the ionophone was the stimulating apparatus, and the peak-to-peak amplitude of the cochlear response was measured from an oscilloscope screen. With the spark technique, the filter was set to a band-pass of 1 kHz–150 kHz and the CMs were recorded on tape to be displayed later on a sound spectrograph as a time-integrated spectrum. This was then replotted for comparison with the response curve obtained by the first technique.

Sound intensity produced by the ionophone was monitored with a B & K 0·25 inch (6·4 mm) microphone. The same apparatus was used to check the sound spectrum of the spark, so that slight, but consistent, corrections could be applied to the response curves from the cochlea. Experimental animals were injected with 'Nembutal', and the rectal temperature was maintained at 36°–38° C during experiments.

Cochlear response curves were obtained for fourteen individual *Apodemus*, eleven *Clethrionomys* and ten *Meriones* by both techniques. The most significant feature common to all three sets of results was the bimodal appearance of the curves obtained. In *Apodemus* peaks occurred in most animals at 17 kHz and 55 kHz with individual variation from 15 kHz to 20 kHz for the first peak and 50 kHz–65 kHz for the second. In *Clethrionomys*, for which specimen curves for one individual are shown in Fig. 1, the peaks appeared at 13 kHz and 50 kHz, with scatter over 10 kHz–17 kHz and 45 kHz–55 kHz, respectively, in different individuals. In *Meriones* the first peak was more variable, appearing at 4 kHz in some, as found by Finck and Sofouglu[9], but at 10 kHz in others. The second peak appeared fairly consistently at 40 kHz–45 kHz with some individual scatter over 35 kHz–50 kHz. In all forms there was a clear dip in sensitivity between the two peaks. There was also specific variation

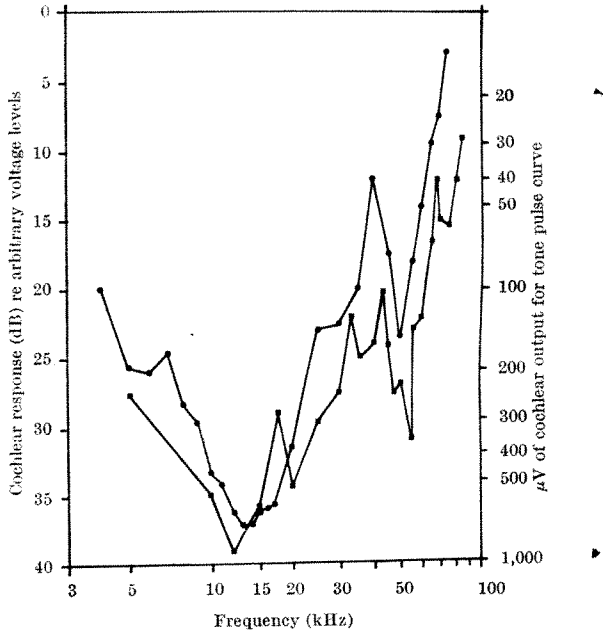

Fig. 1. Cochlear microphonic response curves for an individual *Clethrionomys*, obtained by two independent methods. The stimulating apparatus was: ●, ionophone; ■, spark.

in the height of the second peak, that of *Meriones* being considerably smaller than those of *Apodemus* and *Clethrionomys*.

The significance of these second peaks finds a possible explanation when the work of Sewell on ultrasound production in these species is considered. In all three cases the frequency of the second peak is closely related to the ultrasonic frequencies emitted by the animals, and the height of this peak appears to be inversely related to the intensity of the sounds produced.

Cries of young animals of the species studied have been used to stimulate the cochlea of adults of the same species. The cry has been recorded, simultaneously, as CMs from the cochlea, and with a B & K microphone. The cochlear response was shown to be strong in all cases, but especially when the adult showed a pronounced second peak in its response curve on later analysis.

While the CM response cannot be said to represent hearing at the conscious level[10], it is quite plausible that the marked sensitivity of the cochlea to specific high frequencies will facilitate hearing of these sounds. Sewell[11] has shown, by behavioural techniques, that *Apodemus* respond to the recorded cries of their young.

A bimodal response has also been shown from the colliculus of the bat *Plecotus*[12], where the frequencies of the two peaks of sensitivity correspond to the harmonic sound spectrum used in echolocation. A similar echolocatory connexion has been assigned to the sensitivity of the rat cochlea to 40 kHz (ref. 2), but it now seems more likely that this peak, like those of *Apodemus*, *Clethrionomys* and *Meriones*, could be related to the high frequency sounds emitted in social encounters.

I thank Dr J. D. Pye for help and Professor D. R. Arthur for laboratory facilities. The work was carried out under an SRC studentship and was sponsored, in part, by the Air Force Office of Scientific Research through the European Office of Aerospace Research, US Air Force, under a contract to Dr Pye.

Initiation of Circadian Rhythms in Arrhythmic Churchyard Beetles (*Blaps mucronata*)

IN a recent article Brady[1] has drawn attention to the conflicting evidence on the physiological control of circadian rhythms in insects and concludes that the primary control is not hormonal but nervous. This conclusion is based in part on the failure of Roberts[2] and of Brady[3] himself to repeat Harker's[4] transplantation experiments in which the sub-oesophageal ganglia from rhythmic cockroaches elicited a rhythm in headless recipients. In Brady's work only two of forty-eight implanted animals subsequently became rhythmic. Similar results have been obtained by Fletcher[5] using the churchyard beetle (*Blaps mucronata*). We have subjected arrhythmic beetles to transplantation of organs from rhythmic donors, and sundry other treatments.

The beetles used in the experiments had been kept in culture chambers in constant light at 25° C for at least 2 weeks and mostly for much longer periods. Their locomotor activity was recorded in 6 inch diameter glass chambers with waxed floors. A cadmium sulphide photocell was triggered when the insect interrupted a beam of far red light provided by a 6·5 V bulb fitted with a far red filter. The photocell was connected by a high speed relay to a Rustrak 92 four-channel pen event recorder which marked on a moving paper trace. The number of times the beam was crossed in each hour was counted and the results plotted as a histogram. All recordings were made in a regime of constant light (intensity 40 lux). The rhythmic donors were maintained under conditions of alternating light and darkness, the light period extending from 0800 h to 2000 h. In these conditions *Blaps mucronata* shows a 24 h rhythm with peak activity from 2100–0400 h and little activity during the light phase[5].

The recording chambers were housed in unheated incubators but kept in a room at 25° C and 70 per cent RH. The light bulbs inside the incubators raised the temperature to 27°–28° C but each incubator remained constant to within ±1° C.

Table 1. THE RESULTS FOR TRANSPLANTATIONS OF SUB-OESOPHAGEAL GANGLIA AND BRAINS

Organs implanted	Result
Sub-oesophageal ganglion (12 transplants)	2 Died 3 No response 3 Level of activity dropped; no rhythm induced 4 Rhythm induced; peak in phase with operation
Brain (14 transplants)	4 Died 3 No response 3 Level of activity dropped; no rhythm induced 2 Rhythm induced; peak in phase with operation 2 Rhythm induced; peak in phase with donor

Two of the ten animals that survived the implantation of a brain from a rhythmic donor subsequently became rhythmic themselves, in phase with the activity of the donor. One of these results is shown in Fig. 1*a*. The proportion of implants inducing rhythmicity is similar to that found by Fletcher[5] and slightly higher than the results of Brady[3]. These workers induced rhythmicity by implanting sub-oesophageal ganglia but had no success with brains.

The low proportion of successful transplants may indicate that it is not the transplant itself that induces rhythmicity, but some side effect of the operation. The most likely factors are light and temperature changes. Lights used during transplant operations may be bright enough to initiate a rhythm. Even in headless recipients, as used by Brady[3], light acting directly on sensory cells of the body wall or on the central nervous system itself could be responsible, while thoracic and abdominal temperature receptors will, of course, still be present. A temperature cycle subsequent to the transplant operation has been suggested as the initiator of rhythmicity in headless cockroaches, but this could not be established experimentally[2].

We have tested the effects of single short-duration changes of temperature and illumination on arrhythmic animals in constant light (LL). 60 W lamps were used as a source of light and heat. Of ten animals heated (27° C + 10° C) for 60 min, eight became rhythmic. Eleven other animals were exposed to similar illumination but maintained for 60 min at 10° C below the temperature at which their activity had been recorded; of this group only three became rhythmic. The heat treatment produced a greater proportion of rhythmic animals than did transplants. Moreover, the activity induced is not usually in phase with the time of exposure to higher temperatures but 4–10 h later (Fig. 1*b*).

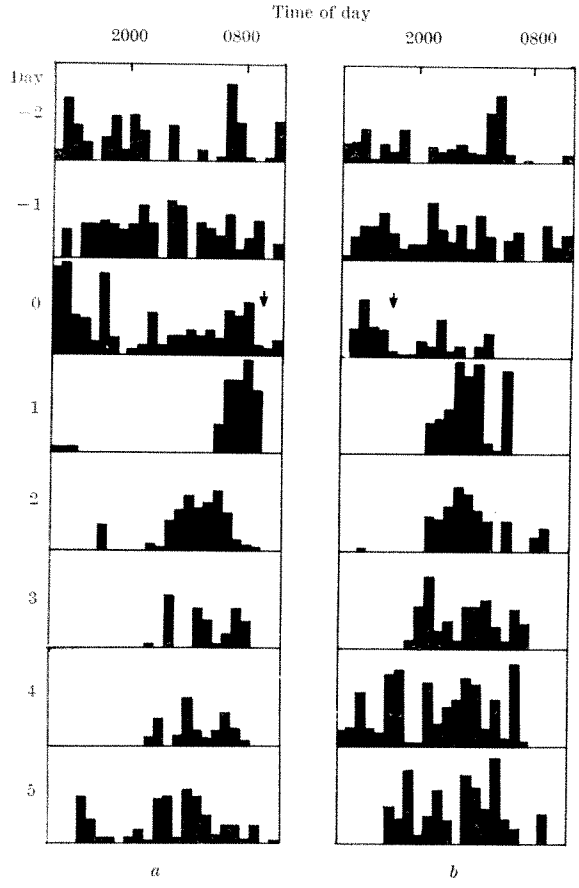

Fig. 1. The effect on the locomotor activity of an animal kept in constant light (LL) at 25° C of: *a*, the implantation of a brain from a rhythmic animal; *b*, heating to 35° C for 60 min. The time of treatment is shown by an arrow. The abscissa represents the number of crossings of the light beam in each hour. Full scale = 40 crossings.

Blaps is known to be sensitive to small changes of temperature: its rhythm will entrain to a diurnal temperature variation of ±1° C (ref. 6). Another treatment that induced rhythms was the application of hot wax to the thorax of an intact animal in simulation of the postoperative treatment given to a wound after a transplantation has been carried out (two out of three animals became slightly rhythmic 15–16 h after the treatment).

We have noticed that a few beetles removed from the culture chamber at 25° C and LL and placed in the experimental chamber in LL of similar light intensity became rhythmic and had to be kept for several days to allow the rhythm to fade. It now seems likely that the rise in temperature, rather than the small change in light intensity, induced a rhythm in these particular beetles.

Our conclusion is that a circadian rhythm may be induced in *Blaps mucronata* kept in constant light intensity by a variety of manipulations of which the most effective is a rise in temperature. An alternative explanation is that the animals have an underlying rhythmicity, as postulated by Harker[7] and Roberts[2], which the experimental treatment caused to become overt. Such an explanation seems unlikely for *Blaps* because in constant conditions the rhythm fades out progressively by an extension at the beginning and the end of the period of activity without any change in the general level of activity. It is difficult to imagine how a rhythm which disappears in such a fashion could still be running unobserved and be capable of resuscitation in its original form. The evidence for persistent latent rhythms is, in any case, insufficiently conclusive for such an explanation to be preferred to the simpler one that the experimental procedures we have described were responsible for inducing circadian rhythms. As the induced peak of activity comes some hours after the treatment it seems that the immediate effect is to depress activity. The physiological mechanisms underlying activity depression may be the key to much of the variability in our experiments and those of other workers.

Haemoglobin in a Monogenean, *Oculotrema hippopotami*

Oculotrema hippopotami is a Polystomatid Monogenean that lives around the eye of the Hippopotamus. The anterior two-thirds of the body of mature worms is a dark red colour, while the posterior part, including the haptor, is almost colourless. Tests have shown that red colour is due to haemoglobin. Haemoglobin has been recorded in Turbellaria[1] and Digenea[2] among other invertebrates, but this is apparently the first record from a Monogenean. *O. hippopotami* feeds on epithelial cells and exudates. No blood is found in the gut caeca, so any haemoglobin that is detected must be of parasitic origin.

An initial positive test with benzidine indicated that the red pigment was probably haemoglobin. Direct observation of living *O. hippopotami* through a microspectroscope then showed 2 absorption bands similar to those of oxyhaemoglobin. After the worms were killed with 20 per cent NaOH and treated with pyridine and sodium thiosulphate, dark bands typical of pyridine haemochromogen were seen with the microspectroscope, and typical crystals developed.

For spectrophotometric analysis, living specimens of *O. hippopotami* were carried alive to Kampala on moist filter paper in Petri dishes, the Petri dishes being packed in vacuum jars. In the laboratory, the golden coloured eggs were removed from the uterus and ootype of the worms, and the worms were then deep-frozen at −13° C within 12 h after being collected from the hippopotamus.

Approximately fifty specimens of *O. hippopotami* were subsequently homogenized in 0·6 per cent saline, and the suspension was clarified by high speed centrifugation. Absorption spectra of the suspension were measured using a manually operated Unicam spectrophotometer. The following absorption maxima characteristic of oxyhaemoglobin were obtained: α band 587 nm, β band 548 nm, γ band 414 nm. Absorption was greater in the β band than in the α band, while the γ band could be measured only after diluting the sample 4 or 5-fold. The sample was then deoxygenated by the addition of a small quantity of sodium hydrosulphite. The α and β bands disappeared completely and were replaced by a single broad band, characteristic of deoxygenated haemoglobin, with a peak

at 560 nm, while the position of the γ band shifted to give a peak at 434 nm. It is concluded that the absorption spectra were those of haemoglobin and deoxygenated haemoglobin, and that any contaminants from the tissues of the worm were present in too small quantities to affect the absorption spectra.

The newly hatched larva of *O. hippopotami* has been described previously[3]. It is not pigmented, and small worms are also colourless. Immature worms in which the genitalia are developing are pale pink, with a concentration of pigment around the ootype. Mature worms retain the concentration of pigment around the ootype, but the anterior two-thirds of the body are a dark red colour. Histological sections were examined for the distribution of ferric iron by Perl's technique[4]. Although the staining reaction was weak, it showed that, apart from the concentration around the ootype, the main concentration of haemoglobin is probably just below the tegument, where a pale blue colour developed. Crompton and Smith[1] found that in the Turbellarian *Phaenocora unipunctata* ferric iron was concentrated around the pharynx but was also present just beneath the dorsal epidermis. They noted that respiratory pigments often occur in or near muscular tissues in which sustained or powerful contractions take place. In *O. hippopotami*, however, the haptor with its powerful suckers is virtually colourless. Stephenson[5], on the other hand, found that the haemoglobin of *Fasciola hepatica* was present in the region of the vitellaria and anterior uterine coils, and suggested that its function was to supply oxygen to these organs. The distribution of haemoglobin is similar in *O. hippopotami*, and it may similarly facilitate the transport of oxygen to tissues needing a good supply. Haemoglobin may also act as a store of oxygen, which might be necessary for *O. hippopotami* if the worm retreats under the eyelids of the hippopotamus to escape from drying or from excessively high temperatures.

Altered Dihydrofolate Reductase associated with a Pyrimethamine-resistant *Plasmodium berghei berghei* produced in a Single Step

THE phenomenon and associated dangers of transferable drug resistance between enteric bacteria are now well established, but little information is available about the possibility of such transfers between eukaryotic cells. Evidence for the transfer *in vivo* of resistance to the widely used anti-malarial drug, pyrimethamine, from the rodent malarial parasite, *Plasmodium vinckei vinckei*, to another rodent malaria, *P. berghei berghei*, has recently been presented by Yoeli *et al.*[1]. They have coined the term "synpholia" to describe this occurrence. The method used involved the concomitant development of the two species in the mouse. This was followed first by the inoculation of blood from the mouse into hamsters to filter out the *P. v. vinckei* (they do not develop patent parasitaemias in this host), and second by the treatment of the hamsters with high doses of pyrimethamine to remove all the *P. b. berghei* except those that had acquired resistance to the drug. Ferone *et al.*[2] subsequently showed that this resistance to pyrimethamine in the strain of *P. b. berghei* was associated with changes in the amount and properties of the dihydrofolate reductase in the organism. We have found now that a pyrimethamine-resistant line of *P. b. berghei* containing a dihydrofolate reductase with these altered properties can be produced merely by treating hamsters or mice, infected by a sensitive strain, with high doses of pyrimethamine.

Patent infections of *P. b. berghei* (NK 65 strain) in twenty hamsters (40 g) and fifty male TFW-1 albino mice (20 g) were treated with doses of 200 mg/kg pyrimethamine base triturated in 0·5 per cent carboxymethylcellulose by subcutaneous injection on four consecutive days. Four days after completion of drug treatment, one hamster exhibited parasitaemia. In the 4 day suppressive test[3], the line derived from this infection was shown to be over 160 times less sensitive to pyrimethamine than the parent strain and this resistance remained stable even after twenty blood passages. The pre-two per cent bioassay technique[4] confirmed that the line was resistant to pyrimethamine. Infections were obtained in the mosquito *Anopheles stephensi* at 19° C but sporozoite inoculations of mice were unsuccessful.

Table 1. PROPERTIES OF PYRIMETHAMINE-SENSITIVE AND RESISTANT *P. b. berghei*

Strain of *P. b. berghei* (NK 65)	Percentage potency of parasites after 10 mg/kg doses of pyrimethamine*	Dihydrofolate reductase† V_{max} (mμmoles/min/mg protein)	K_m (× 10^6 M)	Concentration of pyrimethamine‡ (× 10^9 M) for 50 per cent inhibition
Sensitive	< 0·1	1·6	3·5	1·0
Resistant	100	5·0	30	30

* Estimated by the method of Warhurst and Folwell[4].
† 5,6,7,8-Tetrahydrofolate : NADP$^+$ oxidoreductase (EC 1.5.1.3).
‡ 2,4-Diamino-5-*p*-chlorophenyl-6-ethylpyrimidine.

Of the fifty mice treated with pyrimethamine, only one developed an infection which became patent 7 days after completion of drug treatment. This line had a pyrimethamine sensitivity similar to that of the resistant, hamster-derived line (Table 1) and was transmissible through *A. stephensi* at 19° C. Resistance was maintained after blood and mosquito passage.

Young and Burgess[5] have suggested from their work with *P. vivax* that resistance to pyrimethamine can develop in a single step. Our studies show that this can occur with *P. b. berghei*.

Batches of dihydrofolate reductase were prepared from our pyrimethamine sensitive strain of *P. b. berghei* and also from our resistant, mouse-derived line and their properties were compared. We have used the method of preparation of W. E. G. and P. I. T.[6], except that parasites were released from the red cells by lysis with saponin as described by Ferone *et al.*[7] rather than by lysis with anti-red cell serum. Enzyme was assayed as described elsewhere[6] except that 0·1 M Tris-HCl (*p*H 7·2) was used instead of potassium phosphate buffer. Properties compared were the specific activities of the preparations, affinities of the enzymes for the substrate, dihydrofolate (K_ms) and sensitivities of the enzymes to inhibition by pyrimethamine. The results (Table 1) indicated that resistance to pyrimethamine in our line of *P. b. berghei* was associated with an increase in the level of enzyme within the organism, a decrease in the enzyme's affinity for substrate and a decrease in its sensitivity to inhibition by pyrimethamine. Such changes are similar to those reported previously for other pyrimethamine-resistant lines of *P. b. berghei*[2,8].

We have produced a pyrimethamine-resistant line of *P. b. berghei* in a single step and have correlated this resistance with changes in the amount and properties of the dihydrofolate reductase in the organism. Our resistant line was produced by the method used for the control series in the demonstration by Yoeli *et al.* of drug resistance transfer among rodent *Plasmodia* and it contains

an altered dihydrofolate reductase similar to that present in their resistant *P. b. berghei* line. We do not know why a similarly resistant line did not arise in their control series, though a possible reason is that too small a number of animals was used. Our results do not disprove the claim that their pyrimethamine-resistant *P. b. berghei* arose by a transfer of genetic material between two malaria species. They indicate, however, that further experiments are necessary to demonstrate that greater numbers of resistant parasites appear after "sympholia" than after selection by drug treatment.

This study was supported in part by the US Army Medical Research and Development Command, Department of the Army, and in part by the World Health Organization. We thank Professor W. Peters for valuable discussions during the course of this work.

Control of Moulting in an Insect

Moulting in insects is controlled by the prothoracic glands after they have been activated by the brain[1–6]. α-Ecdysone and 20-hydroxyecdysone stimulate moulting and are thought to be the principal moulting hormones[7–11]. It is common to assume that the prothoracic glands control moulting by synthesizing ecdysone, even though there is no direct evidence for this[12,13]. The experiments reported here show that the head and thorax of *Calpodes* larvae isolated with intact activated prothoracic glands do not moult; they can only do so if moulting hormone is injected or if at least part of the abdomen is present. This suggests that more than an activated prothoracic gland is needed for moulting.

Calpodes ethlius Stoll (Lepidoptera, Hesperiidae) has three phases of development in the last (fifth) larval stadium. Events in the fifth stadium can be timed accurately and the exact stage of development can be confirmed by physiological markers. There is a phase of growth from ecdysis up to 66 h by which time the brain is no longer needed to induce pupation; the prothoracic glands are activated, that is they can cause pupation without further influence from the head. After 66 h ligature around the neck to remove the head, removal of the brain or suboesophageal ganglia, or cutting the ventral nerve cord causes no delay in pupation[14,15]. Pupation is only blocked by ligature around the thorax which prevents the prothoracic glands from affecting the abdomen. These experiments rule out neuronal inhibition of prothoracic gland activation of the sort described in *Galleria*[16]. The second phase from 66 to 156 h is devoted to larval syntheses. At the end of this time the prothoracic glands are no longer needed and no operations are known to block the overt pupal syntheses leading to pupation at 192 h[17].

Because *Calpodes* has a long second phase, when the prothoracic glands are activated and necessary for pupation, it is possible to test whether they alone can induce pupation. Larvae in this phase were ligatured at one of the three positions shown in Fig. 1. Pupation was judged to have taken place if pupal cuticle could be seen after removal of the exuvium or in thick (1 μm) epoxy sections stained with methylene blue. Retraction of the epidermis from the cuticle is not sufficient indication of pupation; it occurs in isolated abdomens in which further development is blocked.

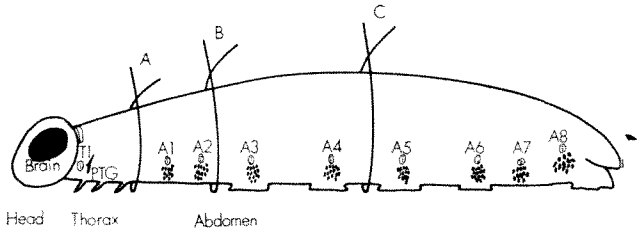

Fig. 1. Diagram of *Calpodes ethlius* showing the position of ligatures and the principal endocrine tissues, the brain and the prothoracic gland (PTG). Spiracles are labelled by region (T, thorax; A, abdomen) and by corresponding segment number. Ligature *A* between thorax and abdomen includes the brain, PTG, foregut and some fat body in the isolated anterior portion. Ligature *B* between the second and third abdominal segments adds to this anterior part some midgut, more fat body and four clusters of moult oenocytes (between thirty and forty oenocytes in a cluster). Ligature *C* between the fourth and fifth abdominal segments adds more midgut, still more fat body, four more clusters of oenocytes and the most anterior loops of the Malpighian tubules. The cells ventral to the abdominal spiracles are the oenocytes, postulated to be necessary in interacting with the prothoracic glands.

Most ligated anterior regions were viable for more than 2 days, many for 3–8 days after the operation. Ligatured abdomens were viable for 5 to 10 days. There was no pupation of either part in sixty-nine larvae ligatured between the thorax and abdomen (Fig. 1*A*). Twenty per cent of the isolated thoraxes were dark pink with a retracted epidermis. The pink pigment disappears at about 156 h in normal larvae going on to pupate. When the ligature was made between the second and third abdominal segments (Fig. 1*B*), one anterior portion out of twenty-eight had a partial new cuticle; no abdominal portions pupated. Ten out of twenty-three anterior portions, however, pupated when the ligature was between the fourth and fifth abdominal segments (Fig. 1*C*).

These experiments show that an activated prothoracic gland is not itself a sufficient stimulus for pupation in the isolated head and thorax. To test whether the failure of these anterior portions to pupate is a result of nutritional deficiency or generalized wounding, larvae were injected with moulting hormone 1 h after ligature. When 10 μg of 20-hydroxyecdysone (10 mg/1 ml. of 10 per cent EtOH; ecdysterone, Mann Research Labs; animals weighed between 0·9 and 1·3 g each) was injected into either anterior or posterior portions of larvae ligatured between the thorax and abdomen, pupation took place. When 5 μg of synthetic α-ecdysone (1·0 mg/0·1 ml. of 10 per cent EtOH) was injected in anterior portions ligatured in the same way pupation also took place. The new cuticle seen in material prepared for electron microscopy had a complete epicuticle and lamellate endocuticle. This normal pupation after the injection of hormone shows that the block to pupation in an isolated thorax is not due to an inability of the tissues to respond to ecdysones.

Neither hormonal[18] nor neuronal inhibition by the brain can explain the inability of the isolated thorax to pupate: when fifteen larvae in the second phase were ligatured between the head and thorax and between the thorax and abdomen, no thoraces pupated.

These experiments show that the prothoracic glands normally competent to cause pupation in the headless larva cannot induce pupation in an isolated thorax,

although the thoracic tissues themselves can respond to ecdysones. We presume that this is not a selective injury to the prothoracic gland, and that the failure of isolated thoraxes to pupate is caused by the absence of an essential interaction with a component present in the abdomen.

The ultrastructure of the activated prothoracic gland in *Calpodes* seems inconsistent with its independent stimulation of pupation. The newly activated prothoracic gland contains smooth endoplasmic reticulum confronting mitochondria and diverticula of the plasma membrane[19]. These structures are appropriate for steroid metabolism but for the most part the structures can be correlated with larval activities. Larvae decapitated at 66 h go on to pupate but have reduced larval syntheses and little structure appropriate for steroid metabolism in the prothoracic gland.

We postulate an additional step in the control of moulting—interaction of the prothoracic glands and some abdominal tissue. This would not be in conflict with the classical work showing control by the prothoracic gland, for earlier experiments have used whole abdomens or isolates with several abdominal segments to test the stimulatory effect of activated prothoracic glands on moulting[1–6].

α-Ecdysone is converted to 20-hydroxyecdysone in isolated abdomens[20]. Perhaps more than this hydroxylation can occur in the abdomen, for isolated abdomens are more sensitive to 20-hydroxyecdysone than isolated thoraces. When injections of 10 μg were given pupation occurred in eight out of ten abdomens but only in nine out of forty-three thoraces, even though the thorax is considerably smaller than the abdomen. The greater sensitivity of the abdomens to the injected hormone could be explained by stimulation of an abdominal site of ecdysone synthesis. Intermediates of ecdysone metabolism injected into diapausing pupae of the tobacco hornworm stimulate hormone synthesis from endogenous precursors[21].

Oenocytes, sometimes called abdominal endocrine glands[22,23], are the cells most probably interacting with the prothoracic glands in the control of moulting. Isolated pupal abdomens moulted after removal of gonads, digestive tract, Malpighian tubules and the entire central nervous system when an active brain and prothoracic glands were implanted[2]. The only significant abdominal tissues remaining in this experiment were oenocytes, fat body, muscle, trachea and epidermis. Oenocytes, found in all insects, have the appropriate ultrastructure, a cyclic nature of specialization and an unknown function[24]. Oenocytes have large amounts of smooth tubular endoplasmic reticulum which is typical of vertebrate steroid secreting cells. In *Calpodes*, the permanent oenocytes (seventh and eighth abdominal segments) maintain their ultrastructural specializations until about 156 h when they undergo massive autophagy[24]. The moult cycle oenocytes (first to sixth abdominal segments inclusive) increase dramatically in size and in development of endoplasmic reticulum at about 135 h (my unpublished work). Little specialized structure is evident in the prothoracic glands at this time although they are still needed for moulting (personal communication from M. Locke). The oenocytes concerned with the moulting cycle decrease in size and specialization at ecdysis. The development of these oenocytes is complementary to that of the prothoracic glands. Further evidence that the oenocytes are the abdominal tissue involved in the control of moulting comes from experiments on *Tenebrio*. Isolated larval abdomens go on to pupate and even to produce adults[25–26]. *Tenebrio* has exceptionally long cords of very large oenocytes along the length of the abdomen perhaps indicating that they are maintained in an activated state without the interaction of the prothoracic glands.

The work was supported by a NASA predoctoral fellowship and by a US Public Health Service grant. α-Ecdysone was given by Dr John S. Siddall, Zoecon Corp., Palo Alto, California. I thank Dr M. Locke for his advice and discussions.

Negative and Positive Behavioural Contrast in the Same Animals

The reactions of animals to situations that suddenly become more attractive or less attractive have long seemed potentially useful for the evaluation of drugs and other treatments assumed to affect emotional responsivity[1]. Crespi[2,3] reported that rats shifted to a larger (or smaller) amount of reward ran faster (or slower) to the goal in a runway than control rats who were accustomed to the larger (or smaller) amount. But it has usually been difficult to find reliable overshooting or "positive contrast" effects to an increase in reward magnitude, and even the more reliable negative contrast effect (undershooting to a decrease in reward magnitude) has proved troublesome when separate experimental and control groups are used[4]. Furthermore, the transient character of the effects, even when obtained, makes them inconvenient for the chronic testing of various treatments, such as antidepressant drugs or brain lesions. Finally, recent demonstrations of "behavioural contrast" have depended on somewhat complex multiple schedule situations, not necessarily related to that originally used by Crespi[5–7]. Here we report a simple technique for the repeated study of both positive and negative effects in the same animals, with results that are stable over weeks of daily testing.

Our subjects were pairs of groups of experimentally naive male albino rats (Tierfarm AG, Sisseln, Switzerland) maintained at 80 per cent of the body weight that they would have reached if feeding freely. The apparatus consists of two identical single lever Skinner boxes housed in sound-attenuated chambers. A force of 8 g was required to activate the levers.

The animals were gradually introduced during 12 days to a two-minute variable interval schedule, with one pellet per reward. Thereafter, small and large magnitudes

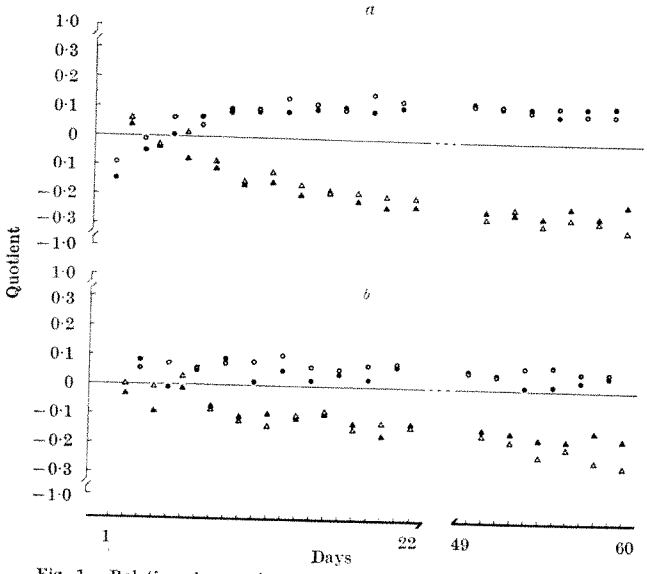

Fig. 1. Relative changes in response rate during intrusions in which reward magnitude was increased or decreased. *a*, Within sessions; *b*, between sessions (contrast). ○△, Strain 1; ●▲, strain 2; ○●, increased reward; △▲, decreased reward.

of reward (one and four pellets) were alternated daily for each group, with stimulus conditions associated with each magnitude also alternating appropriately. The differential stimuli were the standard illumination of the Skinner box (the house light) and a light on the front panel. The two stimuli associated with the reward magnitudes were varied from experiment to experiment, and on any given day one group was tested with the small reward and the other group with the large reward.

The reinforcement period was 4 s for the smaller reward and 16 s for the larger reward. The four pellets forming the larger reward were dispensed at 4 s intervals. During reinforcement the food tray was illuminated. Animals received the remaining portion of their daily food ration in their home cages. They were tested daily; each session lasts 63 min, excluding reward time.

After a few days of such alternating experience each group daily received two relatively brief intrusions of the contrasting reward condition, together with its relevant stimulus. An intrusion always started immediately after a reward, and last, 4·5 min. The temporal position of the intrusion periods was changed daily on a quasi-random basis. Thus, on any given day at the final stage one group received, as the principal reward, one pellet and there were two short periods with rewards of four pellets; for the other group this was reversed. Conditions were alternated daily.

The effects of the intrusions within each session were assessed by a quotient of the difference between the rates during and just before the intrusion divided by the sum of the two rates. Behavioural contrast was assessed by comparing each animal's rate on the intrusion conditions with its rate on the baseline conditions during the immediately preceding day (using the pre-intrusion period for this purpose.)

The results of one representative experiment are shown in Fig. 1, starting with the first day of intrusion training. (In this experiment two different strains of albino rats were used.) The intrusion experiment was continued for 60 days; during the last 12 days all animals received injections of NaCl as a control for subsequent drug trials.

The effects of intrusion within sessions are clear (Fig. 1*a*). Rates were consistently increased by the intrusions signalling larger rewards, and consistently decreased by smaller rewards. During days 11 to 22, when the results had become relatively stable, all thirty rats showed an average increase in rate to increased reward, and an average decrease in rate to decreased reward. Twenty-six days later during the final 12 days of the experiment, the same unanimity of results obtained, reflecting a remarkable stability in the conditioned increases and decreases in rates. Statistical analysis obviously is unnecessary.

Behavioural contrast results, based on between session comparisons, are shown in Fig. 1*b*. Negative contrast was easy to demonstrate: during days 11 to 22 all but one rat (out of thirty) showed an average undershooting of rate of response when they were switched from the larger to the smaller reward, as compared with their baseline rates for the smaller reward. Positive contrast effects for the same period were seen in fourteen out of fifteen rats in strain 1 ($P < 0{\cdot}001$) and eleven out of fifteen rats in strain 2 ($P < 0{\cdot}001$). About 26 days later, a similar pattern still obtained: all the strain 1 and thirteen out of fifteen strain 2 rats showed average positive contrast effects from days 48 to 60. A marginally significant greater positive contrast effect was seen in strain 1 over strain 2 at the beginning of the experiment (t test, $P < 0{\cdot}05$) but this was not significant by the end ($P < 0{\cdot}20$). With the two periods combined, however, the strain difference was significant ($P < 0{\cdot}01$).

In keeping with previous results, therefore, positive contrast is less marked than negative contrast, but the statistical reality of both phenomena seems unmistakable. The positive effect in our experiments cannot be explained by gradual trends in baseline rate, which in any event becomes stable after a few weeks[8]. The positive contrast effect could be masked by a "ceiling effect"[9]. Another possibility is that there are genuine individual differences in the tendencies of rats to show the positive effect, which might be amenable to genetic and/or biochemical analysis. There was a possible strain difference in the experiment described here. Finally, the precise values of experimental parameters are obviously important and could probably be made more nearly optimal. In pilot experiments we found that the control exercised by the intrusions was greatly reduced if: (*a*) the mean interval of the variable interval schedule was reduced from 2 min to 90 s, 60 s, or 30 s (with a corresponding reduction in the duration of the stimulus intrusion periods); (*b*) the magnitude of the basal reward was increased from one to two pellets, and (*c*) liquid reward (dilute milk) was used instead of food pellets. In all cases the positive shifts were more sensitive than the negative shifts to such variations.

The experiments clearly demonstrate that brief stimulus-associated changes in magnitude of reward can modulate continuing behaviour. The relative effect seen within sessions is highly stable for both directions of change. Stable positive and negative behavioural contrast effects, with animals serving as their own controls, are also readily produced.

We thank Mr T. Werren for technical assistance.

Book Reviews

CHEMICAL MNEMOLOGY

Molecular Mechanisms in Memory and Learning

Edited by Georges Ungar. Pp. xiv+296. (Plenum: New York and London, 1970.) $15.00.

Molecular Approaches to Learning and Memory

Edited by William L. Byrne. Pp. xxix+358. (Academic: New York and London, April 1970.) 168*s*.

MOST neurophysiologists whose interests are not primarily chemical are aware that there has grown up since 1965 a substantial and largely bad literature on the induction of chemical changes in the brains of animals by training or conditioning procedures. The changes are detected in extracts of whole brains. Usually the extracts are examined by injecting them (sometimes after chemical pretreatment) into fresh animals, and observing the performance of these animals in training or conditioning schedules similar to those used to induce the chemical changes in the original animals. Some experimenters have examined the extracts by purely chemical means.

This new subject may be called chemical mnemology. I need not hesitate to call its literature "largely bad", because it is full, to a degree unprecedented in ordinary neurophysiology, of reports of failures to replicate published experiments. But among the mass of bad work, many outsiders have wondered whether there may not be some true observations that very severely upset orthodox neurophysiological thinking. What seems to be needed is a clear guide to the new and muddy subject, and outsiders looking at these two books for the first time will immediately want to know whether they provide such a guide.

It can be said at once that the book edited by Ungar is a better guide than that edited by Byrne. Neither book has any general cohesion, but the Ungar book, written by only nine authors, contains chapters (the first five of its eight) that are serious attempts to review aspects of the new subject. The Byrne book, with thirty-three authors, is a jumble of writings of various kinds. Many chapters are merely drafts of research papers; I hope that they will be well revised before they are submitted to journals. The better chapters of the Byrne book are comparable with the first five of the Ungar book, but they are shorter, mostly less critical, and in several cases marred by a strange facetiousness.

What no chapter of either book does is to concentrate on the central question of chemical mnemology: whether the changes in chemical composition produced when a memory is laid down are, at a molecular level, so finely related to the details of the memory that one might, in principle, discover what memories an animal has stored by studying the chemistry of an extract of its minced or homogenized brain.

If the answer to this central question of chemical mnemology were yes, the implications for neurophysiological thought would be revolutionary, and the new subject would be established as an immensely exciting one. Any disputes as to the soundness of the biochemical techniques used by the experimenters, and as to whether the relevant substances are nucleic acids or proteins, would be matters of minor detail.

In all the early papers on chemical mnemology, the central question was, roughly speaking, answered affirmatively, though it was often not stated as sharply as I have stated it above. Some of the experimental observations on which the affirmative answer was based seem to have been wrong, and some, even if right, obviously do not suffice to support so revolutionary a notion. One would expect a discussion of whether there remain any that do sustain an affirmative answer to be the core of any book published in 1970 on chemical mnemology. I can find no such discussion in the books edited by Ungar and Byrne.

Suppose that the answer to the central question is no; then what remains of chemical mnemology? It is not surprising or informative that any large difference of environment between two batches of rats taken from the same inbred strain should affect the chemical composition of their brains. On almost any theoretical notions one would expect such effects, and expect them to involve RNA, protein, lipids and other constituents. The finding that brain extracts, when injected into rats, affect behaviour was perhaps not altogether predictable. But it belongs only to toxicology, and does not clarify any neurophysiological problem, unless between the behavioural effects of a brain extract and the details of training or conditioning of the animal from which it was obtained there is a correlation so close as to support an affirmative answer to the central question.

Since Cajal, most neurophysiologists have thought it probable that memories are stored as changes in the conductivity of synapses. The difference between the old orthodoxy (which I support, but shall abandon if an affirmative answer to the central question is proved) and the view of the pioneers of chemical mnemology is that the old orthodoxy holds that the engrams of any two different memories differ as to which synapses have had their conductivity altered, and in no other important way. The change in conductivity of modifiable synapses may well involve change in the amounts of RNA and protein in them or near them. But if the rest of biochemistry is a fair guide, these synapses are likely to be built all to the same pattern, or at most to a handful of different patterns. The elucidation of their mechanism is an important problem, but it is not clear that the observations of chemical mnemologists up to now have contributed to solving it.

G. S. BRINDLEY

MIND DRUGS

Principles of Psychopharmacology

A Textbook for Physicians, Medical Students and Behavioural Scientists. Edited by W. G. Clark and J. del Giudice. Pp. xxvi+814. (Academic: London and New York, April 1970.) 182*s*.

"WHAT drug started it? Mandrake, morphine, mescaline or mushrooms? Maybe rauwolfia in India if not in Nigeria, teonanacatl in Mexico or the American Indians peyote? Perhaps alcohol, ibogaine, cannabis, cocaine, ololiuqui or yohimbine? Opinions vary as to drug, time and place. But if one defines psychopharmacology precisely as the utilization of drugs in restoring or maintaining mental health and for exploring the mind, then everyone is agreed: the drug is chlorpromazine, the time: 1952, and the place: Val-de-Grâce, the famed military hospital in Paris."

With such a start to the chapter by Caldwell on the history of psychopharmacology, one's hopes are raised that this book will not be yet another collection of disconnected articles written by research workers with little flair for communication. These hopes are fulfilled. The surprise at finding that the chapter on the pharmacology of chlorpromazine is only just over three pages long soon turns to admiration that the subject can be treated so concisely. Most of the fifty-five chapters are short and cover a specific topic in an authoritative manner. The achievement of this book far outweighs any errors which the expert may detect in the chapter

on his own speciality. Much of the credit must go to the editors, who have persuaded most of the seventy-one authors to write in a style that is clear and relatively free from the jargon so common in the clinic or laboratory. No budding psychiatrist need be put off by the size of the volume: he will find no better book to serve both as an introduction to the subject and as a standard reference work.

Beginning with a section on the history of psychopharmacology, the book is divided into ten sections; the subjects include basic anatomy and physiology, the biochemical mode of action of drugs, the pharmacological basis of therapy, methods of studying the actions of drugs in humans, and drug abuse. A valuable feature of this arrangement is that individual sections or chapters can be read independently. The cross-referencing and bibliographies allow the reader to go more deeply if he desires. Unfortunately the index is not quite up to the standard of the rest of the book; for example, under "dopamine" no reference is made to the excellent chapter on the extrapyramidal side effects of drugs, where this neurotransmitter features prominently.

By 1965 some fifty million people had taken chlorpromazine, and yet the fundamental mode of action of this drug is still not understood. The reader of this book will wonder whether there is too much emphasis at present on the theories which explain the action of drugs in terms of synaptic transmission in the central nervous system. Nevertheless, strong support for these theories was given by the discovery that reserpine depletes some nerve terminals of their transmitter (noradrenaline, dopamine or 5-hydroxytryptamine). If we remember, as Aghajanian points out in his chapter, that neurones containing monoamines represent less than 1 per cent of all brain neurones, we can be optimistic about the future of psychopharmacology. For the time being, "Clark and del Giudice" provides a balanced, clear and comprehensive introduction to existing knowledge.

A. D. SMITH

WORK FOR BIOLOGY TEACHERS

Nuffield Advanced Science

Biological Science. (Penguin: Harmondsworth, Middlesex, 1970. Published for the Nuffield Foundation.)

Maintenance of the Organism

A Laboratory Guide. Edited by C. F. Stoneman. Pp. xii + 158. 16*s*.

Organisms and Populations

A Laboratory Guide. Edited by John H. Gray. Pp. ix + 142. 16*s*.

Teachers' Guide

Vol. 1: Maintenance of the Organism, Organisms and Populations. Pp. xiv + 213. 25*s*.

Topic Reviews

Circulation. By W. H. Freeman. Pp. 43. 5*s*. Control of Breathing. By Margaret K. Sands. Pp. 17. 12*s*. Metabolism. By C. F. Stoneman. Pp. 35. 5*s*.

Key to Pond Organisms

By Alison L. Brown. Pp. 45. 6*s*.

THESE publications are those so far issued by the Nuffield A-Level Biological Science Project. The mass of printed material devised for the A-level trials has crystallized out into a modest set of interrelated books and it is only regrettable that all could not have become available simultaneously because together they form an integrated programme of work and, incomplete, the careful system of cross-reference and flexibility of treatment proposed by the promoters to some extent breaks down. Moreover, any review of present publications can only be an interim evaluation and might be considered premature.

The full set of materials will include, in addition to those reviewed here: for students, two more *Laboratory Guides* (*The Developing Organism* and *Control and Co-ordination in Organisms*), a *Study Guide* (*Evidence and Deduction in Biological Science*) and at least nine further *Topic Reviews*; for teachers, *Teachers' Guide 2*, complementary to the second two students' *Laboratory Guides*, *Teachers' Guide 3*, for the students' *Study Guide*, a *Laboratory Book* and *Projects in Biological Science*. A number of film loops will also be available.

The current *Laboratory Guides* are compact, clearly printed, systematic work books which fulfil their claim to provide a coherent treatment of a series of biological topics based on laboratory investigations. This enquiry approach leads students to gain information for themselves and, in doing so, to get some understanding of the processes whereby biological knowledge is acquired. Each set of investigations is preceded by an explanatory introduction and is followed by questions which give direction to the enquiry and by a bibliography which suggests supplementary reading and includes reference to the relevant *Topic Reviews*. In addition to this basic practical work, there is also optional "extension" work.

The *Students' Guides* are unusually and refreshingly explicit about certain points too often taken for granted, such as the interpretation of sections in relation to three dimensional structure and the detailed explanation of the successive stages in various technical procedures. The *Key to Pond Organisms* is simple and well illustrated by small line drawings. It has a generous bibliography and will obviously be of use as a ready means of identification in many ecological contexts. The *Topic Reviews* are concise and self-contained. They include much interesting information related to their particular subjects and have further bibliographies of their own. Although the standard of accuracy is high throughout, *Circulation*, page 7, paragraph 3, states that, "In a double circulation the left side of the heart always receives oxygenated blood". Presumably the writer refers to mammalian double circulation only and not to birds, although these are mentioned in a previous paragraph.

The *Teachers' Guide 1* is complementary to the two *Students' Laboratory Guides* with which it is linked by numerical cross-references. It distinguishes between students' elementary and main work and explains how the *Laboratory Guides* should be used. Each investigation is treated under five headings. (1) "Associated Materials", which refers to complementary work in the *Study Guide* and to appropriate visual aids; (2) "Principles", which gives an outline of the aims of the investigation; (3) "Teaching Procedure", which suggests approaches, gives links with work in the *Laboratory Guide* and pinpoints possible difficulties; (4) "Practical Problems of Teaching"; and (5) "Questions", which delineates expected answers to the questions posed in the *Students' Laboratory Guide* and suggests possible further discussion.

It is justly claimed that these materials do not represent a rigid syllabus. They could be used in a variety of ways related to the different circumstances found in schools, and the varied abilities, backgrounds and aspirations of students. "A flexible approach has been adopted for presenting biological science as an interesting and important subject related to the potential biologist and non-biologist alike." A teacher with access to the complete set of materials should certainly be able to "develop that balance between the theoretical and practical best suited to his own students". All the same, I suspect that this programme could be just as much of a strait-jacket as the traditional external syllabus and the work makes stringent demands on teacher and student. Still, the priorities are right, investigation is paramount and biology really could come to life as a relevant, exciting and absorbing pursuit for individual study at a level appropriate to the previous experience and future prospects of the sixth-former concerned. The onus is on the teacher.

JOYCE VINNICOMBE

IMMUNE SYSTEMS

Factors Regulating the Immune Response

Report of a WHO Scientific Group. (World Health Organization Technical Report Series, No. 448.) Pp. 88. (WHO: Geneva, 1970.) 10*s*; $1.75; Sw.fr.5.

A PANEL of wise men was assembled by the World Health Organization in Geneva on September 1–6, 1969. This report is a distilled version of their deliberations. It is easily the bargain of the year for immunologists. The presentation is somewhat didactic, but this is probably an advantage; to have dotted all the i's and crossed all the t's would have extended the booklet tediously.

The first five chapters define the immunological apparatus and the basic variables in immune responses. Current theories of cellular immunology are enunciated concisely and in a readable manner. The next two chapters are concerned with intrinsic regulatory factors in primary and secondary immune responses. A chapter follows which is largely devoted to the effect that extrinsic regulators may have on the course of immunity. The last chapter is grandly named "How Does the Entire Immune System Become and Remain Functional ?". In a way this chapter heading epitomizes the comprehensiveness of the book. It is a most remarkable production which should be required reading for all those interested in current developments in immunology.

It is perhaps sad that a booklet of only eighty-eight pages takes a year to produce and it is unfortunate that points of fact in the text may not easily be traced (except by the expert who knows, anyway) to specific entries in the abbreviated reference lists which relate to each subject. These are minor flaws and the members and secretariat of the group of scientists involved are to be congratulated on a first-class piece of work.

A. J. S. DAVIES

VETERINARIAN IMMUNOLOGY

Veterinary Immunology

By W. J. Herbert. Pp. xi + 356 + 22 plates. (Blackwell (Scientific): Oxford and Edinburgh, 1970.) 85*s*.

IMMUNOLOGY transcends the boundaries of scientific disciplines gaining in stature as it draws upon the resources of each. It has emerged from its historical association with microbial infections, from the days when immunity was first recognized, to become an all-embracing science attracting followers from most sections of the scientific community. Therein lies its strength and dynamism and the explanation for its recent dramatic transformation.

For these reasons it is desirable that textbooks of immunology should be written specifically for definitive groups of students and others, whose need for knowledge of the subject was once thought to be subsidiary or peripheral to their chief objectives. Such books should be designed to introduce these large numbers of undergraduates and graduates to a fuller understanding of fundamental and updated immunological concepts. Hopefully then, individual interest, enthusiasm and participation may follow, and gaps in our understanding of many diverse aspects of the subject be filled. One such specific group is the veterinary profession many of whose members have been actively participating in the development of immunology during its emergence as a subject.

In this book Dr Herbert has succeeded in producing a text that is well orientated to the requirements of veterinary undergraduates and practising veterinary surgeons, as well as being of benefit to those biologists interested in immunological responses of the various species of domesticated animals. Fundamental physiological mechanisms, theories of antibody production, descriptions of diagnostic serological tests, and physicochemical techniques for characterization of immunoglobulins are necessarily similar whether one is dealing with humans or animals. There is, nevertheless, considerable diverse data recorded in this book on the various species of domesticated animal, and sufficient examples of clinical disease states, the diagnosis and prevention of which are dependent on immunological methods, to make it an extremely valuable aid to the student of veterinary science and medicine. Good veterinary examples of allergy and atopy are perhaps rather lacking, but this is no fault of the author; indeed, he makes specific reference to these gaps in our knowledge of veterinary allergic conditions.

The diagrams, figures and photographs are clearly reproduced and well chosen to illustrate the text. They introduce the reader, in a concise and clear manner, to the subject, giving him a sound grasp of the various concepts of antigen–antibody reactions. Details of molecular configurations, spatial arrangement and steric hindrance are wisely left for the enquiring reader to consult texts of immunochemistry; indeed, such readers are provided with suggestions for further reading. Some errors creep into most textbooks and this book is no exception. In a rapidly expanding subject it is, however, difficult to be precise and the author does well to maintain clarity in an eminently instructive book with wide appeal to students of veterinary and biological science alike.

D. ALLAN

FISH OF COLD CLIMES

Biology of Coregonid Fishes

Edited by C. C. Lindsey and C. S. Woods. (Proceedings of an International Symposium held in Winnipeg, Canada, August 25–29, 1969.) Pp. 560. (University of Manitoba: Winnipeg, 1970.) $8.

THE coregonid fishes are a dominant group in cold freshwaters of the northern hemisphere. They are distributed across the northern Eurasian and North American land masses and limited at the southern extreme of their range to mountainous regions, as in the British Isles and the Alps. Especially in inland areas they are valuable commercially. Perhaps because of their wide distribution and fisheries value they have attracted the attention of many workers, yet they still remain a difficult and elusive group to ichthyologists.

This volume comprises thirty-five papers read to an International Symposium on Biology of Coregonid Fishes held in 1969. It has been reproduced photographically from typewritten contributions, with the result that it was available only eleven months after the symposium meetings and at a remarkably low price. The editors, Dr C. C. Lindsey and Dr C. S. Woods, are to be congratulated on this considerable achievement.

The coregonid fishes thrive in regions which have been repeatedly and recently disrupted by glaciation, and they have acquired variable body forms and plastic life styles that challenge conventional classification. It is understandable therefore that most of this volume is devoted to studies bearing on the classification or systematics of the group. The remaining papers cover a variety of subjects including parasitology, ecological aspects, reproductive biology and fisheries topics.

Coregonid systematics are certainly involved, but with recent advances in their study, particularly the use of protein properties, a clearer picture is emerging. Given such a plastic group, with populations often living in isolation in lakes, with the introduction of exotic forms, and introgression within lakes also taking place, descriptive systematics has become very complex. Populations have been described as species, or subspecies, until nobody could see the wood for the trees. Present trends, however, are towards systematic rationalization, with many fewer species, and the recognition that phenotypic variants do not require names.

This is nowhere more apparent than in northern Europe where Berg and Pravdin had named numerous forms from Karelia, although Himberg in a comprehensive review of the zoogeography of the North European coregonids in this volume reduced them to two only, one of which, *Coregonus lavaretus*, is represented by three "cryptic species". Himberg further considers that Europe was populated following the last glacial epoch by two ancestral forms which at that time were ecologically distinct, and have since given rise to many phenotypic populations, and hybridized extensively in isolated waters.

A contribution which I found particularly interesting is that discussing the origin and distribution of *Coregonus* in the British Isles by Peter S. Maitland. There has been a similar confusion of nomenclature over the British populations, some fifteen in number, traditionally recognized as belonging to three species and eight subspecies found in lakes in Scotland, the Lake District, North Wales and Ireland. Maitland suggests that all could have originated from two (or three) sympatric species in a single post-glacial water body in the site of the present Irish Sea. The connexion between this western water mass and the central European one implied by Himberg's hypothesis has yet to be established. In the light of advances in taxonomy of the European forms it is disappointing to find Maitland still advocating the retention of Regan's scientific names for the British coregonids. This nomenclature has confused the relationships and affinities of these populations in the past, and was based on what by present day standards would be regarded as inadequate samples. Modern studies[1] show that the British freshwater forms are referrable to the two species widespread in Europe, *Coregonus lavaretus* and *C. albula*.

SIEVE PLATES AND TUBES

The Phloem

By Katherine Esau. (Encyclopaedia of Plant Anatomy. Second edition. Histology: Vol. 5, part 2.) Pp. ix+505. (Gebrüder Borntraeger: Berlin and Stuttgart, 1969.) DM 188.

IT was almost inevitable, once the editors had decided to include a volume on the phloem in the "Handbuch der Pflanzenanatomie", that the task should be entrusted to Professor Katherine Esau, for she has established for herself a world reputation, not only as a plant anatomist, but specifically as a student of the phloem. This splendid volume is the outcome of three and a half years of work, interspersed, no doubt, with research of the same original and stimulating up-to-the-minute quality which one has come to expect from her, and which shows no signs of falling off in either quality or quantity.

Professor Esau happily relates her treatment, on the one hand, to the place of the phloem in the life of the plant, and on the other to the historical development of our knowledge of the subject. Both these emphases are evidence of her breadth of sympathy, and both are important in these days of narrow technology-orientated specialization, when knowledge of the natural world is too often valued merely in terms of the use we can make of it in the interests of physical existence. The historical note finds expression in a recall of the original occasions on which significant new ideas were put forward: "sieve plate", "slime", "nacré walls" all come alive in the words of their originators. This is a welcome feature.

In the systematic development of the subject, the sieve element naturally comes first in this book, and is given a thorough treatment (about one hundred pages). The electron microscope evidence is discussed fully as far as the summer of 1968. Esau herself has contributed very largely to this; and although, to single out one crucial point, she inclines to the view that the functioning sieve plate pores are "open", she is nevertheless very fair to the opposite view. "There is hardly a feature in the sieve element that does not arouse some controversy," she remarks, with justice. Sieve tube physiology is not neglected.

Sections on parenchymatic elements and sclerenchymatic elements follow (about thirty pages), that on the companion cells being particularly full. Then, moving from histology to anatomy, there is a section on the distribution of the phloem in the plant body (twenty pages) and on its development as a mature system, the latter naturally lengthy (eighty pages) and including references to experimental work. Professor Esau has a well known interest in the phloic transmission of virus diseases. There is a section of ten pages on this, followed by a much longer section (100 pages) on comparative studies, which ranges from the larger brown algae and mosses to present-day angiosperms and the fossil record. This leads naturally to the discussion of phylogenetic trends, to which Esau devotes ten pages. Here, as with comparative studies, she acknowledges a great dearth of information.

Professor Esau concludes her great work with twenty pages attempting to relate structure to function. Here, few final conclusions are at present possible; but, as a physiologist, I was struck by the comprehensiveness of the author's grasp of a subject not her primary interest.

Needless to say, there is a large selection of first-rate figures and plates, about one hundred in the text and fifty in a terminal collection. These include many electron micrographs. There is a bibliography of more than a thousand references, and three indexes (author, plant and subject). The printing and paper are of high quality. This is clearly a book which every library must have, and which many researchers would wish to be able to afford. It will long remain a classic. D. C. SPANNER

PETROLOGICAL TOPICS

Mechanism of Igneous Intrusion

Edited by G. Newall and N. Rast. (*Geological Journal* Special Issue No. 2.) (Proceedings of a Symposium held in the University of Liverpool, January 9–11, 1969, under the auspices of Liverpool Geological Society.) Pp. 380. (Gallery: Liverpool, 1970.) 140*s*.

PROVIDED the reader of this book does not expect a comprehensive, authoritative or even fully relevant series of articles on the subject of the mechanism of igneous intrusion, he will not be disappointed, for, judged as an array of petrological topics, both descriptive and theoretical, representative of current research and thinking, this is a useful and stimulating publication. It has the merit of bringing together ideas and conclusions stemming from radically different approaches; all of these must be reconciled in the formulation of coherent genetic theory. An attempt at such a synthesis is the subject of the final chapter by N. Rast, which owes much to records of the discussion at the symposium as well as to notions of his own. This, indeed, is an aspect of symposium reports, namely, the opportunity to express ideas in invited contributions that would doubtfully find place in the literature of standard journals. Correspondingly, however, the reader himself must recognize the need to exercise a critical appraisal of the contents.

Some of the contributions are essentially reviews. The first article, on igneous activity in orogenic cycles by E. K. Ustiyev, is appropriately of this nature and introduces the subject of the symposium on the broadest scale in terms of Earth history. A very relevant review, by W. S. Pitcher, is concerned with an assessment of the

geometry of well-studied granite plutons in their various structural settings.

More specific descriptive articles are those by J. W. Aucott, on the Galway granite, which analyses the tectonic and intrusive history of the mass, and by B. E. Leake, a most instructive account of the mode of dislocation and disruption of basic and ultrabasic intrusions by Caledonian deformation in Connemara. The remarkable intrusions within the volcanic superstructures of Réunion, described by G. J. Upton and W. J. Wadsworth, add significantly to our knowledge of the relations between "plutonic" and effusive formations in central volcanoes; these have become increasingly well documented in recent years, but by their diversity have given rise to somewhat conflicting data on the question of the nature of "magma reservoirs" to central volcanoes. Geophysical methods are currently providing an important source of information even if they rarely allow of unequivocal interpretation; in this respect the paper by M. H. P. Bott and others on the crustal structure beneath the granites of south-west England has the additional merit of leading to a geologically acceptable model.

Ring structures are represented in contributions by A. C. Dunham and C. J. Stillman, and papers by D. Bridgwater and K. Coe and by B. F. Windley are concerned with basic dykes; the latter is of interest in describing dykes of dolerite composition, which have a garnet-amphibolite primary mineralogy.

Among the physico-chemical and geochemical contributions are papers by B. G. Jamieson, D. K. Bailey, P. G. Harris and others which relate to processes of magma generation and to considerations of thermal conditions on ascent and emplacement; if they do no more than cover familiar ground, their themes have a place in the context of the volume. W. S. Fyfe introduces some naïve thoughts on granites; thus he says, more happily in lecture than in print, "Once a melt forms, it may rise. There is no 'room' problem . . .". Fortunately, it is possible to turn to the thoughtful and ingeniously contrived experiments on intrusion mechanisms by H. Ramberg, for these have been inspired by an appreciation of geological problems, and the conclusions are correspondingly critical in their appraisal both of the usefulness and the limitations of the models, while J. L. Roberts in an extremely well-considered study evaluates the factors involved in magmatic emplacement in the environment of brittle rocks. J. W. Elder, arguing from slender and doubtful assumptions, gained a vantage point from which he could comment on every other contribution without any feasible rejoinder. S. A. F. Murrell in the first part of his paper ably summarizes earlier work of his own on rock mechanics, but follows this with an unappreciative review of global tectonics and vulcanism; the significance of the contribution as a whole is obscure and its value doubtful.

The list of titles is completed with the articles by H. Tazieff on ignimbrites and by J. M. Ade-Hall and E. A. Lawley on opaque minerals in lavas and dykes. Both are important contributions on their particular topics, but their relevance to the subject of the book is even less obvious than are several others.

B. C. KING

PLUTONIUM CHEMISTRY

The Chemistry of Plutonium

By J. M. Cleveland. Pp. xxii + 653. (Gordon and Breach: New York and London, July 1970.) $23.40; 195*s*.

THIS very useful book is divided into four parts; a short general introduction is followed by seven chapters on the solution chemistry of plutonium, including a very complete (107 pp.) coverage of solvent extraction systems. The third section, nine chapters on the compounds of plutonium, provides a very comprehensive account of this aspect of plutonium chemistry and the final part on chemical processing is just as complete.

From the data which have been collated and critically examined it is evident that by far the greater part of the work, in the 30 years since the discovery of the element, is related either to the process chemistry or to nuclear fuel applications, as one would expect for an element of such importance in the field of nuclear energy. For example, 1,118 references are cited, covering published (and some classified) material to the beginning of 1969, and no less than 533 of these deal with the chemistry of the complexes in aqueous solution, the related methods of solvent extraction, the separation of plutonium from reactor fuels and the chemistry of the halides, which are also of importance in metal production and halide separation processes.

Related to these aspects of plutonium chemistry, one would have expected there to be a great deal of published work on the thermodynamics of such systems, but it is evident from Dr Cleveland's careful assessments of the reported data that there are more conflicting estimates of thermodynamic quantities in this field than there are reliable measurements.

One minor criticism of this valuable assembly of data is the omission of any information on the molecular structure of plutonium compounds; admittedly very few complete X-ray structure analyses of plutonium compounds have been recorded, but tables of the known X-ray crystal data are provided in the book and it would have been useful to have stereochemical information as well.

The book is very attractively produced, with exceptionally few typographical errors, all of which are trivial. One which might possibly mislead occurs on p. 434 (line 33), where "concentrations N_3 of Pu (IV) and H_4NO" should be "concentrations of Pu (IV) and NH_4NO_3"; there are also two Tables 2.1 (pp. 12 and 20). These are only very minor points, and the book is warmly recommended to any chemist interested in the chemistry of the actinides; indeed, it is a book which no chemist working with plutonium, whether in a research laboratory or in a production plant, can afford to be without.

K. W. BAGNALL

COLLISION RESEARCH

Atomic Collision Phenomena in Solids

Edited by D. W. Palmer, M. W. Thompson and P. D. Townsend. Pp. xxvi + 678. (North-Holland: Amsterdam and London; American Elsevier: New York, 1970.) Hfl. 100; 233*s*; $28.

THIS book presents the proceedings of an international conference held at the University of Sussex in September 1969. A valuable aspect of the holding of specialist conferences is said to lie in the opportunities provided for informal and fruitful contacts between workers with shared interests; perhaps this spirit is evoked for those who could not be present by the inclusion of a list of conference participants and a group photograph. But in the more formal activities, with liberal use of visual aids, the density at which information is transmitted can daunt even the most alert and assiduous note-taker, so that a printed record is invaluable for later reference as well as for disseminating the proceedings to a wider audience. The contributors and editors are to be congratulated on the quality and on the speed with which this record has been produced.

The book consists of more than fifty papers, some available in abstract only, which range from short reports to papers which are more nearly review articles. The

extensive and recent references given with some of the longer papers is a helpful feature. The editors warn in their preface that the conference, and hence by implication this book, was not intended to be educational in character. The book is intended as a tool for the active worker in the field. Although authoritative and up to date, some of the papers are rather esoteric and make hard reading—this is certainly not the book for the beginner.

The principal sections of the book cover electron channelling, atomic collision theory, radiation damage, sputtering, inelastic atomic collisions, ion channelling, electron excitation and photon emission, surface scattering of ions, and ion penetration profiles. There is a fair balance between presentation of theory and of experimental results. The sputtering of KI by exposure to ultraviolet radiation is interesting because of the support which the results lend to current theories of the mechanism of the formation of colour centres by irradiation of the alkali halides. The description of the direct observation of heavy ion collision cascades by field ion microscopy is very convincing. The papers on the channelling of electrons—important in the transmission electron microscopy of thin crystals—emphasize the need for a proper wave mechanical treatment of the interaction of the electron beam with the Bloch waves. There have been further refinements in the calculation of interaction potentials; Robinson has calculated these using the method of Firsov and starting from the simple scattering cross-section introduced by Lindhard. All in all, this book gives a picture of a flourishing and active field of study.

T. P. P. HALL

SPINS IN SOLIDS

Spin Temperature and Nuclear Magnetic Resonance in Solids

By Maurice Goldman. (International Series of Monographs on Physics.) Pp. ix+246. (Oxford University: London; Clarendon: Oxford, July 1970.) 85*s*.

THE aim of this book is to present a unified description of the high temperature approximation to spin temperature theory. Its chief application is to nuclear spin systems in solids. Although the treatment throughout is theoretical, appropriate experimental information is discussed whenever possible.

The concept of temperature in spin systems is introduced in the first chapter and modifications applicable to nuclear magnetic resonance are described. This chapter is followed by a study of the properties of nuclear spin systems which are isolated from the crystal lattice but subject to both sudden and adiabatic changes in the Hamiltonian. The effects on the spin temperature of a finite spin-lattice interaction are introduced. The two following chapters describe in detail the Provotorov theory of saturation which is applicable to cases when the probabilities of radio-frequency induced transitions are comparable with those for transitions induced by spin-lattice coupling. This theory is basic to much of nuclear magnetic resonance. The effects of spin-spin interactions on the spin temperature concept are then discussed. Finally, a description is given of dynamic polarization methods, which is particularly appropriate to the "solid effect" of thermal mining in low fields. The appendix contains some of the more important results found useful in spin-temperature theory.

This monograph will be of value to both the experimentalist and theoretician interested in the properties of interacting spin systems and particularly to research workers in nuclear magnetic resonance. The material is presented in a clear and logical way and the subject matter is very carefully arranged and indexed. The text may be regarded as complementary to the book by Professor A. Abragam on the *Principles of Nuclear Magnetism* (1961) and could prove an equally valuable addition to the literature of physics.

C. A. BATES

FOR TRANSLATORS OF RUSSIAN

Russian–English Scientific and Technical Dictionary

By M. H. T. Alford and V. L. Alford. Vol. 1: Pp. xxvi+1–764. Vol. 2: Pp. 765–1422. (Pergamon: Oxford, London and New York, October 1970.) 240*s*; $32.

ACCORDING to the dustjacket, this dictionary, containing "over 100,000 entries drawn from 94 different disciplines, technologies and other professional subjects", is specially intended for "people with weak or moderate knowledge of Russian grammar" and will be "invaluable to scientists learning the language". To facilitate its use by the latter, it is provided with a preliminary chapter, "Instructions for Learning Large Vocabularies", based on work carried out in the University of Essex and supported by the Office for Scientific and Technical Information, for developing new methods of learning to read foreign languages. New methods of vocabulary learning are presented, based on methods of identification of stimulus and remembering the stimulated response, and a procedure for learning large vocabularies by means of special prompt cards. Valuable as these methods may be to the language student, it is open to doubt whether this emphasis on those beginning Russian contributes much of value to this dictionary. A book of this size and price will surely be purchased chiefly by libraries, and by already competent translators of Russian wishing to extend and modernize their vocabularies, rather than by beginners, who would be more suited initially with one of the existing smaller dictionaries limited to their own field of study.

Used in practical translation, the potential use of this book is greatly decreased by this emphasis on the student. Some years back, L. M. Milne-Thompson, in his *Russian-English Mathematical Dictionary* (University of Wisconsin, 1962), introduced the practice of equipping each entry with a reference to the basic root of the word: "*primechanie* remark, note (*met* mark), *prodolzhenie* continuation, extension (*dolg* long)" which, although a valuable aid to learning, did not impede the fluent Russian speaker from using the dictionary. In this new work, however, each word is dissected into a complicated morpheme structure (prefix-root-suffix-inflexion) in which the elements are separated by raised points: *pri·mech·ani·e, pro·dolzh·eni·e*, which proves wearisome to the eye and considerably slows down the process of word-finding.

With regard to the content of the dictionary, it is, as claimed, extremely comprehensive (including such fringes of technology as "*korset* corset (garment)", "*kosilka* a mowing machine" and "*mast* colour of animal hair, suit at cards"). There are, however, a number of misprints, some of which (for example, "Lynds" for Lyrids) are not corrected in the errata. Russian versions of Latin-script proper names, (often a stumbling block) are given, though not always cross-referenced (thus the *Fabri-Pero* (Fabry and Perot) interferometer is listed under *Fabri*, but there is no cross-reference for Perot under *Pero*).

Apart from these (admittedly minor) defects, the vocabulary contained in this dictionary will be an invaluable aid to anybody regularly involved in the reading or translation of scientific papers in Russian. It is, however, somewhat too large and unwieldy a vocabulary for the beginner (even with the use of learning aids), and it is a pity therefore that the emphasis in format on the student (who will be less likely to use it) detracts from its undoubted value to those already proficient in the language.

VERA RICH

Correspondence

Scientific Censorship

SIR,—Recently we submitted a paper to a leading chemical journal in Czechoslovakia—*Collection of Czechoslovak Chemical Communications*. The whole work described in our paper was performed at the Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Sciences, Prague, between 1967 and 1969. We felt it our obvious duty to publish our paper in the journal where most of our previous papers had appeared. Moreover, our work was done exclusively on Czechoslovak territory and completely funded by the Czechoslovak Academy of Sciences.

We have been informed that in view of the publishing policy adopted by the present Czechoslovak authorities, which prohibits Czechoslovak authors who are currently living abroad without the approval of the Czechoslovak government from publishing in the Czechoslovak journal, our paper cannot be accepted for publication.

We would like to point out that the submitted paper deals exclusively with problems of the natural sciences without any relation to the present political situation in Czechoslovakia. The decision of the Czechoslovak authorities can hardly be labelled otherwise than as a discrimination of scientific work.

Yours faithfully,

JIRI ZEMLICKA

Michigan Cancer Foundation,

Medvedev's Complaint

SIR,—Bikerman (*Nature*, **228**, 297; 1970) has offered a completely misleading analogy between the refusal of the National Science Foundation to supply travel funds for his trip to France, and the refusal of the Soviet government to permit Zhorez (that is *not* Jaurès) Medvedev to attend a Ciba Symposium. In Medvedev's case, authorization to leave the country was adamantly denied, although travel funds were actually available. Presumably Bikerman, as a naturalized US citizen, would have had no trouble in obtaining a visa to enter France.

Bikerman says that the excerpt from Medvedev's book strikes him as subtle communist propaganda. Since Medvedev, for publishing a book exposing Lysenkoism and advocating international cooperation in science has (i) lost his job, (ii) been prevented from moving to another district to look for a new position, (iii) been hauled off forcibly to a "psychiatric" institution, the way of a subtle propagandist would seem to be a steep and thorny road.

Yours faithfully,

THOMAS H. JUKES

University of California,
Berkeley, California 94720.

Definition of Intelligence

SIR,—H. A. Fatmi and R. W. Young (*Nature*, **228**, 97; 1970) propose a definition of intelligence for use in drawing distinctions between machine and human behaviour. They base their definition on the ability of the system to perceive order in a situation previously considered to be disordered.

While this definition is valid within extremely narrow constraints, it has serious limitations in defining the difference between men and machines. In the first place it excludes many aspects of intelligence which are of the greatest interest from a human point of view, namely, the relation between set theory on the one hand and the ability of intelligent systems not only to perceive but also to generate and choose new structures and instruction sets and ascribe meaning to both internal states and input sets.

A single machine with a finite phrase-structure grammar would not be able to realize the extended definition of intelligence given above. An extension of Fatmi and Young's definition allows us to include the missing elements on the human side of the equation.

> "Intelligence is that faculty, of mind, by which order is perceived in a situation previously considered to be disordered, and whereby similar structures can be generated, recognized and semantically defined without the necessity of complete *a priori* specification."

This revised definition permits the inclusion of linguistic competence, as defined by Chomsky, as an aspect of intelligent behaviour, which it certainly is. In the trivial case, we know that the child produces valid grammatical sentences in the absence of a complete instruction set. On a deeper level we also know that the set of valid grammatical statements is an infinite set and that the instruction set for a natural language cannot be completely specified. By Fatmi and Young's argument all linguistic behaviour is only apparently intelligent or, in the trivial case, we would have to assume that the same sentence uttered by a child or a parent or teacher would be sometimes a sign of intelligent and sometimes a sign of intelligence-like behaviour.

My own work leads me to the view that attempts to relate simplicistic finite set theory and automata to faculties of mind and the mechanisms of the brain inevitably leads to such difficulties. I suggest that the brain should be seen as a transfinite automaton, which cannot be defined by restricted set theory (ZF), but only by extended set theory including the all important "axiom of choice"[1-3].

Yours faithfully,

GORDON HYDE

Decimal Lakh

SIR,—As the day of formal and wide acceptance of the decimal system draws closer, may I make a public request in favour of an Indian unit ?

It is Laksha, written in English as Lakh, standing for 100,000. Surely, a lakh is a better way of saying one hundred thousand.

Yours faithfully,

S. ROY

Department of Mechanical Engineering,
University of Aston,
Birmingham 4.

Anomalous Water

SIR,—K. S. Chua (*Nature*, **227**, 834; 1970) has proposed certain structures to account for the density of anomalous water (1·4 g cm^{-3}) with a resulting oxygen-oxygen bond length of 2·4 Å. We add that the work of J. C. Speakman *et al.* (University of Glasgow) also reveals shared O-H-O bonds of similar lengths for certain crystalline acid salts.

Although unmentioned in the article, however, it turns out that the first of Chua's structures simply reduces to a scaled down (2·4/2·76) version of the well known ice structure (but with hydrogens shared between the oxygens). The second is the similar equivalent of the ice Ic structure —a low temperature polymorph of ice.

Can one really believe that these particular crystal structures as such could demonstrate the properties of liquid anomalous water?

Yours faithfully,

IAN CHERRY

Obituary

Dr K. Biswas

DR KILIPANDA BISWAS, the Indian botanist famous for his study of the flora of India and Burma, died on December 29 last year at the age of seventy.

Early in his career he was superintendent to a number of botanical gardens in India, including the Royal Botanic Gardens of Calcutta and the Indian Botanic Gardens. For this work, he was awarded the Elliott gold medal and prize in 1928 and 1936, and the coronation medal in 1937. He came to Europe in 1936 and worked in the Herbarium of the Royal Botanic Gardens of Kew and Edinburgh and in the British Museum. In 1937 he was awarded a DSc at the University of Edinburgh for his valuable contributions to the knowledge of the Indian flora, and in 1938 he was elected a fellow of the Royal Society of Edinburgh.

In 1954 he was appointed director of the Botanical Survey of India and in the following year he became director of medicinal plants, a post he held until his retirement. During this time, his task was to develop the large scale cultivation of ipecac. His success here was important to the economy of India and earned him the Barclay memorial medal for the best research work in biological science in Asia in 1961.

After 1964, he continued as honorary lecturer in botany at the University of Calcutta and as a member of various organizations in India, Britain and UNESCO.

He had been suffering from a heart disease and chronic uraemia for one and a half years. He leaves his wife, two sons and a daughter.

Announcements

University News

Professor C. Rimington, formerly of University College Hospital Medical School, London, will join the Department of General Medicine, **University of Capetown,** for about four months as Royal Society Leverhulme visiting professor.

Dr D. B. Moffatt has been appointed to a personal chair in the Department of Anatomy, **University College, Cardiff.**

Dr R. F. Churchhouse, head of the Programming Group of the SRC Atlas Computer Laboratory, Oxford, has been appointed director of the Computing Centre and professor of computing mathematics.

Dr Elmar Seitler, assistant chief of biophysics in the US Armed Forces Institute of Pathology, Washington DC, has been appointed professor in the Departments of Physics and Biophysics, **University of Chicago.**

Appointments

Dr Ruth M. Davis, director of the Lister Hill National Center for Biomedical Communications, has been appointed director of the Center for Computer Sciences and Technology of the **US National Bureau of Standards.**

Sir Edward Bullard, University of Cambridge, **Professor A. D. Bradshaw,** University of Liverpool, and **Dr C. E. Lucas,** Department of Agriculture and Fisheries for Scotland, have all been appointed members of the **Natural Environment Research Council.**

The following have been elected officers of the **International Astronautical Federation:** president, **Professor A. Jaumotte** (Belgium), vice-presidents, **Dr G. E. Mueller** (USA), **Mr H. G. S. Murthy** (India), **Professor L. G. Napolitano** (Italy) and **Professor L. I. Sedov** (USSR).

An **Academic Advisory Committee** has been appointed to the **Cranfield Institute of Technology** to monitor and advise on academic standards. Members of the committee are: **Lord Caldecote,** Delta Metal Company (chairman); **Mr H. F. R. Catherwood,** National Economic Development Council; **Professor A. R. Collar; Sir George White,** University of Bristol; **Dr H. M. Finniston,** British Steel Corporation; **Dr F. R. Jones,** Mullard Limited; **Sir Morien Morgan,** Royal Aircraft Establishment; **Mrs M. K. McQuillan,** Imperial Metal Industries (Kynoch) Limited; **Professor S. C. Redshaw,** University of Birmingham.

Miscellaneous

Professor Brinley Thomas, University College, Cardiff, has been awarded a fellowship by the **US National Science Foundation.**

The **International Meteorological Organization prize** for 1970 has been awarded posthumously to **Professor R. Scherhag** who was director of the Institute for Meteorology and Geophysics at the Free University of Berlin.

Dr Richard D. O'Brien, director of the Division of Biological Sciences at Cornell University, has won the **1970 International Award for Research in Pesticide Chemistry,** sponsored by Burdick and Jackson Laboratories Inc., Muskegon, Michigan.

The 1970 **Edward B. Rosa award** of the US National Bureau of Standards has been won by **Mr P. R. Achenbach,** chief of the Sensory Environment Branch of the NBS Building Research Division. **Dr Robert P. Madden,** chief of the Far Ultraviolet Physics Section in the NBS Optical Physics Division, will receive the 1970 **Samuel Wesley Stratton award** of the NBS. Each award consists of a bronze plaque and a $1,500 honorarium.

Nominations are invited from academies or scientific societies concerned with zoology for membership of the **International Commission on Zoological Nomenclature** which has seven vacancies arising from the resignation or retirement of Commissioners from Brazil, Germany, Japan, the Netherlands, the UK and the USA. Candidates may be of any nationality and should have a distinguished record of work in any branch of zoology. The Commission is particularly interested in recruiting members concerned with herpetology, parasitology, marine biology, Protista and Coelenterata. Nominations should be sent to the Secretary, International Commission on Zoological Nomenclature, c/o British Museum (Natural History), Cromwell Road, London SW7, before December 31.

ERRATUM. The title of the article by R. G. Crounse, A. J. Bollet and S. Owens which appeared in *Nature* for October 31 (**228**, 465; 1970) should have read "Quantitative Tissue Assay of Human Malnutrition using Scalp Hair Roots".

ERRATUM. In the article entitled "Synthetic DNA-RNA Hybrids and RNA-RNA Duplexes as Templates for the Polymerases of the Oncogenic RNA Viruses" by S. Spiegelman *et al.* (*Nature*, **228**, 430; 1970), the title of Table 1 should read "RESPONSES OF ONCOGENIC VIRAL DNA POLYMERASES TO ADDED DNA AND A SYNTHETIC RNA-DNA HYBRID". Table 4 should read as follows:

Template	Incorporation (pmoles/5 min/10 g viral protein)			
dA·rU	dT	(0·8)	dA	(<0·1)
dC·rG	dG	(141·0)	dC	(1·9)
dC·rI	dG	(44·5)	dC	(1·9)
dG·rC	dC	(1·2)	dG	(13·3)
dI·rC	dC	(1·3)	dG	(104·6)
dT·rA	dA	(0·9)	dT	(10·3)

ERRATUM. In the article by J. N. Mehrishi entitled "Cell Surface Charge Increase by both Tumour Inhibitory and Tumour Growth Promoting Polyanions" (*Nature*, **228**, 364; 1971), references 14 to 46 were unfortunately printed on page 375 of the same issue of *Nature*.

International Meetings

January 18–22, 1971, **Chemical Oceanography** (Gordon Research Conference), Santa Barbara (Dr Alexander M. Cruickshank, director, Gordon Research Conferences, Pastore Chemical Laboratory, University of Rhode Island, Kingston, Rhode Island 02881, USA).

January 18–22, 1971, **Electrochemistry** (Gordon Research Conference), Santa Barbara (Dr Alexander M. Cruickshank, director, Gordon Research Conferences, Pastore Chemical Laboratory, University of Rhode Island, Kingston, Rhode Island 02881, USA).

January 25–29, 1971, **Polymers** (Gordon Research Conference), Santa Barbara (Dr Alexander M. Cruickshank, director, Gordon Research Conferences, Pastore Chemical Laboratory, University of Rhode Island, Kingston, Rhode Island 02881, USA).

March 29–31, 1971, **Non-Ionizing Radiation Safety,** Cincinnati (Laser Laboratory, Children's Hospital Research Foundation, Cincinnati, Ohio 45229, USA).

British Diary

Monday, November 9

Batteries mW to kW (6.30 p.m.) Mr C. J. Bruce, Institution of Electrical Engineers, London Graduate and Students Section, at Savoy Place, London WC2.

How Does the Introduction of SI Units Affect the Mechanical Engineer? (6 p.m., discussion) Institution of Mechanical Engineers, Thermodynamics and Fluid Mechanics Group, at 1 Birdcage Walk, London SW1.

Proofs: Positive and Presumptive (5.30 p.m.) Mr B. Gower, British Society for the Philosophy of Science, in the Joint Staff Common Room, University College London, Gower Street, London WC1.

Semiconductor Gamma Camera System (6 p.m.) Mr E. Moss and Mr W. Gore, Institution of Electronic and Radio Engineers, Joint IEE/IERE Medical and Biological Electronics Group, at 9 Bedford Square, London WC1.

Training Engineers to Use Computers (7.30 p.m.) Mr W. S. Meadows, Institution of Electrical Engineers, at Mander College, Bedford.

Tuesday, November 10

Adrenocortical Function in Psychiatric Disorder (5.30 p.m.) Professor J. L. Gibbons, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Sixth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Anthraquinones as Analytical Reagents (5.15 p.m.) Mr M. A. Leonard, Society for Analytical Chemistry, jointly with the Leeds University Union Chemical Society, at the University, Leeds.

Changes and the Future in Electrical Engineering (2 p.m. and 7 p.m.) Mr S. Z. de Ferranti, Institution of Electrical Engineers, at Usher Hall, Edinburgh (Faraday Lecture).

Clearing the Air (6 p.m.) Mr F. E. Ireland, Institution of Chemical Engineers, at the Renold Building, UMIST, Manchester.

Construction of the Monmouth Tunnels in Soft Rock (5.30 p.m.) Mr R. R. Parry and Mr G. D. Thornton, Institution of Civil Engineers, at Great George Street, London SW1.

Laboratory Automation (three-day conference) Institution of Electronic and Radio Engineers, jointly with IEE and other Institutions, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

Noise and Vibration in Motor Vehicles (7.30 p.m.) Dr D. Saunders, Society of Environmental Engineers, at the University of Birmingham.

Present and Future Problems of Operation of British Grid System (7.30 p.m.) Mr J. I. Bird, Institution of Electrical Engineers, at the University of Reading.

Project Evaluation and Technological Forecasting in Agriculture (10 a.m.) Society of Chemical Industry, Agriculture Group, jointly with the Management Group, at 14 Belgrave Square, London SW1.

Social Implications of Automation (6 p.m. discussion) Institution of Mechanical Engineers, jointly with IEE and the Institute of Measurement and Control, at 1 Birdcage Walk, London SW1.

The Seasonal Reproductive Changes in the Red Deer Stag, Mr G. A. Lincoln; **Studies on Caddis Flies,** Dr M. I. Crichton; **Monuments in Mangroves—a Study of Bird Life on a Small Island Off the Coast of Florida** (film) (5 p.m.) Zoological Society of London, at the Zoological Gardens, Regent's Park, London NW1.

Training of Microanalysts for Industrial Laboratories (6.30 p.m. discussion meeting) Society for Analytical Chemistry, Education and Training Group, at Imperial College, London SW7.

Wednesday, November 11

Analytical Applications of Lasers (6 p.m.) Mr P. J. Hendra, Society for Analytical Chemistry, Midlands Section, at the University, Birmingham.

Applications of Thermal Analysis (7.30 p.m. discussion meeting) Society for Analytical Chemistry, Thermal Analysis Group, at the Leicester Lounge, 44 Glasshouse Street, London W1.

Conservation and the Electrical Industry in the 70s (9.30 a.m. colloquium) Institution of Electrical Engineers, at Savoy Place, London WC2.

Discussion Meeting (two days) Geological Society of London, Volcanic Studies Group and the Royal Society, at the Royal Society, 6 Carlton House Terrace, London SW1.

Economic Comparisons in Planning for Electricity Supply (6.30 p.m.) Mr T. E. Norris, Institution of Electrical Engineers, at the Great White Horse Hotel, Ipswich.

Jacques Besson's "Livre des Instruments Mathematiques et Méchaniques" (1 p.m.) Dr A. G. Keller, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Stirling Cycle Engine (6 p.m.) Dr A. Organ, Society of Environmental Engineers, in the Mechanical Engineering Department, Imperial College, Exhibition Road, London SW7.

The Biological Assays of the British Pharmacopoeia (6.30 p.m.) Mr V. J. Birkinshaw, Society for Analytical Chemistry, North East Section, at the School of Pharmacy, Sunderland Polytechnic.

The Development of Inventions (6 p.m.) Mr T. A. Coombs, Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

The Human Pharmacology of Sedatives and Hypnotics (5.30 p.m.) Dr M. H. Lader, University of London, at the Institute of Psychiatry, Maudsley Hospital, Denmark Hill, London SE5.

The Large Scale Production of Unexpected and Unexplained Laboratory Results (2 p.m.) Professor T. P. Whitehead, University of London, at the Royal Postgraduate Medical School, Du Cane Road, London W12.

The Optical Variables in White Paint Films, Mr D. F. Tunstall; **Uniform Radical Tolerance Method of Colour Difference Assessment,** Mr J. S. Mudd (3 p.m.) Colour Group (Great Britain), in the Mechanical Engineering Department, Imperial College, London SW7.

The Significance of Glass Transition Temperatures of Paint Films (7 p.m.) Mr J. L. Prosser, Oil and Colour Chemists' Association, at the Borough Polytechnic, Borough Road, London SE1.

Volcanism and the Structure of the Earth (two-day discussion meeting) Royal Society, at 6 Carlton House Terrace, London SW1.

Thursday, November 12

Addition Copolymers of the Vinyl Esters of Branched Chain Fatty Acids for Cure with Isocyanates (6.30 p.m.) Mr P. de Carpentier, Oil and Colour Chemists' Association, at the Royal Turks Head Hotel, Grey Street, Newcastle upon Tyne.

Aircraft Pavement Design (9.30 a.m. symposium) Institution of Civil Engineers, at Great George Street, London SW1.

Applications of Silicas and Silicates in the Surface Coating Industry (6 p.m.) Mr L. Muller-Fokken, Oil and Colour Chemists' Association, at the St Enoch Hotel, Glasgow.

Electronic Aids in Medicine (6.30 p.m.) Mr J. L. Gedye, Institution of Electrical Engineers, at the University of Essex, Colchester.

Fresh Observations on Calcium and Phosphorus Metabolism in Chronic Renal Failure (5.30 p.m.) Professor H. E. de Wardener, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Seventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Handkerchief Perfumes (7.30 p.m. demonstration meeting), British Society of Perfumers, at the Tropical Products Institute, 127 Clerkenwell Road, London EC1.

Hybrid Engineer (6.15 p.m.) Mr W. G. Evans and Mr C. S. Gledhill, Institution of Electrical Engineers, at Sumpner Building, University of Aston, Birmingham.

Thermal Analysis in Mineralogy (3 p.m.) Mr F. W. Wilburn, Mr H. G. Midgley and Mr W. B. Jepson, Society for Analytical Chemistry, Thermal Analysis Group, at the Wellcome Building, Euston Road, London NW1.

What Management Expects from Electronic Engineers and What the Young Graduate Expects from Management (6 p.m. discussion) Institution of Electronic and Radio Engineers, at 8–9 Bedford Square, London WC1.

Friday, November 13

Cosmic Ray Electrons (4.30 p.m.) Professor H. C. van de Hulst, Royal Astronomical Society, in the Scientific Societies Lecture Theatre, 23 Savile Row, London W1. (George Darwin Lecture; Chairman: Sir Bernard Lovell.)

Photoaddition of Amines to Unsaturated Compounds (1 p.m.) Dr Silva de Brito Costa, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

The Plastics Revolution (9 p.m.) Professor J. C. Robb, Royal Institution, at 21 Albemarle Street, London W1.

Water in Industry (6.30 p.m. discussion) Society for Analytical Chemistry, Western Section, at the George Hotel, Chepstow.

X-ray and Gamma-ray Astronomy (2 p.m. discussion; Chairman: Dr K. A. Pounds) Royal Astronomical Society, at Burlington House, Piccadilly, London W1.

Monday, November 16

Developments in the Science of Wood Preservation (10.30 a.m. symposium) Society of Chemical Industry, Pesticides Group, at 14 Belgrave Square, London SW1.

Inflation and Eruption of Kilauea Volcano, Hawaii, 1965-68 (5.30 p.m.) Dr R. S. Fiske, University of London, in the Chemistry Lecture Theatre, King's College, Strand, London WC2.

Space Technology and the Future (6.30 p.m.) Mr G. K. C. Pardoe, Institution of Electrical Engineers, at the University, Liverpool.

The Origins of Money (5.30 p.m.) Mr P. Grierson, University of London, at Senate House, London WC1.

The University's View of Industry (6 p.m.) Professor J. W. Linnett, FRS, Royal Society of Arts, at John Adam Street, London WC2. (Cantor Lecture.)

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

***12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire.....**£14 0 0** each

United States of America.....(by air freight).....**$48** each

Canada.....(by air freight).....**$52** each

Elsewhere overseas by surface mail.....**£14 0 0** each

(Charge for delivery by air mail on application)

*Shorter periods *pro rata*. (Minimum three months.)

NOVEMBER 14, 1970

What Next at CERN?

EUROPEAN members of the European organization for nuclear research (CERN) are once more screwing up their courage for a decision about the future of the project to build a 300 GeV proton accelerator (see page 597). In the past four years, this proposal has served powerfully to challenge a great many of the conventional assumptions about European collaboration in science. In spite of the success with which the first of the two storage rings at Geneva has been commissioned, and in spite of the ingenuity with which Dr J. B. Adams and his colleagues have been able to modify the original proposal for a very much larger accelerator, it remains unsure just what the outcome will be. Theoretically, the next meeting of the CERN council should be in a position to decide what happens to the project.

The first need is for a reappraisal of the part played by high energy physics in European science. To say this is not to question in any important way the success with which CERN has provided a focus for a great deal of research in physics and also a model of good behaviour in international relations but, rather, to suggest that the time has come for a more thorough look at the way in which high energy physics is carried out not merely at the collaborative centre at Geneva but in Europe as a whole. And for all its virtues, it is only proper to acknowledge that CERN itself has often been too presumptuous in its belief that Europe owes high energy physics a living.

When the scheme for building a machine with an energy of about 300 GeV was first proposed in 1964, CERN did its cause a good deal of damage by asking not merely that European countries should build the large machine on a collaborative basis but also that they should provide a broader base for European high energy physics by building more national facilities as well. In reality, it would have been more tactful and probably more realistic as well to acknowledge that many if not all of the governments then asked to contribute would be more inclined to do so if they could feel that collaboration would help to reduce the cost and not increase it. More recently, in May 1967, when the European committee on future accelerators produced its detailed proposals, this lesson had been learned but the organization was still over-rigidly committed to the minutiae of its proposals. The argument was that flexibility would be interpreted by unwilling governments as irresolution about the merits of the project as a whole. The fact that CERN has since then been able to modify its supposedly final proposals on at least two occasions suggests not merely that it would have been wise to be more flexible at the beginning (see *Nature*, **214**, 1283; 1967) but, to outsiders perhaps, that the organization's pronouncements are less credible than they might be. When only six of the twelve potential members of the 300 GeV project declared their willingness to contribute, for example, the organization was able to lop off from the original bill some 15 per cent of the cost.

More recently, since 1969, CERN has been working on a design in which flexibility is everything. One proposal would make it possible to increase the energy by adding to or improving the magnets around a ring 3 km in diameter from 250 GeV at the beginning to 1,300 GeV some years later. Another more modest version of this proposal, based on a ring 2 km across, would allow the operating energy to be increased from 300 GeV to 800 GeV. One of the advantages of this second version is that the new machine could be built near the present laboratory at Geneva, using the existing proton synchrotron as a source of protons. In real terms, the cost of the first stage of this preferred design is merely two thirds of that quoted originally for a 300 GeV machine. The paradox is that if CERN had been prepared in 1967 to admit the possibility of substantial cost reduction, it might well have found more than six European governments prepared to help foot the bill.

As things have turned out, much of the enthusiasm for high energy physics which made the outlook for the 300 GeV accelerator seem bright in the mid-sixties has now tended to evaporate. The French Government, for example, was then considering a project since abandoned for a 40 GeV machine. In the past four years, it is clear that there will be a British contribution to the 300 GeV machine only if there is a more rapid decline than originally planned in the operation of the existing laboratories at Harwell and Daresbury. But in these circumstances, is it wise that the building of the 300 GeV machine should be considered independently of the plans being made by separate governments for the continued operation of the machines which exist already? Might it not be preferable to devise some means by which European collaboration in high energy physics is not centred on a single machine or even a group of machines such as could emerge on the outskirts of Geneva, but, rather, diffused throughout high energy physics in Europe? One possibility, not to be dismissed on the grounds of sheer novelty, would be to make arrangements for allowing individuals with projects of some virtue to be able to carry these out at whichever of the high energy physics laboratories in Europe seem to be the most appropriate. To do this would require nothing less than a research foundation for European high energy physics, drawing financial support from member

nations not merely for the operation of the machines which exist at present but also, with luck, for the building of the 300 GeV accelerator as well.

But is there time to think of negotiating such a complicated arrangement at this late stage? This is what the enthusiasts will say. The truth is, however, that ever since the publication of the Swann report which formed the basis for the British Government's decision not to participate in the 300 GeV project, it has been clear that the continued financing of high energy physics could not be accommodated within the ordinary framework of support for basic scientific research. In Britain, the fear is that high energy physics can only continue to exist at the expense of other more worthwhile activities. Elsewhere the sheer cost of what is now proposed seems to be a sufficient disincentive, while other nations in Europe are understandably disinclined to participate either because they have recently acquired reasonable facilities of their own or because they attach low priority to the work proposed.

There is no cause for the high energy physicists to complain about this state of affairs—instead, they must learn to live with it. On the long view, the 300 GeV machine would be an asset to European science but it would be even more valuable if it could be built within a framework giving expression to the belief that physicists in particular are fond of quoting that branches of physics like these are already thoroughly international.

Warm and Cheerful

THE British Government has put itself into an awkward box on fuel policy and there is no assurance that the Conservative Cabinet will be any better than its Labour predecessor in finding a way out. A part of the difficulty seems to be that of forecasting the demand for energy a few years ahead. By now, the record of failure in this field is as long as any arm. In the mid-fifties, people were anxious that Britain would be brought suddenly to a halt by a lack of fuel, and miners were exhorted to dig more coal. Then, in 1955, the government pinned its colours to the mast of nuclear power, and miners were exhorted to find jobs outside the coalfields. Since then, the prevailing view has swung radically between the promise of shortage of coal and the threat of glut. The most recent development in Britain is that a shortfall in the output of nuclear power from nuclear fuelled power stations has been aggravated by a decision some years ago that there should be a reduction in the rate of capital investment in electricity generating plant and by a wastage of miners from the coalfields at such a rate that the miners now think themselves in a position in which they can successfully launch the first substantial strike since 1926.

The fluctuations in the available supply of energy which seem to create difficulties are, it must be remembered, exceedingly small. The fuel economy is still so precariously balanced that a few million tons of coal either way, or the delay in the commissioning of a single nuclear power station, can tip the balance substantially towards surplus or shortage. Governments have a natural tendency to hope to manage their affairs with such precision that failures of this magnitude are rare or even non-existent but that is a great conceit—prudent management would suggest that fluctuations of a few per cent, equivalent to ten million tons of coal a year, in the fuel budget ought to be expected. In short, if the new government is anxious to devise a fuel policy to replace that of its predecessor, it ought to legislate for some system under which the substitution of one fuel for another is comparatively straightforward.

What should this device be? For the best part of a decade, the British Government has done its best to make sure that the Central Electricity Generating Board will be discouraged from replacing indigenous coal by imported oil by means of a levy on fuel oil imported into Britain. This tax of ten per cent has been sufficient not merely to reduce the volume of oil imports but, alas, also to persuade the electricity generating board that taking out an option to burn fuel oil in British power stations would be an expensive luxury. By the same test, the electricity generating board has been discouraged from providing the excess capacity necessary to insure against unexpected developments. It is, however, idealistic to expect that newly commissioned innovations such as nuclear power stations will function perfectly in the first year of their service, and it is wrong to suppose that there is something wrong with the process of innovation if these devices fail to work perfectly the first time round. The moral should be, on the practical level, that the time has come to abolish artificial restraints on the British fuel economy and, in particular, that restraint on the use of fuel oil embodied in the present tax. In the long run, however, the British Government must sanction at least enough capital expenditure to ensure that there is enough give and take in the fuel economy for the most advantageous mixture of fuel to be that chosen by the market. It will be a lesson to us all to see whether a government which has flaunted its respect for market forces in the past few weeks is prepared to let these market considerations be acted out when a little extra capital investment may thereby be necessary.

Telling It Like It Is

ONE of the problems of contemporary biography is that it is bound to read a little like obituary. Certainly the article on Dr Francis Crick in the current issue of *Daedalus* (**99**, 938) by Dr Robert Olby is not merely an intriguing preview of the full length manuscript on which Dr Olby has been working for several years but also a device that almost succeeds in fixing Crick in amber, or at least in aspic. What Dr Olby and the

other contributors to a symposium on "The Making of Modern Science" have done is to attempt to provide an account of current or recent events in the development of science. What Professor Gerald Holton, the editor of this issue of *Daedalus*, and his collaborators have been looking for is a way of writing about the way in which science is done that lies somewhere in between the reverential history and Watson's *The Double Helix*. Their objective was partly to record important events, partly to provide an insight into the authors of them and partly to throw light on the workings of the institutions which provide refuge and sustenance for scientists and other kinds of scholars.

How well is it possible to succeed? Most of this issue of *Daedalus* is as readable as any editor could wish. Professor Erik Erikson, to be sure, has more to say about Freud than about himself. Professor Talcott Parsons is more revealing of the sources from which sociologists draw their strength. The hard scientists are, however, more explicit in what they have to say and everybody seems to be preoccupied with molecular biology. Professor Curt Stern marvels at the way in which the abstract concept of the gene has been made more subversive by being made more tangible. Professor Gunther Stent takes the view that now that biology has been made a branch of physical chemistry, only the nervous system remains a serious challenge—the kind of fallacy on which many heads have already

Nature plus TWO

As already announced, *Nature* will appear on Monday, Wednesday and Friday each week in 1971. The intention is that this reorganization of the pattern of publication should enable readers of all kinds to find their way more easily to the items which concern them most directly. The new development is not meant as an extra demand on the time of busy scientists but, rather, as an attempt to help them to decide what not to read.

To this end, the Monday edition of *Nature* will be called *Nature Physical Science* and will carry original research which seems likely to be predominantly of interest to specialists in the physical sciences together with comments on research, news and book reviews which are similarly restricted in interest to the physical sciences. In the same way, the Wednesday issue of *Nature* will be called *Nature New Biology* and will be so composed that the material it contains is unlikely to interest people working in the physical sciences.

The Friday issue of *Nature* will as now contain original research articles in all fields of science together with news, comment and book reviews. One advantage of the new development is that it will provide scope for increasing the space devoted to the brief reviews of important papers appearing elsewhere in the literature ("News and Views") and review articles of general interest. The Friday issue of *Nature* will be designed in such a way that those reading it will also be provided with information about much of the content of the editions appearing on Monday and Wednesday in the following week. In short, the Friday edition of *Nature* should provide not merely a record of important developments in the whole of science but a guide to matters of more specialized interest elsewhere in the journal.

Under the new arrangement, the pages in the three weekly issues of *Nature* will be numbered consecutively. In order that the increased volume of publication should not lead to inconveniently large bound volumes, there will be six complete volumes in 1971. Copies of the Monday and Wednesday editions will be supplied only to subscribers to the Friday edition. Unexpired portions of subscriptions at January 1971 will be fulfilled by the supply of issues of the Friday edition. The subscription rates for 1971, applicable at least until March 1, 1971, are as follows:

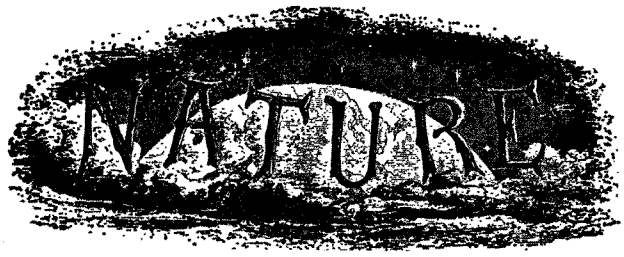
Annual subscription to:

Nature	£14
Nature + *Nature Physical Science*	£24
Nature + *Nature New Biology*	£24

For subscribers taking all three editions there will be a special rate of £29.50. The cover price of each journal will be 5*s*.

For North American subscribers the journal is sent by airfreight. The annual subscription rates are:

	US	Canada
Nature	$48	$52
Nature + *Nature Physical Science*	$83	$90
Nature + *Nature New Biology*	$83	$90



For subscribers taking all three editions there will be a special rate of $108.00 (US) or $116.00 (Canada).

Existing subscribers will be notified by letter in the next few days of these new rates.

been broken. Professor Linus Pauling is more anecdotal than Dr Olby, but what he has to say throws very little light on the reason why his own contributions to molecular biology came bubbling to the top. Dr R. R. Wilson of the Batavia accelerator is perhaps the most amusing of the contributors, for he has the chance to reflect on the irony that he was once a campaigner against large laboratories and is now the originator of one of the largest of them all.

What is to be made of all this? *Daedalus* has demonstrated that scientific biography is as intriguing as anybody could ask. This symposium makes a good read. At the same time, however, it is also clear that autobiographical writing is by no means sufficient to provide an illuminating record of the present or the recent past. On the whole, those contributors who write about themselves tend to dodge the awkward questions. What they have to say is invaluable, for nobody else could say it, but what they have to say is also incomplete. For what it is worth, this special issue of *Daedalus* has demonstrated the need for a contemporary understanding of the mechanisms of science and also, by its inevitable defects, for some method of making this record at once more incisive and more objective.

100 Years Ago

The Electric Telegraph and Earthquakes

THE use of the electric telegraph for recording earthquakes is not so new as the *Echo* (quoted in your last number, p. 35) supposes. Dr. Hector, Director of the Geological Survey, has, ever since the last great convulsions, systematically used the telegraph for this purpose in New Zealand, where indeed it forms an important element in the admirable system he has inaugurated for recording shocks throughout the islands. In his last letter he writes as follows:—"Not long ago, one operator asked another 200 miles distant 'Did you feel that?' and got the answer, 'No. What? Yes; there it is,' all in a breath, so to speak!"

Dr. Hector, writing in August last, goes on to say, "I have called attention to the coincidence of the aurora in both hemispheres on April 5, and can't help thinking that when our observations are sufficiently extended, we shall find many phenomena that are looked upon as local to be general. Could not NATURE give us a column recording such phenomena as auroras, earthquakes, tornados, &c., experienced in all parts of the world, somewhat in the form of an almanac? At the present one has to rummage over all sorts of periodicals, and after all find the matter most imperfectly recorded. We shall soon have a capital earthquake register here, since I induced the Government to cause the observers to report every shock they felt in the colony. Their number and coincidence is very remarkable, and I shall publish the results as soon as I have collected a sufficient number. I feel a great want of a good table eusmometer which should be cheap enough to distribute to all telegraph stations." Perhaps some of your readers can inform Dr. Hector where he can procure this great desideratum. JOS. D. HOOKER

From Nature, **3**, 47, *November* 17, 1870.

OLD WORLD

EUROPEAN SPACE

More Confusion in Brussels

THE European Space Conference in Brussels last week turned out to be a series of misunderstandings and misrepresentations. The outcome of the conference is, on the face of things, another wide difference of opinion between the member countries, this time over participation in the US post Apollo programme. France, West Germany and Belgium have decided to go ahead independently with a more detailed study of NASA's proposal for Europe to take a 10 per cent share in the space shuttle and tug programme. But Britain, Sweden, Italy and Norway have declined to participate.

Debate on the post Apollo programme centred around the report made to the conference by its chairman, Mr Theo Lefevre, the Belgian research minister, of his visit to Washington to hear NASA's proposals. The confusion started with conflicting ideas of what the NASA proposals entail. On the one hand, Mr Lefevre maintained that the United States would only make launchers available for European satellites—as it has done in the past—if Europe decides to participate in the post Apollo programme. But on the other hand, the British delegation, briefed by Lord Bessborough who was present at the Washington meetings, believed that no such provision was made. The full story turned out to be somewhere in between these two extremes—it seems that if Europe does not participate in the post Apollo programme, the United States will consider launching European satellites case by case, but a blanket agreement would be given if Europe decides to accept NASA's invitation.

It was on this point, however, that much of the debate hinged, because Britain stuck to its well worn theme that it would be foolish for Europe to develop its own launch capability while it can buy American launch facilities. This, of course, is the argument which Britain used for pulling out of ELDO when that organization decided to go ahead with development of Europa III.

Confusion also arose over a proposal by Mr Lefevre that $35 million should be spent on a more detailed study of the NASA offer. But it was later made clear that the money would be spent on development of Europa III. The British delegation found such a proposal unacceptable, in spite of the argument that development of Europa III would be useful if Europe decided to take part in the space tug programme, and Britain decided not to participate in the study.

The upshot of the debate about participation in the post Apollo programme is that only France, West Germany and Belgium decided to go ahead with the study, and to put up the $35 million between them, in the hope that other countries may join in later. Britain, however, seems to have made up its mind to stay out. Mr Frederick Corfield, Minister of Aviation Supply, said in London last week, for example, that participation in the project would probably cost Britain alone about £100 million over ten years. Given the government's pledge to reduce public expenditure, this entry fee is too high and, in any case, Mr Corfield pointed out that the full financial implications of the

post Apollo programme are so vague that the offer of participation must be turned down. He did, however, say that "If the Europeans can come up with a firm project, balancing costs with benefits, we could reconsider".

CHEMISTRY

Merging Chemists Beware

THE Chemical Society and the Royal Institute of Chemistry will be legally merged by January 1972 if the arrangements, now well advanced, go ahead as planned. The merger of several of the principal British chemical bodies was first talked of in 1967, when the councils of the Chemical Society, the Royal Institute of Chemistry and the Society of Chemical Industry agreed to start negotiations on a possible amalgamation. Sir James Taylor produced a working document in June 1968 which suggested an equitable method of effecting the merger. The three bodies later held referenda and an overwhelming majority of the members of the Chemical Society and the institute voted in favour of the amalgamation. Only 68 per cent of the membership of the Society of Chemical Industry felt the same way, however, and their council withdrew from the negotiations on the grounds that it favoured a looser confederation. This prospect did not appeal to the other two bodies, however, who looked forward to the increased impact which a unified body of about 40,000 chemists would have in matters of mutual interest. The Society of Chemical Industry, the smallest and least financially secure of the three, was obviously worried about negotiating from a position of relative weakness.

Sir James Taylor's proposals were to accommodate other interested bodies on equal terms within the Chemical Society and to create an overall amalgamation between the society and the institute. To date, the Faraday Society and the Society of Analytical Chemistry have agreed in principle to become incorporated into the Chemical Society as the Faraday and Analytical Divisions. The president of the Faraday Society, Professor G. Gee, believes that its status as a multidisciplinary society of considerable international standing will be enhanced by closer integration with the main body of British chemists and that this integration will not be to the detriment of, for example, its members who are physicists. The Society of Chemical Industry also has a neat slot, into which it could fit if it so chose, in the shape of the existing industrial division.

The linkup of the Chemical Society, with its new offshoots, and the institute is a more complex affair and it is to be hoped that it will cause less friction both now and in the long run than has been generated during the negotiations of the Institute of Physics and the Physical Society for a Royal Charter. The situation is, however, somewhat different because both the society and the institute already have charters. The plan is that they should continue to operate under their respective charters, both because older charters are much wider in scope and freer in their provisions and because of the enormous expense of renegotiating a single one. The added advantage of this arrangement is that the existence of the Chemical Society within the new framework is assured for future years by the retention of its charter. Both bodies plan to use the same buildings as at present but there will inevitably be staff reorganization because of the centralization of financial control and the shift of most of the publishing onus to the Chemical Society.

The chief restrictions which are to be written into the merger agreement reflect the different purposes of the society and the institute. The society is essentially a learned society whose membership has always been open to all with an interest in chemistry, as is the case with the now almost defunct Physical Society. The institute is, however, the chemists' professional body and as such must require its members to be suitably qualified in chemistry, either by a university degree or through its own graduateship examination. It is proposed that the two councils should govern the new body jointly and that matters should be voted on by all members at a general meeting, except, of course, those items which are professional in nature and can only be decided by the members of the institute.

Dr Timofeev-Resovskii

THE recent appointment of Dr Nikolai V. Timofeev-Resovskii to a consultancy in the Moscow Institute of Space Biology and Medicine (see *Nature*, **228**, 4; 1970) does not, unfortunately, signify an end to his harassment by the Soviet State. A special meeting of the Moscow Society of Naturalists was recently called to mark his 70th birthday, but official pressure to cancel the meeting was brought to bear on the society and it had no option but to give in.

Dr Timofeev-Resovskii, who was forced to retire last year from the Obninsk Institute of Radiology, is now in hospital recovering from an abdominal operation. But it seems that the cancellation of the jubilee meeting had nothing to do with his illness, because he asked for a long-standing intestinal complaint to be investigated after he heard that the meeting had been cancelled.

HIGH ENERGY PHYSICS

First Spin for Storage Ring

AT long last, the first of the two intersecting storage rings at CERN has been commissioned and, by all accounts, a shudder of excitement has spread through the establishment. One witness of the occasion on November 3, when a beam of protons at an energy of 15 GeV was fed into the anticlockwise ring, said afterwards that the experience had been "totally remarkable". What seems most of all to have impressed the people concerned is the great stability of the protons in the storage ring. On the very first injection, a proton current of 5 mA was allowed to circulate for twenty minutes and tests carried out suggested that the lifetime of this beam would have been fifty-six minutes. More densely packed beams of protons will, of course, be less stable, but the stacking procedure which allows successive pulses of protons to be stored in the ring has so far been used to accumulate a current of 1·5 A—a much more intense beam than that provided by the proton synchrotron at CERN.

The team at CERN is also pleased about the accuracy with which the performance of the storage rings had been predicted. The oscillatory characteristics of the beam seem, for example, to have been predicted accurately. The efficiency of stacking is close to what calculations had predicted while the efficiency of injection seems to have been virtually ideal. It is also remarkable that the first of the two storage rings which will ultimately be used for arranging for collisions between protons travelling in opposite directions should have been tried out some weeks before the date on which it was due to be commissioned. A spokesman at CERN also made much of the fact that the cost of the project as now nearly completed is well within the budget.

Financial probity is no doubt one of the virtues of which CERN will make much in the weeks ahead, when member states will once more be screwing up their courage to decide whether or not to go ahead with the 300 GeV proton accelerator as now modified in design. More may be known about the status of this project when the council of CERN meets in Geneva on December 17 and 18. In the meantime, it seems clear that the final decision will depend very much on what the British delegation has to say. Since the visit of Mrs Margaret Thatcher and Sir Brian Flowers in the summer, it has been assumed that the British Government's decision not to contribute to the new project was at least up for reconsideration. The Italian Government has let it be known that it will not itself agree to belong to the new project if there is no British contribution, which only goes to strengthen the belief that the future of the 300 GeV accelerator will be determined by Mrs Thatcher.

NUCLEAR REACTORS

Export Hopes Revived

THE announcement this week that the Nuclear Power Group (NPG) of Great Britain is among the last four contenders for the contract for Australia's first nuclear power station has revived hopes that the steam generating heavy water reactor (SGHWR) may yet break into the export market for which it is designed. Canadian, West German and United States consortia are also still in the running for the Jervis Bay station in New South Wales, but it seems likely that the final decision really lies between the British and Canadian designs. The Australian government has specified that the reactor chosen must be able to run on the natural uranium recently found in the Northern Territory. Although only the Canadian design fulfils this requirement, the British package includes granting Australia access to European gas centrifuge technology, for the slight enrichment required for the NPG reactor. Such an agreement would be subject to international safety precautions.

The only SGHWR reactor in operation in the UK is the 100 MW station at Winfrith in Dorset. Designed to the specifications needed for a 300 MW reactor, this has always been seen by the NPG as an export proposition rather than a competitor on the home market with the more sophisticated and expensive advanced gas cooled reactors. Early in its development an SGHWR reactor was offered to Finland, who chose a Russian design instead. More recently, the Greek government approached Britain with an offer for one of these reactors which included other trading deals (notably in tobacco) in one package. This offer has so far proved unacceptable, but it seems that Greece is still interested in the reactor and that it is the associated trading arrangements which have blocked progress.

The outcome of the Australian decision may be important because similar stations will certainly be required by other Australian states in due course. With reports that Brazil and South Africa will also be asking for tenders for nuclear reactors in the near future, success in Australia could open up the southern hemisphere and Latin America to the NPG, which is ready to press its case as soon as requests for tenders are made.

FRENCH SPACE CENTRE

Engineers back to Work

ENGINEERS and technicians at the site of the Conseil National d'Etudes Spatiales at Bretigny returned to work last week after a stoppage of five weeks, the longest in the history of the French Space Agency with the exception of that during the national crisis in May 1968. Although the dispute was ostensibly about salary, arising out of the failure of the CNES to implement an agreement with the unions reached last April, it became clear during the course of the strike that a major concern of the engineers and technicians was the threat of the transfer of personnel to the new CNES site at Toulouse.

There seems to have been some confusion about the amount of work apportioned to the new site. The only major projects already earmarked for Toulouse are the testing of the Franco-German satellite, Symphonie, and the construction of a meteorological satellite called Météosat. The 250 engineers and technicians on strike had been asked to decide by March 1971 whether they would be willing to accept a transfer to Toulouse, but it seems that there had been some doubt about the role of the new site, or at least about the rate at which work would be shifted to Toulouse.

The agreement reached between the unions and the CNES last week includes an indemnity from transfer to Toulouse and an assurance that the restructuring of the space centre will not mean redundancies at the CNES. One result is that it now seems improbable that many of the engineers and technicians will accept a transfer to Toulouse with the French space programme in such a state of uncertainty. It is thought likely that a large number will prefer to move into the aerospace industry following the lead of the hundred or so men who have already made the move during the past eighteen months.

SCIENTIFIC INSTRUMENTS

Astrolabes at Greenwich

A GLIMPSE back to the days when scientific instruments were also works of art is given by the permanent exhibition of astrolabes and other models of the heavens in the Bliss Gallery of Flamsteed House at the Old Royal Observatory, Greenwich. The collection is second only to that in the Museum of the History of Science, Oxford, and has been accumulated since about 1935.

The planispheric astrolabe, a sort of circular astronomical slide rule, is the most common type. As a

Islamic astrolabe made in 1707–8, now part of the Greenwich collection.

mathematical model of the heavens, instruments like these can be used to compute the positions of heavenly bodies at any time, and, conversely, to determine the time from the altitudes of the Sun and stars. The origin of the astrolabe may well be Greek (a forerunner was possibly invented by Hipparchus in 150 BC) but it was certainly in regular use from the 4th century AD to the 17th century.

The National Maritime Museum is planning to commemorate the tercentenary of the foundation of the Greenwich Observatory in 1675 by a special exhibition to be mounted in the main part of the Observatory building, the Queen's House. Some of the telescopes used by John Flamsteed—appointed "astronomical observator" by royal warrant in 1675—are also expected to be re-erected for the occasion.

DIABETES

Drug Fears Dismissed

THE nervousness with which the American Food and Drug Administration regards the anti-diabetic drug tolbutamide is clearly not shared by British health authorities. Although doctors in the United States were warned earlier this month by the US Department of Health, Education and Welfare not to prescribe tolbutamide or any of the related sulphonylureas unless there was no alternative, the British Diabetic Association and the Scowen Committee on the Safety of Drugs agreed unanimously last week that there is little substance to the American fears.

Tolbutamide is the best known of a group of compounds which have been used for more than a decade in the treatment of some forms of diabetes mellitus. The drug is now used by about one third of the 500,000 British diabetics, and by about the same proportion of American sufferers. It is administered orally, in contrast to the classical treatment for diabetes of insulin injections, but because it works by stimulating the production of insulin by the pancreas, it can only be used for those diabetics in whom the pancreas is still functional.

American anxiety over tolbutamide is based on a study carried out by the University Group Diabetes Program (UGDP) which indicated that the risk of cardiovascular disease is greatly increased in patients treated with the drug. In dismissing this conclusion, a spokesman for the British Diabetic Association emphasized that the American evidence had been unconvincing. The patients chosen for the study were not a typical group, other possible causes of cardiovascular disease and death had not been taken into account, and no comparison with the normal death rate from cardiovascular disease had been taken into account. Furthermore, the UGDP results were in direct conflict with two careful European studies which suggested that patients derived positive benefit from taking tolbutamide, but which induced no adverse cardiovascular effects. The British attitude, therefore, is that there are no grounds for recommending changes in treatment policy for diabetics.

While everyone holding recent tragedies like thalidomide in mind will agree that there is no room for laxity in drug supervision and control, it seems strange that the American Diabetic Association—which seems to have turned about face in the last few months—the Council on Drugs of the American Medical Association and the Food and Drug Administration should be so eager to jump onto this particular bandwagon on the basis of such unsatisfactory evidence.

WAR

Slaves and Prophets

WAR is a pathological condition of human society and as such it must be treated not by blind application of politics but by scientific methods based on an understanding of human biological needs. This is the claim of the Medical Association for Prevention of War, an association formed in 1951 to promote the objective study of war from the standpoint of medical and biological sciences. The first volume of the association's proceedings has just been published (available from the association, 50*s*); it contains a number of short papers contributed by physicians, psychologists and others during the past five years under the chairmanship of Professor Lionel Penrose.

Interspersed among analyses of human aggression and the psychology of warfare by, for example, Felix Brown and Ismond Rosen, there are individual views on the ethical problems now facing doctors. There are also a few papers on racial conflict, and Malcom Potts talks about family planning. But there is surprisingly little discussion of one of the association's chief problems—the direct involvement of medicine in the development of biological and chemical weapons. Victor W. Sidel and Robert M. Goldwyn presented a paper in 1966 (abstracted from their paper in another journal) that classifies chemical and biological weapons, and in which they say that there has been remarkably little debate, particularly among physicians, on the advisability of developing, stockpiling and using such

weapons. The association itself seems to have added little since then.

Various trumpet calls have, of course, been sounded at intervals throughout the proceedings. In a recent paper, for example, Elisabeth Shoenberg underlines the hypocrisy of the medical code of ethics and the change in the doctors' moral position brought about by chemical, biological and atomic warfare. Doctors, she says, as medical philosophers bound by an acknowledged code of ethics, must opt out of chemical and biological warfare research. They must also start planning for peace—as citizens with a special responsibility, Dr Shoenberg suggests, they must educate and inform, and they must change from slave technicians to prophets.

POLLUTION

Valuing the Environment

LITTLE new thinking emerged from the Liberal Party's conference on "The Pollution of Our Environment" which took place last weekend. But it was a welcome change to hear views expressed in concrete terms, rather than the woolly subjectivity which marks so much of the present concern about the environment.

Two speakers in particular, Dr D. H. Sharp, general secretary of the Institute of Chemical Engineers, and T. C. Sinclair of the Science Policy Research Unit at the University of Sussex, emphasized the importance of equating the costs of anti-pollution measures with the value of the benefits. They pointed out that it is all too often overlooked that pollution control programmes are very subject to diminishing returns. Gross pollution can usually be dealt with cheaply and easily, but the cost escalates sharply if further refinement is required. The real conservation problem seems to be deciding where to draw the line.

An example cited by Dr Sharp is the cost of treating liquid sewage. Water can be purified by a factor of 15 for about 1*s* 3*d* per 1,000 gallons, but to reduce contamination by a further factor of 2 costs more than four times as much.

Some of these problems are clearly food for governmental thought. Sulphur dioxide is a major atmospheric pollutant, but sulphur can be completely removed from crude oil at a cost of $177 a ton, in comparison with the world price per ton for sulphur of $49. It is also now possible to recover sulphur from the sulphur dioxide in stack gases at a much more attractive price. In such a case, Dr Sharp believed that only the government can take a view broad enough to equate the cost of recovering sulphur with the cost of importing it, and to balance these costs against the expense of eliminating sulphur dioxide as a pollution hazard.

Mr Sinclair thought that it will soon be necessary to develop a formula which can be used to compute the value of free natural amenities such as clear air and water so that these could be compared with the costs of material products. The cost, for example, of air pollution in damage to health and fabric has been estimated at about £400,000,000 a year. Against this, the cost of building a single stack 425 foot high to disperse gaseous effluents is about £200,000. If the stack was twice as tall, the concentration of effluent reaching the ground would be halved, but the cost of construction would then be £1,250,000, and the danger to low-flying aircraft would have to be taken into consideration.

Parliament in Britain

Thames Flood Barrier

THE government has decided that the Thames flood barrier should be constructed at Silverton in Woolwich Reach. Announcing this decision, Mr Peter Walker, Secretary of State for the Environment, said that the Greater London Council is being asked to press ahead with detailed site investigation and that detailed design work will begin as soon as a decision can be taken on the type of barrier. The government, he said, considers the need to construct a movable barrier to be urgent.

The decision to site the barrier at Silverton was attacked, however, by Mr James Wellbeloved, who said in an adjournment debate that a more suitable site would be downstream from the proposed housing development at Thamesmead. If the barrier is placed at Silverton, Mr Wellbeloved suggested, some 60,000 people would be at risk if the banks at Thamesmead collapsed.

But Mr Eldon Griffiths, Under Secretary for the Environment, pointed out that the Silverton site was chosen on the basis of cost, ease and speed of construction, availability of land and on safety to shipping. (Written answers, November 4, and debate, November 9.)

Nancekuke

MR IAN GILMOUR, Under Secretary, Department of Defence, gave details of the Registar General's report comparing the incidence of death among those who have worked at the Chemical Defence Establishment outstation at Nancekuke with figures for Britain as a whole. He said that the report shows there is no evidence that workers at Nancekuke run an increased risk of death from any group of causes. Deaths from all causes, and in particular deaths from respiratory diseases among workers at Nancekuke, are slightly less than would be expected from figures for the rest of England and Wales. (Written answers, November 2.)

Smoke Control

MR PETER WALKER, Secretary of State for the Environment, said that 139 smoke control orders have been suspended in London, and another seven have been partially suspended. The suspensions affect 14 London boroughs, and Mr Walker said that they would apply to 40 per cent of the total number of premises usually covered by the orders in each individual borough. These measures have been taken because of the shortage of smokeless fuels. (Written answers, November 4.)

Dutch Elm Disease

THE Ministry of Agriculture cannot recommend any satisfactory chemical method of controlling the spread of dutch elm disease in Britain. Mr Anthony Stodart, Parliamentary Secretary, Ministry of Agriculture, said that a conference has been held to publicize measures for controlling the disease, but at present no satisfactory chemical control method is available. Mr Stodart also said that he does not believe legislation to be necessary for controlling the disease, but the position is being kept under review. (Written answers, November 2.)

NEW WORLD

Bringing Hippocrates to the People

by our Washington Correspondent

MEDICAL educators have so far had little but praise for a recent report which calls for a 50 per cent increase in the annual production of doctors, for two years to be knocked off the present eight year training course and for an immediate doubling of federal expenditures on medical education. The report*, prepared by the Carnegie Commission on Higher Education, gives American health services a sharp nudge towards the European model of socialized medicine. Its underlying theme is that the great advances in medical knowledge made over the last two decades are not reaching the people for whom they were developed.

Released at a meeting of the Association of American Medical Colleges on October 27, the report has been compared with, and takes as its deliberate point of departure, the Flexner report of 1910, which set the pattern of medical education in the United States for the subsequent six decades. The Flexner report, also commissioned by the Carnegie Foundation, established the emphasis of medical training in biomedical research and brought about the close connexion of medical schools with universities. The new report in no way repudiates the emphasis on research—and indeed provides mechanisms for establishing the volume of research at its present level—but it criticizes the Flexner model for ignoring the delivery of health care outside the medical school and its own hospital. Another major criticism is that the Flexner system sets science in the medical school apart from science on the general campus, with a resulting duplication of effort.

Despite the fact that it is calling for radical changes in a conservative profession, the new report seems likely to be welcomed by everybody except the Administration, which is called upon to foot the bill. The Association of American Medical Colleges has endorsed the report in principle, and the medical education director of the American Medical Association has termed it "consistent with the AMA's feelings and beliefs". Dr Robert Q. Marston, director of the National Institutes of Health, said last week the report is a "very timely and uesful document which clearly displays the results of a lot of serious discussion. We are now doing a critical analysis of it". Although many deans of medical schools may be apprehensive of tampering with a system that has produced an outstanding product, there seems to be a wide measure of support for one of the Carnegie Commission's most radical suggestions, that of reducing the length of training by two years. But how fast the Administration moves to implement what is, in its own way, an inflammatory document, may depend on the extent to which the public and the Congress takes up the Commission's suggestions. At a time when the Administration is seeking hard to reduce expenditure, the Carnegie Commission calls for the federal government, which in the last financial year devoted some $275 million to the support of medical education, to spend almost double that amount in 1971–1972. Adding to the Administration's probable inertia is the recent accession of Mr Elliot Richardson as Secretary of Health, Education and Welfare—he may not yet be ready to embark on a radical restructuring of this part of his domain. For these reasons the initiative in pushing the Commission's reforms is likely to come from Congress.

The immediate focus of the Carnegie Commission's concern is the present critical shortage of all levels of medical personnel. Estimates vary as to the size of the deficit but Dr Robert Egeberg, Assistant Secretary of Health, Education and Welfare, has put it at 50,000 physicians, a couple of hundred thousand nurses and 150,000 technicians. Whatever figures are taken, the fact that 46,000 graduates of foreign medical schools practise in the United States, amounting to 15 per cent of all physicians, is undeniable evidence that the native supply is insufficient. So too is the long working week of the typical doctor—60 hours was the median in 1968.

The chief bottleneck in the system is a shortage of places at medical schools, which habitually turn away half their applicants. Simple, old fashioned prejudice has also helped: only 6 per cent of all physicians are women (compared with 20 to 30 per cent in some European countries) and less than 2 per cent are black. An equally formidable barrier to talent is the cost of medical education (tuition charges at present range from $750 to $2,000 a year) which has put the ambition of a medical career largely beyond the reach of students from poor families; nearly two thirds of medical students in 1967 reported that they came from families with incomes of $10,000 or more.

The Carnegie Commission believes that an attainable and desirable goal is to increase the production of physicians by 50 per cent before the end of the decade. If the intake into medical schools can be raised from the 10,800 who entered this year to 16,400 by 1978, and assuming the brain drain infuses some 13,000 more foreign doctors between 1968 and 1977, it should be possible to raise the number of physicians per 100,000 of population from 147 to 161 before the end of the decade.

The extra 5,600 places in medical schools can be achieved by reducing from four years to three the course between the BA and MD degree, by increasing the average class size in medical schools to at least 100, and by establishing 9 new medical schools in addition

*_Higher Education and the Nation's Health_. The Carnegie Commission on Higher Education. McGraw-Hill, October 1970. $2.95.

to the 107 existing schools and the 27 already under development.

The switch from a four-year to three-year MD is to be effected by straightforward revision of the curriculum, by cancelling much of the summer vacation, and by demanding higher standards of students on entry to the MD course. The Commission also follows the American Medical Association in approving the elimination of the internship year. With these two changes the production cycle for doctors would be reduced from eight years to six.

Another major change recommended in the structure of the medical education is to shift instruction in the basic sciences out of the medical schools and on to the main university campuses. The courses should be arranged so as to increase the student's options, allowing him after basic training in the "health-related sciences" to pursue a variety of health-related professions as well as medicine and dentistry. The Commission also calls for serious attention to be paid to students' wishes, in particular the demands for more flexible admission standards and for greater student participation in deciding what is to be taught.

To improve on delivery of medical services, the Carnegie Commission envisages a two-tier hierarchy comprised of campus-based medical schools, or "university health science centres", and regionally based "area health education centres". Describing the role of the health science centres, the Commission says that their education and research programmes must be broadened to include concern with improving the delivery of health care and with innovations such as group practice and prepaid health plans. This will require closer cooperation with social science departments on the main university campus as well as with organizations and individuals in local communities. Each university health science centre should be capable of handling the most complex medical problems but should also serve as the coordinating hub and reservoir of expertise for a system of institutions ranging from area health centres to rural clinics and group practice organizations.

The role of the area health education centres is to be satellites of the university health science centres. Their education programmes would be developed and supervised by the health science faculty to which they were affiliated, and they in turn would provide assistance to community health care facilities, including the private practitioner. The chief functions of the health education centres would be to maintain a community hospital serving smaller communities in the surrounding area, to conduct education programmes and to provide clinical instruction for candidates from the university health science centre.

Turning to the financial support of medical education, the Commission argues the case for increased involvement by the federal government in underwriting the necessary improvements. This should not be done at the expense of federal funds for research, although the practice of funnelling federal funds for education through research grants to medical schools should cease and support of the education function should be made separate and direct. "In the years since World War II," the Commission notes, "the federal government has assumed major responsibility for providing funds for biomedical research. The Commission believes that this support should continue, but the time has now come for an equally vigorous effort to expand the education of health manpower and to stimulate major changes designed to relate the future education of health manpower to probable changes in the delivery of health care." In a proposal that may catch the attention of scientists in other fields, the Carnegie Commission suggests that federal research funds provided to university health science centres should be pegged at their present percentage of the GNP (0·042 per cent) though with changes in appropriations being based on a moving average of the total GNP so as to avoid abrupt shifts in funding. Between 10 and 25 per cent of the research grants to any university should be in the form of institutional grants rather than grants for specific research projects.

To make more equal the opportunity of entering the medical profession, a means-tested system of student grants is recommended whereby a maximum grant of $4,000 a year would be accorded to medical and dental students. The federal government should, in addition to research funds, provide cost-of-instruction grants to health science centres. These grants would be made conditional on the institution concerned abolishing admission requirements that either favour residents of the state or discriminate against minority groups.

Federal government would also be required to provide construction grants for new buildings and funds for the continuing education of physicians who, such is the pace of advances in knowledge, "must remain students throughout their professional careers or face partial obsolescence in five to ten years". In sum, the Carnegie Commissioners are asking the federal government to double its present level of support for medical education to $547 million in 1971–72, rising to $728 million by the end of the decade.

The Carnegie report has come at a time when health services in the United States are facing not one but several different crises. In addition to the shortage of doctors and other medical workers, medical schools in common with other academic institutions have suffered an abrupt decline in income, particularly that from private sources. More than half of the country's 107 medical schools have become eligible for special distress grants from the federal government. The cost of medical treatment increasingly concerns a public which is coming to regard health care as a right. The national expenditure on health care now amounts to $60,300 million, or nearly 7 per cent of the GNP, but little more than half of this great burden is met by insurance schemes—the Medicare and Medicaid programmes were meeting 36 per cent of the total in 1968–69, while private insurance schemes, despite the fact that about four fifths of the population had some insurance protection, were covering only 22 per cent.

In the light of these deficiencies there is less surprise in the Carnegie Commissioners' verdict that "although the best medical care in this country is as good as any in the world, many Americans receive inferior care, and some health needs go entirely untreated".

Accompanying the rising expectation of health care has been a shift in public attitudes towards doctors. According to a Louis Harris poll published this week, 78 per cent of Americans have a high personal regard for their family doctor but many nurture a long list of grudges against the medical profession in general. A majority (63 per cent) believe that doctors try to see so many patients they don't give enough time to anyone; 62 per cent agreed to the assertion that doctors

have jumped their fees to take advantage of the Medicare and Medicaid programmes, and half of those polled thought justified the statement that "the patient who gets sick on Wednesday afternoon or Sunday could die before getting a doctor off the golf course". Whatever the significance of these sentiments, the issues raised by the Carnegie Commission report are unlikely to be forgotten when Congress reassembles next spring.

Carnegie Commission

Summary of Chief Recommendations

- THE number of students entering medical school should be increased by half over the next eight years, from 10,800 admitted this year to 16,400 in 1978.
- Universities should develop plans for accelerating premedical and medical education. The Commission favours particularly reducing from four years to three the time after the BA degree to obtain the MD, and abolishing the internship year, thus reducing the total period to become a practising doctor from eight years to six.
- All university health science centres should give serious consideration to curriculum reforms. Admission policies should be made more flexible and their programmes more responsive to the expressed needs of students.
- More women and members of minority groups should be trained as doctors.
- The federal government should award means-tested grants of up to $4,000 to students from low income families training to be doctors or medical associates or assistants, as well as cost-of-instruction subsidies to university health science centres for each medical student enrolled.
- Federal support of research at university health science centres should be maintained at its present percentage of GNP (0·042 per cent). Federal allocations should cover the total cost of research projects. Between 10 and 25 per cent of the research grants to any university health science centre should take the form of institutional grants rather than grants for specific research projects. Funds should be made available to support research on methods of improving medical education and delivery of health care as well as for biomedical research.
- National requirements should be set for the periodic re-examination and recertification of all physicians and dentists by specialty and other appropriate bodies.

A National Health Manpower Commission should be appointed to study changing patterns of medical education, health care delivery and the use of health manpower, as well as the feasibility of setting national licensing requirements for all types of medical worker.

- Universities should plan for medical schools to expand, to offer a broader curriculum, and to integrate their instruction in the biomedical and social sciences more closely with that given by the relevant university departments.

POLITICS

Addio Daddario

by our Washington Correspondent

MR EMILIO Q. DADDARIO, six times elected Congressman, chairman of the House Subcommittee on Science, Research and Development, most conspicuous of science's few friends in either chamber of Congress, was defeated last week in his campaign for the governorship of his home state of Connecticut. Since the Nixon Administration is unlikely to cross party lines to offer him a job in government, Mr Daddario's experience of science policy making seems likely to lie fallow for some time. He will probably return to the successful law practice he ran in Hartford, Connecticut.

With the loss of the governorship that a few months ago seemed almost assured, Mr Daddario's political career seems set for a long recess. He is unlikely to run for governor again, and his safe seat as representative for the first district of Connecticut has been won by a Democrat, who by etiquette will have the party's support if he chooses to stand again. Mr Daddario's earliest chance of re-entering Congress will probably be when the Senate seat of Democrat Abraham Ribicoff comes up for re-election in 1974, should the present incumbent not wish to try for another term.

Mr Daddario's defeat is the more the pity in that it is commonly supposed he would have preferred to run for the Senate seat that was up for re-election this year, but was persuaded by the Democratic party machine in Connecticut to stand instead for the governorship, which disposes of more patronage. The House Subcommittee on Science, Research and Development, whose first chairman he became in 1963, now passes into the hands of Representative John W. Davis of Georgia. Mr Davis inherits the subcommittee along with much unfinished business, notably the proposals to set up an Office of Technology Assessment and the structure to be known as the National Institute of Research and Advanced Studies. There is also Mr Daddario's newest and grandest design, the inquiry into national science policy, which asks the Administration to consider again the whole machinery of science policy making, starting with its own creature, the Office of Science and Technology.

Even if all the projects that issued from Mr Daddario's subcommittee had met with the legislative success they deserved, a more significant achievement may prove to be one whose full fruits are not yet apparent—the way in which Mr Daddario laid down the basis for intelligent and informed discussion in Congress and beyond of how science should be done and what part government should play in it.

NASA

Astronomers' Favourite Satellite

by our Astronomy Correspondent

EXPERIMENTS and experimenters have now been picked for the High Energy Astronomical Observatory (HEAO), the satellite that astronomers would most like to see in orbit. Although the project is being given the highest priority by the scientific community (see *Nature*, **228**, 204; 1970), it has not yet become an approved NASA programme. The project will be considered during a series of congressional hearings this

winter. The reason for the excitement about HEAO is that it will be a platform for the study of cosmic X-rays and gamma rays that up to now has been carried out from temporary platforms on rockets and balloons, with a few notable exceptions. Now that there is practically incontrovertible evidence from the rocket flights that X-ray sources come and go, there is an urgent need for the continuous monitoring that can only be carried out from a satellite. The same goes for gamma ray observations, at last becoming respectable, and detectors on satellites away from the influence of the atmosphere are the only way of identifying the isotropic gamma ray background that was hinted at from the OSO 3 measurements.

Twelve experiments have been chosen out of fifty-five submitted for the two satellites planned in the HEAO programme. The first satellite intended for launch in 1974 is being designed chiefly for a sky survey, but according to NASA it should also provide crude spectral measurements. In the X-ray field the chief piece of equipment is a large area detector sensitive from 100 eV to 100 keV from Dr H. Friedman's group at the Naval Research Laboratory which will provide an X-ray map of the sky. To fix the positions of the sources found in Dr Friedman's survey to one arc second there will be a low energy experiment fitted with modulation collimators and sensitive from 900 eV to 20 keV (Dr H. V. D. Bradt of MIT and Dr H. Gursky of American Science and Engineering), and a similar experiment for the higher energy sources from Dr W. H. G. Lewin's group at MIT, sensitive from 13 to 150 keV. To provide extra sensitivity for soft X-rays there is an experiment from Dr R. Novick's group at Columbia University to map weak sources in the range 500 eV to 1·5 keV. Extending the measurements to higher energies than those covered by the NRL detector there will be a gamma ray detector from Dr L. E. Peterson's group (University of California at San Diego) sensitive to high energy X-rays and low energy gamma rays (300 keV to 10 MeV). There will also be two cosmic ray experiments, one to study the elemental abundances of heavy and superheavy nuclei (Dr M. H. Israel of Washington University at St Louis, Dr E. C. Stone of Caltech, and Dr C. J. Waddington of the University of Minnesota), and the second to measure the charge composition and spectra of cosmic rays with energies between 10 BeV and 100 GeV (Dr J. F. Ormes, Goddard Space Flight Center).

The second HEAO is dependent on the successful working of the first in that it will carry equipment to measure in detail the spectra of sources turned up by the sky surveys. It should also provide more information about the background radiations that possibly play an important and so far not understood part in the energetics of the universe. X-ray spectra will be provided by a high resolution Bragg spectrometer (Dr A. B. C. Walker of Aerospace Corporation and Dr J. R. P. Angel of Columbia University), and spectra covering the transitional region between X-rays and gamma rays, 60 keV to 10 MeV, from an experiment from Dr A. S. Jacobson's group at JPL. An unusual experiment supplied by Dr L. W. Alvarez (University of California at Berkeley) will, it is hoped, measure the momentum of cosmic ray particles from the curvature of their paths in the magnetic field of a superconducting magnet. There will be two experiments on the background radiation. Dr E. A. Boldt of the Goddard Space Flight Center and Dr G. P. Garmire of Caltech will be observing the X-ray background from 200 eV to 60 keV, and Dr C. E. Fichtel of Goddard and Dr R. Hofstadter of Stanford University are hoping to learn more about the background radiations observed from OSO 3 by means of an equipment sensitive to high energy gamma rays.

X-ray and gamma ray astronomy in the US will also be encouraged by a series of small astronomy satellites now planned, with the first launch this winter, and the first two satellites will be devoted to X-ray and gamma ray sky surveys.

The gamma ray telescope in SAS-B, for example, will have twenty-five times the sensitivity and ten to fifteen times the angular resolution of the gamma ray equipment on OSO 3. HEAO is still at the design and definition stage, however, which is expected to take between ten and twelve months, after which money will have to be appropriated if the project is to go ahead.

PEACEFUL ATOMS

Plowshare Ploughed Again

by our Washington Correspondent

WITH the hearings for next year's budget of the Atomic Energy Commission now at a close, it is beginning to look as if the Plowshare programme for the development of peaceful uses for nuclear explosions is once again going to lose funds. Up to the current financial year, the Plowshare programme, which has its most vivid expression in a scheme to use nuclear bombs to excavate a new Panama canal, has been receiving $12 million to $14 million each year. But in transmitting the current budget to congress in January this year President Nixon requested virtually no funds for the excavation aspects of the programme, but continued the funding for what are called the underground engineering aspects. Thus the Plowshare budget was cut from an estimated $14·5 million for the fiscal year 1970 to a presidential request of $8 million, which was then further trimmed by Congress to $7·5 million. It is now thought that President Nixon will be taking the same action this year with the 1972 budget which comes into action on July 1, 1971. What this means is that once again there will not be enough money in the Plowshare programme to carry out tests of the excavative ability of nuclear explosives.

The distinction between the two aspects of the programme arises partly because in excavative explosions there is the danger of radioactivity escaping from the state carrying out the explosion, prohibited by the test ban treaty. In underground explosions such as the gasbuggy series there should be no release of radioactivity. That there is likely to be a continuation of the standstill on the more ambitious parts of the plowshare programme will not come amiss to those who doubt the wisdom of using nuclear explosions for earth-shifting projects in the first place.

FUNDING CRISIS

Science Throttled, but Can Live

by our Washington Correspondent

TOTAL expenditures on academic science in the United States have increased by 15 per cent over the last two years, but the growth has not been enough to cover

Table 1. PER CENT CHANGES IN MANPOWER, BY FIELD, SPRING 1968–69 AND 1969–70

Selected science departments, by field	Faculty		Post-doctorates		Graduate students	
	1968 to 1969	1969 to 1970	1968 to 1969	1969 to 1970	1968 to 1969	1969 to 1970
